The Foreman and the serif family

Handbook of the general definitions, constructions and theorems

2 November 2026

How this handbook is written

This handbook states the general theory of the Foreman and the serif family: the members of the serif family and their relations; the tables and families they evaluate; the Foreman's classification of a family and his tree; the generalized integrals the Foreman sets; the constructions and compositions of families; the motive of a family and the arithmetic of its values; rays of data and the laws their values obey; the relations among values; and the family read as a model of data. Every definition, construction, theorem and procedure of the program is stated here, once, at the place where it is first needed.

The order of the book. The serif family comes first (Part I), because every value the theory produces is closed in it. Then the path of a computation: a list of marks and the tables and families built on it (Part II); the classification of a family by its realizations, its reading, its bunches and the Foreman tree (Part III); the integrals the Foreman procedure sets, and their evaluation along the tree (Part IV); the constructions that build families from cells, holds and bunches, and price them (Part V); the motive of a family and the coaction along its tree, positivity and the gap (Part VI); rays of data, their modules, their two ends and the reading of their values (Part VII); relations among values and the content they live in (Part VIII); and the family as a model of data (Part IX). No statement and no proof uses a statement of a later chapter, and a later chapter is mentioned only as a pointer; inside a chapter a statement may point ahead to a result proved below it, and then says so.

Proofs. A statement that is more general than its counterpart in the reference *The Foreman and the serif family* (16 October 2026), or that has no counterpart there, is proved in Part X, one section per chapter in the order of the chapters; the other statements are proved in the reference. In the source file every statement is preceded by a comment that says which: either the label and line of the statement in the reference, or that it is proved in the last part.

Exercises. Computations on particular lists, tables and rays are the exercises of Part XI. Each is a guided example with its solution worked in full: every step names the statement or procedure it uses, and every quantity the next step needs is displayed in exact arithmetic.

Names. The text uses the program's own names. The classical names of its objects, and the classical names of results that the program reaches by its own route, are collected in the Aliases at the end.

One governing definition per object. Each object of the theory is defined once, with all of its slots. Every later appearance of the object is that definition with particular data in its slots, written through the full signature of its governing symbol: a specialization displays the data it chooses, and it never receives a symbol of its own. Thus a Breta on one scale is a Breta with one bunch, a Trailmoment on a line is a Trailmoment whose cut region is a half-line, and a value of interest at particular exponents is the interest with those exponents in its slots.

Abbreviations are local. Inside one statement an abbreviation may be declared, once and in words, for data that the statement holds fixed; the declaration displays the full symbol it

abbreviates, and it lapses at the end of the statement.

Relations are stated at their height. A relation holds on the values of the slots on which its proof establishes it (Definition 5.6). A hypothesis that restricts a slot is written into the statement that needs it, and nothing outside that statement restricts the object.

Final answers are written with exp, log, the stacked Gamma and the serif family (Definition 1.1(vi)).

Contents

How this handbook is written **1**

I The serif family **14**

1 Conventions, the stacked Gamma and the finite part **15**
1.1 The stacked Gamma 16
1.2 The finite part 17

2 The Gramma and the Zamma **19**
2.1 The Gramma 19
2.2 The Zamma 21

3 The Breta **24**
3.1 Definition and the tower 24
3.2 Letters 26
3.3 The shape integral 27
3.4 Products of shape integrals 28
3.5 The Beta port 28

4 Fibre integrals and closing **31**

5 The Trailmoment **34**
5.1 Definition 34
5.2 Slots, corners and heights 35
5.3 Relations at free slots 36
5.4 Lattices 38
5.5 The Gamma read by Trailmoments 38
5.6 Reflections of the index 41
5.7 Joint sources 42
5.8 Trails 43
5.9 Products of Trailmoments 44
5.10 Convolutions of inputs 46

6 Rational words and live inputs **48**
6.1 Live inputs 51

II Tables and families **54**

7 Tables **55**
7.1 Characters, tables, lists 55
7.2 Circuits and molecules 55
7.3 The Skeleton 56
7.4 Multivectors of any tensor rank 58

8 Families **60**
8.1 The interest and its walls 60
8.2 The native gauge 65

III Classification **67**

9 Realizations and the still **68**
9.1 Realizations 68
9.2 The potential and the still 69

10 The reading, classes, atoms **71**
10.1 Views and the reading 71
10.2 Identifying writings 72
10.3 What a class holds 73

11 Lean, gauge and label **74**
11.1 The lean 74
11.2 The gauge 74
11.3 Answers and the label 75
11.4 Maps as certificates 76

12 Restriction to a bunch **77**
12.1 Patterns and the Taylor cube 77
12.2 The Skeleton polynomials of a bunch 78
12.3 Levels 80
12.4 Shares and the native split 83

13 The order of classes and the Foreman bunch **84**
13.1 The rises of a class 84
13.2 The order 85
13.3 What the first stages read 86

14 Peel, children and the Foreman tree **88**
14.1 The peel and the tree 88
14.2 Patterns of one kind 89
14.3 What the room keeps 90

IV Evaluation **93**

15 The integral at a bunch **94**
15.1 The scale of a bunch 94
15.2 Closing 96
15.3 The port 99
15.4 Signed letters 100

16 Integrals, expectations and the Foreman procedure **101**
16.1 Forms, sections, completions 101
16.2 Three integrals and their expectations 103
16.3 Quasi-integrals as Laurent data 107
16.4 The pseudointegral 109

17 The family as one Laplace transform **114**
17.1 Questions and the law of the tilt 114

18 The Breta law and the port on the balance wall **119**
18.1 The laws 119
18.2 The port on the balance wall 122
18.3 Cycles 126

19 Bunches of width one: pooling and cleaning **128**
19.1 Bunches of width one 128
19.2 Pooling 130
19.3 Walls glue 131
19.4 Full leans 131
19.5 Partial leans 132
19.6 Closing at a wall and closing at the gauge 135
19.7 The scale on the totals 141
19.8 Width zero 146
19.9 Pooling is a move 147
19.10Cleaning a molecule 147

20 Words of a tree **149**
20.1 The two letters of a table at once 149
20.2 The junction in pattern form 150
20.3 The word of a tree 151
20.4 Closing the tree by draws 153
20.5 Devices at the centre 157
20.6 The junction under level form 159
20.7 The node in one scale 160
20.8 The reach read on the law 168
20.9 One tree 173

V Construction and composition **177**

21 Gluing and what crosses it **178**
21.1 Gluing along a mark . . . 178
21.2 Splicing hinges in pairs . . . 183
21.3 What crosses a gluing . . . 184

22 Periods of constructions **187**
22.1 The core reads its cells . . . 187
22.2 Pinned cells . . . 189
22.3 Chains and transfer . . . 190
22.4 A bunch of any width . . . 191

23 The law of a cell **193**
23.1 Cells and their laws . . . 193
23.2 Absorbing a cell . . . 194
23.3 Closures . . . 195
23.4 Cores and their markers . . . 196
23.5 Two cells glued . . . 197
23.6 What a cell retains . . . 200
23.7 Series and parallel nodes . . . 202
23.8 Hinge trees . . . 203

24 Repetition and the change of query **207**
24.1 Repetition at a node . . . 207
24.2 Chains . . . 209
24.3 The weight of a hinge . . . 210
24.4 Changing masses and weights . . . 211

25 Holds and the lean convolution **213**
25.1 Newton words . . . 213
25.2 Holds and the periods at the full leans . . . 215
25.3 The lean convolution . . . 217
25.4 Holding some marks . . . 218

26 Periods at the full leans and networks along a hinge tree **220**
26.1 Molecules and marker loads . . . 220
26.2 The periods of a substitution at its full leans . . . 221
26.3 What a node costs . . . 222
26.4 Blocks aggregate . . . 223
26.5 The network theorem . . . 224
26.6 Nodes in hold form . . . 226
26.7 The procedure and its cost . . . 227
26.8 Changing the query in hold form . . . 228

27 Finite interfaces and certified enclosures **231**
27.1 The joint law of the channels and its moments . . . 231
27.2 Repetition is a finite matrix . . . 233
27.3 A certified enclosure of the period . . . 234
27.4 Changing the query with finite data . . . 235
27.5 Certified parameter banks . . . 235
27.6 Procedures . . . 237

28 Bunches of any width **239**
28.1 The seam of a bunch . . . 239
28.2 Pieces, their laws, and the glue . . . 242
28.3 The Gramma of a set of pairs . . . 248
28.4 What a piece retains . . . 251
28.5 Storage, and what replaces it . . . 252

29 Composing bunches **256**
29.1 Cores, nested pieces and chains of bunches . . . 256
29.2 The procedure . . . 261
29.3 The correspondence . . . 262

30 Foreman fusion **264**
30.1 Quotients, lifts and the level cell of a pair . . . 265
30.2 The fused table . . . 265
30.3 The seam of the fusion bunch and the glue . . . 268
30.4 The price of width . . . 271
30.5 Cousins and hidden symmetry . . . 273
30.6 Two-sums and repair . . . 274
30.7 The procedure . . . 276

31 Closing a glue along a direction **278**
31.1 Closing along a direction . . . 278
31.2 Closing along a path . . . 279
31.3 Retained crossings as joint words . . . 289
31.3.1 Completing the retained fibre before taking its size . . . 289
31.3.2 Coincident crossings and the boundary at root rate one . . . 296

32 Laws at their ends: regions of equality and reach **299**
32.1 Regions on which a law is represented . . . 299
32.2 The reach along a direction . . . 304
32.3 What the calculus of bunches settles . . . 313

33 Price and complexity **316**
33.1 Constructions and their price . . . 316

VI The arithmetic of the output **319**

34 The motive of a family and the coaction along a tree **320**
34.1 The model . . . 320

34.2 Motivic periods . . . 322
34.3 Steps along a tree of bunches . . . 324
34.4 The weights of the coaction . . . 324
34.5 The node . . . 326
34.6 Pinned cells . . . 327
34.7 Rational data . . . 329
34.8 Separation by conjugates . . . 330

35 Positive words **331**
35.1 Coefficient jets and basis contrasts . . . 331
35.2 Manufactured tables and their port words . . . 333
35.3 Mark relations with the room integrated . . . 335

36 The critical-line law **339**
36.1 Critical-line words . . . 340

37 The gap and the shape words **343**
37.1 Clearing and the gap . . . 343
37.2 Shape words with polynomial insertions . . . 343
37.3 Rows . . . 346
37.4 The Beta port ladder and the filters . . . 346
37.5 Growing Beta ports . . . 348

VII Rays **350**

38 Rays, native gauges and tiers **351**
38.1 The relations along a ray . . . 351
38.2 Native gauges carry solutions . . . 352
38.3 The centre ray of a family . . . 354
38.4 What a wall carries . . . 357
38.5 Corners of a wall of width one . . . 359
38.6 What a value can contain . . . 361

39 The two ends of a ray **363**
39.1 The module of a ray . . . 364
39.2 The motive of a ray . . . 366
39.3 Symmetries of a ray . . . 367
39.4 The box of the walls . . . 369
39.5 Sources at the high end . . . 373
39.6 Closings at the low end . . . 376
39.7 Separating the sources and gluing them . . . 379
39.8 The pencil of a ray . . . 381
39.9 The pencil along a hinge tree . . . 383
39.10What the closings see . . . 385
39.11Wheels: the letters as a holonomy . . . 388
39.12The procedure . . . 390

40 The stride's law and the gauge end **392**
40.1 The stride's law . . . 392
40.2 The gauge end . . . 394
40.3 The torus value . . . 397

41 Reading a ray **399**
41.1 The low end and the slit . . . 399
41.2 Positive selection . . . 401
41.3 Positivity as a moment problem . . . 401
41.4 The procedure . . . 403
41.5 What a reading costs . . . 406

42 Inputs along a ray **409**
42.1 Inputs read from a ray . . . 410
42.2 Closing an input . . . 410
42.3 A mark opened at an integer strength . . . 411
42.4 Boundaries and minimality . . . 412
42.5 The two ends paired . . . 413
42.6 The centre ray of $\binom{\mathcal{E}}{1}$ . . . 413
42.7 The centre ray of a substitution . . . 418
42.8 The value of a table as a closed serif word . . . 421
42.9 The class at silence . . . 423
42.10The sources of a substitution of classes . . . 425

43 Arithmetic along a ray **427**
43.1 Closing a free share along a ray . . . 427
43.2 The clearing along a ray . . . 429
43.3 The merit of a ray . . . 430
43.4 Laws at the low end and their closings . . . 431
43.5 The hinge closing as a row over the room . . . 432
43.6 Critical primes . . . 433

VIII Relations and the content **435**

44 Relations and separation **436**
44.1 Words and relations . . . 436
44.2 Relation blocks . . . 437
44.3 Separators . . . 438
44.4 Completeness along a ray . . . 439
44.5 Separating generators . . . 440

45 The content and its coaction **441**
45.1 The content . . . 441
45.2 Chains . . . 443
45.3 The cutting rule . . . 443
45.4 The letter of a live input . . . 445
45.5 Separation of the content . . . 446

45.6 The closing in any number of shares . . . 448
45.7 The group of a period . . . 451
45.8 The group of a word along the tree . . . 455

46 Finite algebra for scale reads **458**
46.1 Complete relations for linear letters and unit columns . . . 458
46.2 Polynomial letters on one scale . . . 462

47 The module of a family **466**
47.1 The data of a family . . . 466
47.2 The module and its shifts . . . 467
47.3 Boxes in all the data . . . 469
47.4 Closings and the elements of value zero . . . 470
47.5 Masters from a box . . . 471
47.6 Value zero on a subspace of the data . . . 472
47.7 The values separate the module . . . 474
47.8 The number of masters . . . 475

48 The module along the tree **477**
48.1 Families of positive letters . . . 478
48.2 Share readings . . . 480
48.3 Paths through a chain of bunches . . . 482
48.4 Shares and scales . . . 484
48.5 Trees of nested bunches . . . 486
48.6 What the word along a tree reads . . . 491
48.7 The module of a family from its nodes . . . 493
48.8 The module of a transform from its block . . . 497
48.9 The procedure in all the data . . . 502

IX The family as inference **509**

49 The family as inference **510**
49.1 Samples of bases . . . 510
49.2 Samples of tilts . . . 513
49.3 Draws, orders and races . . . 519
49.4 The interaction of a bunch . . . 521

X Proofs of the general forms **523**

50 Proofs of the general forms **524**
50.1 Chapter 1: conventions, the stacked Gamma and the finite part . . . 524
50.2 Chapter 2: the Gramma and the Zamma . . . 527
50.3 Chapter 3: the Breta . . . 530
50.4 Chapter 4: fibre integrals and closing . . . 534
50.5 Chapter 5: the Trailmoment . . . 535
50.6 Chapter 6: rational words and live inputs . . . 539
50.7 Chapter 7: tables . . . 542

50.8 Chapter 8: families . . . 544
50.9 Chapter 9: realizations and the still . . . 549
50.10Chapter 10: the reading, classes, atoms . . . 550
50.11Chapter 11: lean, gauge and label . . . 551
50.12Chapter 12: restriction to a bunch . . . 553
50.13Chapter 13: the order of classes and the Foreman bunch . . . 556
50.14Chapter 14: peel, children and the Foreman tree . . . 557
50.15Chapter 15: the integral at a bunch . . . 559
50.16Chapter 16: integrals, expectations and the Foreman procedure . . . 564
50.17Chapter 17: the family as one Laplace transform . . . 570
50.17.1 What the one-table proofs read, and what a family reads . . . 570
50.17.2 The exponent of a question . . . 570
50.17.3 The two ends of strength . . . 572
50.17.4 How far a question can lean, and the tails . . . 574
50.18Chapter 18: the Breta law and the port on the balance wall . . . 576
50.19Chapter 19: bunches of width one: pooling and cleaning . . . 583
50.20Chapter 20: words of a tree . . . 596
50.21Chapter 21: gluing and what crosses it . . . 609
50.22Chapter 22: periods of constructions . . . 613
50.23Chapter 23: the law of a cell . . . 619
50.24Chapter 24: repetition and the change of query . . . 627
50.25Chapter 25: holds and the lean convolution . . . 630
50.26Chapter 26: periods at the full leans and networks along a hinge tree . . . 637
50.27Chapter 27: finite interfaces and certified enclosures . . . 646
50.28Chapter 28: bunches of any width . . . 648
50.29Chapter 29: composing bunches . . . 659
50.30Chapter 30: Foreman fusion . . . 660
50.31Chapter 31: closing a glue along a direction . . . 672
50.32Chapter 32: laws at their ends: regions of equality and reach . . . 683
50.33Chapter 34: the motive of a family and the coaction along a tree . . . 685
50.34Chapter 35: positive words . . . 701
50.35Chapter 36: the critical-line law . . . 705
50.36Chapter 37: the gap and the shape words . . . 706
50.37Chapter 38: rays, native gauges and tiers . . . 708
50.38Chapter 39: the two ends of a ray . . . 720
50.39Chapter 40: the stride's law and the gauge end . . . 750
50.40Chapter 41: reading a ray . . . 758
50.41Chapter 42: inputs along a ray . . . 768
50.42Chapter 43: arithmetic along a ray . . . 790
50.43Chapter 44: relations and separation . . . 797
50.44Chapter 45: the content and its coaction . . . 799
50.45Chapter 46: finite algebra for scale reads . . . 816
50.46Chapter 47: the module of a family . . . 819
50.47Chapter 48: the module along the tree . . . 831
50.48Chapter 49: the family as inference . . . 871
50.48.1 Samples of bases . . . 871
50.48.2 Statistics from a centre . . . 873

50.48.3 The Grey law, the dial and the sorted draw 874
50.48.4 The interaction of a bunch 876
50.49 Receipts 878
50.49.1 Chapters 35 to 46 878
50.49.2 Chapters 17 and 49 878

XI Exercises **879**

51 Exercises on tables, families and classification **881**
51.1 The list on two marks 881
51.2 The pins of the atom formula 884
51.3 Foreman trees 887
51.4 Skeleton values at width two 892
51.5 The record of a peel 892

52 Exercises on evaluation and construction **895**
52.1 One share per station 895
52.2 The width of the marks left in place 898
52.3 Fusing a uniform list 899

53 Exercises on the motive and the arithmetic of values **901**
53.1 Uniform lists at their centres 901
53.2 Substitutions of dual pairs 909
53.3 Full leans 911

54 Exercises on rays: the small centres **914**
54.1 The centre ray, bracketed 914
54.2 The centre ray by its box 919
54.3 The centre ray from its gauge end 922
54.4 The torus at three marks 924
54.5 A lean of three marks 928
54.6 The balanced directions 930
54.7 The centre of $\binom{[4]}{1}$ 932
54.8 The centre of $\binom{[5]}{1}$ 941
54.9 W_3 at $(\mathbf{1}; 0, 2)$ 948
54.10 Positivity against the gauge end 951
54.11 What the closings see 952

55 Exercises on rays: other lists **960**
55.1 The list H_4 960
55.2 The five-mark lists 969
55.3 Larger lists and the cost of a reading 973
55.4 Triangles of classes 990

56 Exercises on the content **997**
56.1 Two centre values in the content 997
56.2 The cutting rule on two trails 999
56.3 Separation of the content 1002
56.4 The closing of a period in any number of shares 1005

Aliases **1007**

Part I

The serif family

Chapter 1

Conventions, the stacked Gamma and the finite part

Definition 1.1 (Conventions)**.** (i) $\mathcal{E}$ and B are finite nonempty sets and $n = |\mathcal{E}|$. For $x \in \mathbb{R}^{\mathcal{E}}_{>0}$ and $v \in \mathbb{C}^{\mathcal{E}}$, $x^v = \prod_e x_e^{v_e}$ with $x_e^{v_e} = \exp(v_e \log x_e)$. For a vector v, $|v| = \sum_e v_e$. $\mathbf{1}$ is the all-ones vector, $\mathbf{1}_S$ the indicator of S, $x^S = x^{\mathbf{1}_S}$, $v_S = \sum_{e \in S} v_e$, $v|_S$ the restriction of v to S, and $x^{-1} = (x_e^{-1})_e$. For a set X and elements a, b, $X - a = X \setminus \{a\}$ and $X + b = X \cup \{b\}$. $\mathbb{N} = \{0, 1, 2, \dots\}$.

(ii) For $\alpha \in \mathbb{R}^{\mathcal{E}}_{>0}$ the *logarithmic coordinates* are $y = \log \alpha$ and the *signed coordinates* are $z = \frac{1}{2} y$, coordinatewise, so $\alpha = e^y = e^{2z}$.

(iii) $\Delta_B = \{u \in \mathbb{R}^B_{>0} : |u| = 1\}$ is the *shape simplex* of B, and $d\omega_B(u)$ is Lebesgue measure in the coordinates $(u_e)_{e \neq e_0}$ for a fixed $e_0 \in B$; a change of e_0 is affine of determinant ± 1. For $|B| = 1$, ω_B is the Dirac measure at the point of Δ_B.

(iv) An integral *converges* when it converges absolutely.

(v) $(a)_j = \Gamma(a + j)/\Gamma(a)$ for $j \in \mathbb{N}$; $d_n = \operatorname{lcm}(1, \dots, n)$ with $d_0 = 1$; e_k is the elementary symmetric polynomial of degree k; for a coordinate x of the unit interval, $\bar{x} = 1 - x$; $[X]\, Y$ is the coefficient of X in Y.

(vi) *Final answers* are written with exp, log, the stacked Gamma and the serif family: the Gramma G and the Zamma Z (Chapter 2), the Breta B (Chapter 3) and the Trailmoment T (Chapter 5). A value of interest is left in another form only with a proof that it has no such expression. A *word* is an expression built from rationals, the data and the variables by sums, products, powers with rational exponents or exponents among the data, these functions, integrals over simplices, half-lines and fibres, and the iterate $\mathcal{Q}^M$ of an integral operator whose kernel is a word. A finite sequence $(w_1, \dots, w_k)$ is a *string* of length k. An *insertion* is a function multiplied into an integrand.

(vii) For masses $\mathbf{m}$, $d\alpha_{\mathbf{m}} := \alpha^{\mathbf{m}-\mathbf{1}} d\alpha$ is a measure on the orthant, and a form $f\, d\alpha_{\mathbf{m}}$ unchanged by $\alpha \mapsto \lambda\alpha$, f homogeneous of degree $-m_{\mathcal{E}}$, is integrated over the rays of the orthant, that is over any section (Chapter 16), as the form $W\, d\alpha_{\mathbf{m}}$ of a family word W (Chapter 8) is on its balance wall; a mark or a set of marks as a subscript, as in $d\alpha_B$, denotes coordinates. The law of a random variable, or of a measure under a map, is its image measure; an identity between members of the serif family is a relation (Chapter 5). An expectation names its random variable and that variable's law, $\mathbb{E}_{U \sim P}[g(U)] = \int g(u)\, P(du)$; inside a statement that has named them once, the subscript may be dropped for the rest of that

statement. The *Gamma law* of index $\nu > 0$ is $\mathrm{Gamma}_\nu(dx) = x^{\nu-1}e^{-x}dx/\Gamma(\nu)$ on $(0,\infty)$, and for $\mathbf{m} \in \mathbb{R}^B_{>0}$, $\mathrm{Gamma}_{\mathbf{m}} = \bigotimes_{e\in B} \mathrm{Gamma}_{m_e}$ is the law on $\mathbb{R}^B_{>0}$ of independent Gamma coordinates of indices m_e. The generalized integrals of Chapter 16 are unnormalized, and their expectations divide them by the period of the centre: on a connected family every expectation of a form is taken under the law of its centre, $\mathbb{P}_{\mathrm{c}}$, of the departure that its evaluation sets.

(viii) The *root rate* of terms a_η indexed by sizes $\eta \to \infty$, as the terms of a lattice by the real parts of their exponents or the terms of a closing by its steps, is $\limsup |a_\eta|^{1/\eta}$. When the number of terms of size at most N grows at most polynomially in N, terms of root rate below one are absolutely summable, and terms of root rate above one do not tend to zero.

1.1 The stacked Gamma

Definition 1.2 (The stacked Gamma)**.** For $\alpha \in \mathbb{C}^p$ and $\beta \in \mathbb{C}^q$,

$$\Gamma_{\substack{p\\q}}\!\left[\begin{matrix}\alpha_1,\ \dots,\ \alpha_p\\ \beta_1,\ \dots,\ \beta_q\end{matrix}\right] := \frac{\Gamma(\alpha_1)\cdots\Gamma(\alpha_p)}{\Gamma(\beta_1)\cdots\Gamma(\beta_q)},$$

wherever no α_i is a pole of Γ; it is a meromorphic function of its entries. The stacked Gamma is *balanced* when $\sum_i \alpha_i = \sum_j \beta_j$.

The subscripts of the bracket record the numbers of its upper and lower entries, so a quotient of Gammas is read off the symbol with no translation. The stacked Gamma $\Gamma_{\substack{|B|\\1}}\!\left[\begin{matrix}\mathbf{m}\\ m_B\end{matrix}\right] = \prod_{e\in B}\Gamma(m_e)/\Gamma(m_B)$ of masses $\mathbf{m} \in \mathbb{C}^B$ over their total m_B is, for $\mathrm{Re}\, m_e > 0$, the integral of $u^{\mathbf{m}-\mathbf{1}}$ over the shape simplex Δ_B (Theorem 3.9).

Proposition 1.3 (Relations of the stacked Gamma)**.** *(i)* Concatenation. $\Gamma_{\substack{p\\q}}\!\left[\begin{matrix}\boldsymbol{\alpha}\\ \boldsymbol{\beta}\end{matrix}\right]\Gamma_{\substack{p'\\q'}}\!\left[\begin{matrix}\boldsymbol{\alpha}'\\ \boldsymbol{\beta}'\end{matrix}\right] = \Gamma_{\substack{p+p'\\q+q'}}\!\left[\begin{matrix}\boldsymbol{\alpha},\ \boldsymbol{\alpha}'\\ \boldsymbol{\beta},\ \boldsymbol{\beta}'\end{matrix}\right]$.

(ii) Cancellation. $\Gamma_{\substack{p\\q}}\!\left[\begin{matrix}\boldsymbol{\alpha},\ c\\ \boldsymbol{\beta},\ c\end{matrix}\right] = \Gamma_{\substack{p-1\\q-1}}\!\left[\begin{matrix}\boldsymbol{\alpha}\\ \boldsymbol{\beta}\end{matrix}\right]$.

(iii) Shift. $\Gamma_{\substack{p\\q}}\!\left[\begin{matrix}\alpha_1+1,\ \boldsymbol{\alpha}\\ \boldsymbol{\beta}\end{matrix}\right] = \alpha_1\Gamma_{\substack{p\\q}}\!\left[\begin{matrix}\alpha_1,\ \boldsymbol{\alpha}\\ \boldsymbol{\beta}\end{matrix}\right]$ *and* $\Gamma_{\substack{p\\q}}\!\left[\begin{matrix}\boldsymbol{\alpha}\\ \beta_1+1,\ \boldsymbol{\beta}\end{matrix}\right] = \beta_1^{-1}\Gamma_{\substack{p\\q}}\!\left[\begin{matrix}\boldsymbol{\alpha}\\ \beta_1,\ \boldsymbol{\beta}\end{matrix}\right]$.

(iv) Residue. *For* $j \in \mathbb{N}$, $\operatorname*{Res}_{\alpha_1=-j}\Gamma_{\substack{p\\q}}\!\left[\begin{matrix}\alpha_1,\ \boldsymbol{\alpha}\\ \boldsymbol{\beta}\end{matrix}\right] = \frac{(-1)^j}{j!}\Gamma_{\substack{p-1\\q}}\!\left[\begin{matrix}\boldsymbol{\alpha}\\ \boldsymbol{\beta}\end{matrix}\right]\Big|_{\alpha_1=-j}$.

(v) Reflection. $\Gamma_{\substack{2\\0}}\big[a,\ 1-a\big] = \pi/\sin\pi a$.

(vi) Laurent data at a pole. *For* $j \in \mathbb{N}$,

$$\Gamma(-j+\varepsilon) = \frac{(-1)^j}{j!}\Big(\frac{1}{\varepsilon} + (\log\Gamma)'(j+1) + O(\varepsilon)\Big), \qquad (\log\Gamma)'(\nu+1) = (\log\Gamma)'(\nu) + \frac{1}{\nu}.$$

Remark 1.4 (Balance is a property of the written stacked Gamma). Balance is not a property of the value of a stacked Gamma: the shift (iii) and the reflection (v) change the sums of the entries,

multiplying the value by an algebraic number when the entries are rational. For rational $a \notin \mathbb{Z}$, (v) at a and at $\frac{1}{2}$, with $\Gamma(1) = 1$, gives

$$\Gamma_{\substack{2\\0}}\big[a,\ 1-a\big] = \frac{1}{\sin \pi a}\,\Gamma_{\substack{2\\1}}\left[\begin{matrix}\frac{1}{2},\ \frac{1}{2}\\ 1\end{matrix}\right],$$

the left side with the sums 1 and 0, the right side balanced, and $\sin \pi a$ algebraic.

1.2 The finite part

Definition 1.5 (The finite part)**.** A function h on $(0,\infty)$ has a *log-power expansion* at 0 if for every N there are finitely many coefficients $c_{k,j}$, with exponents $k \in \mathbb{C}$ of real part below N and $j \in \mathbb{N}$, such that $h(x) - \sum c_{k,j} x^k \log^j x = O(x^N)$ as $x \to 0$; at ∞ the same holds with x^{-k} and $O(x^{-N})$. The coefficients are determined by h. Then $\operatorname{Reg}_{x\to 0} h$ and $\operatorname{Reg}_{x\to\infty} h$ are the coefficients of $x^0 \log^0 x$ in these expansions, zero if absent. If f has a primitive h with log-power expansions at both ends,

$$\operatorname{Reg}\int_0^\infty f\,dx := \operatorname{Reg}_{x\to\infty} h - \operatorname{Reg}_{x\to 0} h,$$

which does not depend on the primitive; on $(0,b]$, $\operatorname{Reg}\int_0^b f := h(b) - \operatorname{Reg}_{x\to 0} h$. A sum is regularized the same way, $\operatorname{Reg}_{N\to\infty}$ of its partial sums. The coordinate is part of the data of a finite part, and for iterated finite parts so is the order.

Proposition 1.6 (A convergent integral is its own finite part)**.** *If $\int_0^\infty f\,dx$ converges and f has a primitive with log-power expansions at both ends, then $\operatorname{Reg}\int_0^\infty f\,dx = \int_0^\infty f\,dx$.*

Theorem 1.7 (A finite part is a constant term)**.** *If f has log-power expansions at 0 and at ∞, then*

$$\operatorname{Reg}\int_0^\infty f\,dx = \operatorname*{CT}_{\varepsilon=0}\int_0^\infty x^\varepsilon f(x)\,dx,$$

the right side continued meromorphically in ε from $\int_0^1$ and from $\int_1^\infty$ separately. Termwise, $x^b \log^j x$ in the expansion at 0 contributes $\int_0^1 x^{b+\varepsilon}\log^j x\,dx = (-1)^j j!/(b+1+\varepsilon)^{j+1}$, whose constant term is $(-1)^j j!/(b+1)^{j+1}$ for $b \neq -1$ and 0 for $b = -1$; the end at ∞ is the same after $x \mapsto 1/x$.

Corollary 1.8 (Finite parts at a pole of a Mellin integral)**.** *Let f have a log-power expansion at 0 and be integrable on $[\delta,1]$ for every $\delta > 0$, and let $I(a) = \int_0^1 x^{a-1} f(x)\,dx$, continued meromorphically. Then $\operatorname{Reg}\int_0^1 x^{a-1} f(x)\,dx = \operatorname{CT}_{a'=a} I(a')$ for every $a \in \mathbb{C}$: it is $I(a)$ at every a that is not a pole, and the poles lie at the points $a = -k$ for the exponents k of the expansion, a term $x^k \log^j x$ giving a pole of order at most $j+1$.*

Lemma 1.9 (A finite part depends on the coordinate)**.** *Let h have a log-power expansion at ∞, and let a_j be its coefficient of $x^0 \log^j x$, $j \in \mathbb{N}$. For $c,p > 0$, $h(cx^p)$ has a log-power expansion at ∞, and*

$$\operatorname{Reg}_{x\to\infty} h(cx^p) = \sum_{j\geq 0} a_j\,(\log c)^j;$$

the same holds at 0. Consequently, if f has log-power expansions at 0 and at ∞, with coefficients f_j^0 and f_j^∞ of $x^{-1}\log^j x$, then for $c,p > 0$

$$\operatorname{Reg}\int_0^\infty f(cx^p)\,c\,p\,x^{p-1}\,dx = \operatorname{Reg}\int_0^\infty f(x)\,dx + \sum_{j\geq 0}\frac{(\log c)^{j+1}}{j+1}\big(f_j^\infty - f_j^0\big)\,:$$

a power of the coordinate leaves a finite part unchanged, and a dilation moves it by a polynomial in $\log c$ *read from the terms* $x^{-1}\log^j x$ *of the integrand at its two ends.*

A finite part is the difference of the regularized limits of one primitive at the two ends, not the integral of a measure. It is linear, it moves with the coordinate (Lemma 1.9), and iterated in several variables it moves with the order. The generalized integrals of Chapter 16 are built from it: a quasi-integral is an iterated finite part along a chart and an order, and the pseudointegral is the value of the native completion (Definition 16.29).

Chapter 2

The Gramma and the Zamma

2.1 The Gramma

Definition 2.1 (Gramma)**.** Let $\mathcal{E}$ be a finite set of *scales*. A *configuration* on $\mathcal{E}$ is a finite family $t = (t_1, \dots, t_N)$ of *exponents* $t_k \in \mathbb{R}^{\mathcal{E}}$; t also denotes the $\mathcal{E} \times N$ matrix with these columns. For *coefficients* $\boldsymbol{\xi} \in (0,\infty)^N$ and an *index* $\nu \in \mathbb{C}^{\mathcal{E}}$, the *Gramma* is

$$\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) := \int_{\mathbb{R}^{\mathcal{E}}_{>0}} x^{\nu-\mathbf{1}} \exp\Big(-\sum_{k=1}^{N} \xi_k\, x^{t_k} \Big)\, dx$$

wherever the integral converges. Put $\operatorname{cone}(t) = \{\sum_k c_k t_k :\ c \in [0,\infty)^N\}$ and $\mathcal{T}_t = \{\nu : \operatorname{Re}\nu \in \operatorname{int}\operatorname{cone}(t)\}$. In $y = \log x$,

$$\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = \int_{\mathbb{R}^{\mathcal{E}}} e^{\langle \nu, y\rangle} \exp\Big(-\sum_{k} \xi_k e^{\langle t_k, y\rangle} \Big)\, dy,$$

the moment generating function, in the index, of the density $\exp\big(-\sum_k \xi_k e^{\langle t_k,y\rangle}\big)$. Exponents and coefficients combine by concatenation, $t \oplus t'$ and $\boldsymbol{\xi} \oplus \boldsymbol{\xi}'$ (configurations on two sets of scales extended by zero to their union), and a shape u dresses coefficients by $u^t\boldsymbol{\xi} := (u^{t_k}\xi_k)_k$. The *unit configuration* on $\mathcal{E}$ is $I_{\mathcal{E}} = (\mathbf{e}_e)_{e\in\mathcal{E}}$, one unit column per scale, and on one scale the configuration of the single exponent 1 is written (1).

The three slots of the Gramma (Definition 5.6) are its index, its configuration and its coefficients. Every structural relation of the Gramma is a statement about how these slots move: the index moves along the exponents, the coefficients are rescaled by the torus of the scales, and the configuration passes to its facets at its walls.

Theorem 2.2 (Domain)**.** $\mathsf{G}_{\nu;t}(\boldsymbol{\xi})$ *converges if and only if* $\nu \in \mathcal{T}_t$*, and it is holomorphic on* $\mathcal{T}_t$*. If* $\operatorname{cone}(t) = \mathbb{R}^{\mathcal{E}}$ *it is entire; if* $\operatorname{cone}(t)$ *lies in a hyperplane it converges nowhere.*

Proposition 2.3 (Affine changes of the logarithmic coordinates)**.** *For* $A \in GL_{\mathcal{E}}(\mathbb{R})$ *and* $\mathbf{h} \in \mathbb{R}^{\mathcal{E}}$*:* $\mathcal{T}_{A^{\mathsf{T}}t} = A^{\mathsf{T}}\mathcal{T}_t$*, and for* $\nu \in \mathcal{T}_t$

$$\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = |\det A|\, e^{\langle \nu, \mathbf{h}\rangle}\, \mathsf{G}_{A^{\mathsf{T}}\nu;A^{\mathsf{T}}t}\big((e^{\langle t_k,\mathbf{h}\rangle}\xi_k)_k\big).$$

At $A = -I_{\mathcal{E}}$ *and* $\mathbf{h} = 0$ *this is the reflection,* $\mathcal{T}_{-t} = -\mathcal{T}_t$ *and* $\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = \mathsf{G}_{-\nu;-t}(\boldsymbol{\xi})$*.*

Theorem 2.4 (Relations of the Gramma)**.** *Let* $\nu \in \mathcal{T}_t$*; then* $\nu + t_k \in \mathcal{T}_t$ *for every* k*.*

(i) Ladder. $\partial_{\xi_k}\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = -\mathsf{G}_{\nu+t_k;t}(\boldsymbol{\xi})$*; for* $\mathbf{w}\in\mathbb{N}^N$, $\partial^{\mathbf{w}}\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = (-1)^{|\mathbf{w}|}\mathsf{G}_{\nu+t\mathbf{w};t}(\boldsymbol{\xi})$.

(ii) Exchange, one relation per scale. *For each* $e\in\mathcal{E}$: $\nu_e\,\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = \sum_k t_{k,e}\,\xi_k\,\mathsf{G}_{\nu+t_k;t}(\boldsymbol{\xi})$.

(iii) Torus homogeneity. *For* $\lambda\in\mathbb{R}^{\mathcal{E}}_{>0}$: $\mathsf{G}_{\nu;t}\big((\lambda^{t_k}\xi_k)_k\big) = \lambda^{-\nu}\mathsf{G}_{\nu;t}(\boldsymbol{\xi})$ *(Proposition 2.3 at* $A = I_{\mathcal{E}}$, $\mathbf{h} = \log\lambda$*).*

(iv) Toric relation. *For every* $\mathbf{v}\in\mathbb{Z}^N$ *with* $t\mathbf{v} = 0$*, written* $\mathbf{v} = \mathbf{v}^+ - \mathbf{v}^-$ *with* $\mathbf{v}^{\pm}\in\mathbb{N}^N$ *of disjoint supports,*

$$\partial^{\mathbf{v}^+}\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = (-1)^{|\mathbf{v}^+|-|\mathbf{v}^-|}\,\partial^{\mathbf{v}^-}\mathsf{G}_{\nu;t}(\boldsymbol{\xi}).$$

The ladder moves the index along one exponent; the exchange relation, one for each scale, is linear in the Grammas at the index and at its N neighbours $\nu + t_k$; the toric relation records the linear dependencies among the exponents themselves. On one scale with integer exponents the exchange relation is a recurrence on the indices $\nu + \mathbb{Z}$ linking the indices from $\nu + \min(0, \min_k t_k)$ to $\nu + \max(0, \max_k t_k)$.

Theorem 2.5 (Product)**.** *If* $\mathcal{E} = \mathcal{E}_1 \sqcup \cdots \sqcup \mathcal{E}_q$ *and each* t_k *is supported in one* $\mathcal{E}_i$ *(zero vectors assigned to* $\mathcal{E}_1$*), then* $\mathcal{T}_t = \mathcal{T}_{t^{(1)}} \times \cdots \times \mathcal{T}_{t^{(q)}}$ *and*

$$\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = \prod_{i=1}^{q} \mathsf{G}_{\nu|_{\mathcal{E}_i};t^{(i)}}(\boldsymbol{\xi}^{(i)}),$$

with $t^{(i)}$ *the exponents supported in* $\mathcal{E}_i$ *and* $\boldsymbol{\xi}^{(i)}$ *their coefficients.*

Corollary 2.6 (Square configurations)**.** *Let* $N = |\mathcal{E}|$ *and let the matrix* t *be invertible, and put* $\mathbf{b} = t^{-1}\nu$*. Then* $\mathcal{T}_t = \{\nu : \operatorname{Re}\mathbf{b}\in(0,\infty)^N\}$ *and*

$$\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = |\det t|^{-1}\prod_{k=1}^{N}\Gamma(b_k)\,\xi_k^{-b_k}.$$

In particular $\mathsf{G}_{\nu;I_{\mathcal{E}}}(\boldsymbol{\xi}) = \prod_e \Gamma(\nu_e)\,\xi_e^{-\nu_e}$*; on one scale* $\mathsf{G}_{\nu;(t_1)}(\xi) = t_1^{-1}\Gamma(\nu/t_1)\,\xi^{-\nu/t_1}$ *for* $t_1 > 0$*; and* $\Gamma(\nu) = \mathsf{G}_{\nu;(1)}(1)$*, whose exchange relation is* $\nu\Gamma(\nu) = \Gamma(\nu+1)$*.*

The Gamma function is thus the Gramma of one scale and one unit exponent, and at every invertible square configuration the Gramma is a stacked Gamma times powers, divided by $|\det t|$. A configuration with more exponents than scales is where the Gramma becomes more than a stacked Gamma times powers: the difference $N - |\mathcal{E}|$ is the dimension of the share side of Proposition 4.2.

Lemma 2.7 (Scale and shape)**.** *The map* $(0,\infty)\times\Delta_B\to\mathbb{R}^B_{>0}$, $(\rho,u)\mapsto\rho u$*, is a bijection with inverse* $x\mapsto(|x|, x/|x|)$*, and* $dx = \rho^{|B|-1}\,d\rho\,d\omega_B(u)$*. Consequently* $(\rho u)^{\pi} = \rho^{\langle\pi,\mathbf{1}_B\rangle}u^{\pi}$ *for* $\pi\in\mathbb{R}^B$*, and* $x^{\mathbf{m}-\mathbf{1}}dx = \rho^{m_B-1}u^{\mathbf{m}-\mathbf{1}}\,d\rho\,d\omega_B(u)$ *for* $\mathbf{m}\in\mathbb{C}^B$*.*

Theorem 2.8 (Scale and shape along sets)**.** *Let* $B_1,\dots,B_q$ *be pairwise disjoint nonempty subsets of* $\mathcal{E}$*,* $R = \mathcal{E}\setminus(B_1\cup\cdots\cup B_q)$ *and* $\nu\in\mathcal{T}_t$*. With the* levels $\ell_{k,i} = \langle t_k, \mathbf{1}_{B_i}\rangle$*, the configuration* $\ell = (\ell_1,\dots,\ell_N)$ *on* q *scales and the coefficients* $\mathbf{b}(u,x_R) = \big(\xi_k\prod_i u_i^{t_k|_{B_i}}x_R^{t_k|_R}\big)_k$ *for* $u = (u_i)_i\in\prod_i\Delta_{B_i}$*,*

$$\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = \int_{\mathbb{R}^R_{>0}} x_R^{\nu|_R-\mathbf{1}}\int_{\prod_i\Delta_{B_i}}\prod_i u_i^{\nu|_{B_i}-\mathbf{1}}\;\mathsf{G}_{(\nu_{B_i})_i;\ell}\big(\mathbf{b}(u,x_R)\big)\,d\omega(u)\,dx_R,$$

with $d\omega = \prod_i d\omega_{B_i}$*, the inner Gramma, on* q *scales at the index* $(\nu_{B_i})_i$*,* $\nu_{B_i} = \sum_{e\in B_i}\nu_e$*, converging for almost every* (u,x_R)*; when* R *is empty there is no outer integral.*

Passing to scale and shape on disjoint sets of scales replaces each set by one scale, its total, carrying the levels of the exponents on the set; what is left of the exponents dresses the coefficients by the shapes. The Breta of Chapter 3 is this passage made into a symbol.

Theorem 2.9 (The walls of a Gramma)**.** *Let $\mathcal{E} = \mathcal{E}' \sqcup \{e\}$, write $t_k = (t'_k, t_{k,e})$ and $\nu = (\nu', \nu_e)$, and suppose $t_{k,e} \geq 0$ for every k, with some $t_{k,e} > 0$. Let $H = \{k : t_{k,e} = 0\}$ be the* facet terms*, suppose* $\operatorname{cone}(t'_H)$ *has nonempty interior in $\mathbb{R}^{\mathcal{E}'}$ and contains t'_k for every $k \notin H$, and let $\operatorname{Re}\nu' \in \operatorname{int}\operatorname{cone}(t'_H)$. Then $\mathsf{G}_{\nu;t}(\boldsymbol{\xi})$ converges for $0 < \operatorname{Re}\nu_e < c$, for some $c \in (0, \infty]$, and extends to a meromorphic function of $\nu_e \in \mathbb{C}$ with at most simple poles at $\nu_e = -p$, $p \in P = \{\sum_{k\notin H} n_k t_{k,e} : \mathbf{n} \in \mathbb{N}^{H^c}\}$, where*

$$\operatorname*{Res}_{\nu_e=-p} \mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = \sum_{\mathbf{n}\in\mathbb{N}^{H^c}:\ \sum_k n_k t_{k,e} = p} \prod_{k\notin H} \frac{(-\xi_k)^{n_k}}{n_k!}\ \mathsf{G}_{\nu' + \sum_{k\notin H} n_k t'_k;\ t'_H}(\boldsymbol{\xi}_H).$$

At $p = 0$ the residue is the Gramma of the facet terms: at its first wall a Gramma factors onto its facet. A linear change of the logarithmic coordinates, $y = Ay'$ with $A \in GL_{\mathcal{E}}(\mathbb{R})$, gives $\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = |\det A|\, \mathsf{G}_{A^{\mathsf{T}}\nu;A^{\mathsf{T}}t}(\boldsymbol{\xi})$ (Proposition 2.3 at $\mathbf{h} = 0$), and with the last column of A the inward normal of a facet of $\operatorname{cone}(t)$ *it puts that facet in the position of H.*

The poles of a Gramma sit on the walls of its cone, and each residue is a Gramma of the facet, of one scale fewer, at an index moved by the exponents that leave the facet. On one scale with positive exponents this is the continuation of the Gramma to the whole index line, with at most simple poles at the points $-p$, $p = \langle \mathbf{n}, t\rangle$ for $\mathbf{n} \in \mathbb{N}^N$, the residue at $-p$ being $\sum_{\langle \mathbf{n},t\rangle = p} \prod_k (-\xi_k)^{n_k}/n_k!$.

Proposition 2.10 (The expansion lattice)**.** *Let S be a set of terms such that the integral with the signs of those terms flipped converges,*

$$\int_{\mathbb{R}^{\mathcal{E}}} \exp\Big(\langle \operatorname{Re}\nu, y\rangle + \sum_{k\in S} \xi_k e^{\langle t_k, y\rangle} - \sum_{k\notin S} \xi_k e^{\langle t_k, y\rangle}\Big) dy < \infty.$$

Then, absolutely,

$$\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = \sum_{\mathbf{n}\in\mathbb{N}^S} \prod_{k\in S} \frac{(-\xi_k)^{n_k}}{n_k!}\ \mathsf{G}_{\nu + \sum_{k\in S} n_k t_k;\ t_{S^c}}(\boldsymbol{\xi}_{S^c}).$$

Theorem 2.11 (The decay polytope)**.** *Let $\nu_0 \in \operatorname{int}\operatorname{cone}(t)$ be real, $\eta \in \mathbb{R}^{\mathcal{E}}$, and $D_t = \{y \in \mathbb{R}^{\mathcal{E}} : |\langle t_k, y\rangle| < \frac{\pi}{2}\ \forall k\}$. For every $y \in D_t$,*

$$\big|\mathsf{G}_{\nu_0 + i\eta;t}(\boldsymbol{\xi})\big| \leq e^{-\langle \eta, y\rangle}\ \mathsf{G}_{\nu_0;t}\big((\xi_k \cos\langle t_k, y\rangle)_k\big).$$

Consequently, with $h_t(\eta) = \sup_{y\in D_t}\langle \eta, y\rangle$, for every $\varepsilon \in (0,1)$

$$\big|\mathsf{G}_{\nu_0 + i\eta;t}(\boldsymbol{\xi})\big| \leq \mathsf{G}_{\nu_0;t}\big(\sin(\tfrac{\pi\varepsilon}{2})\boldsymbol{\xi}\big)\, e^{-(1-\varepsilon)h_t(\eta)},$$

and h_t is a norm when the t_k span $\mathbb{R}^{\mathcal{E}}$.

2.2 The Zamma

Definition 2.12 (Zamma)**.** Wherever $\mathsf{G}_{\nu;t}(\boldsymbol{\xi})$ converges and no ν_e lies in $-\mathbb{N}$, the *Zamma* is the Gramma divided by the Gammas of its own index,

$$\mathsf{Z}_{\nu;t}(\boldsymbol{\xi}) := \frac{\mathsf{G}_{\nu;t}(\boldsymbol{\xi})}{\prod_{e\in\mathcal{E}} \Gamma(\nu_e)}.$$

At the unit configuration it is $\mathsf{Z}_{\nu;I_{\mathcal{E}}}(\boldsymbol{\xi}) := \prod_e \xi_e^{-\nu_e}$ for every $\nu \in \mathbb{C}^{\mathcal{E}}$; where $\operatorname{Re}\nu_e > 0$ for every e this is the quotient $\mathsf{G}_{\nu;I_{\mathcal{E}}}(\boldsymbol{\xi})/\prod_e \Gamma(\nu_e)$. The Zamma carries the continuations of the Gramma wherever the Gramma has them.

The Zamma divides out of the Gramma what is first order in its index, the Gammas that the unit configuration produces on its own; what remains is the content of the configuration. It has the three slots of the Gramma.

Proposition 2.13 (First facts about the Zamma)**.** *(i)* First order. *At the unit configuration the Zamma is the monomial of Definition 2.12; at an invertible square configuration t, $N = |\mathcal{E}|$, with $\mathbf{b} = t^{-1}\nu$,*

$$\mathsf{Z}_{\nu;t}(\boldsymbol{\xi}) = |\det t|^{-1}\,\Gamma_{\!N}\!\begin{bmatrix}\mathbf{b}\\ \nu\end{bmatrix}\prod_k \xi_k^{-b_k}.$$

(ii) A power of a sum is a Zamma. *With N unit exponents on one scale, $\mathsf{Z}_{\nu;(1,\dots,1)}(\boldsymbol{\xi}) = \big(\sum_k \xi_k\big)^{-\nu}$.*

(iii) Relations. *Where the terms converge, with quotients of Gammas in place of the factors the index moves,*

$$\partial_{\xi_k}\mathsf{Z}_{\nu;t}(\boldsymbol{\xi}) = -\prod_e \Gamma_1\!\begin{bmatrix}\nu_e + t_{k,e}\\ \nu_e\end{bmatrix}\mathsf{Z}_{\nu+t_k;t}(\boldsymbol{\xi}),$$

$$\mathsf{Z}_{\nu;t}(\boldsymbol{\xi}) = \sum_k t_{k,e}\,\xi_k\,\Gamma_1\!\begin{bmatrix}\nu_e + t_{k,e}\\ \nu_e + 1\end{bmatrix}\prod_{f\neq e}\Gamma_1\!\begin{bmatrix}\nu_f + t_{k,f}\\ \nu_f\end{bmatrix}\mathsf{Z}_{\nu+t_k;t}(\boldsymbol{\xi}) \qquad (e \in \mathcal{E}).$$

The other relations of Theorem 2.4 are read with the same normalization, and identities persist on the meromorphic continuations.

(iv) As an expectation. *If a configuration on $\mathcal{E}$ contains the unit configuration $I_{\mathcal{E}}$ with unit coefficients, then for real $\nu \in \mathbb{R}^{\mathcal{E}}_{>0}$*

$$\mathsf{Z}_{\nu;I_{\mathcal{E}}\oplus t'}(\mathbf{1}\oplus\boldsymbol{\xi}') = \mathbb{E}_{U\sim\mathrm{Gamma}_\nu}\Big[\exp\Big(-\sum_k \xi'_k U^{t'_k}\Big)\Big];$$

it lies in $(0,1]$, decreases in every coefficient, and, where every $\nu + t'_k$ lies in $\mathbb{R}^{\mathcal{E}}_{>0}$,

$$\mathsf{Z}_{\nu;I_{\mathcal{E}}\oplus t'}(\mathbf{1}\oplus\boldsymbol{\xi}') \;\geq\; \exp\Big(-\sum_k \xi'_k \prod_{e\in\mathcal{E}}\Gamma_1\!\begin{bmatrix}\nu_e + t'_{k,e}\\ \nu_e\end{bmatrix}\Big).$$

Proposition 2.14 (Powers of a polynomial in the scales)**.** *Let t be a configuration and $\nu \in \mathcal{T}_t$ with no ν_e in $-\mathbb{N}$, or $t = I_{\mathcal{E}}$ and $\nu \in \mathbb{C}^{\mathcal{E}}$; let $\xi_k(\rho) = \sum_{l\in\mathbb{N}^d}\rho^l\xi_k^{(l)}$ be polynomials in $\rho \in \mathbb{R}^d$ with real coefficients and $\boldsymbol{\xi}^{(0)} \in (0,\infty)^N$, and let $c_q^\nu = [\rho^q]\,\mathsf{Z}_{\nu;t}(\boldsymbol{\xi}(\rho))$ be the Taylor coefficients at $\rho = 0$. At the unit configuration, where $\mathsf{Z}_{\nu;I_{\mathcal{E}}}(\boldsymbol{\xi}) = \boldsymbol{\xi}^{-\nu}$ is read with the principal branch near $\boldsymbol{\xi}^{(0)}$, the coefficients $\xi_k^{(l)}$ with $l \neq 0$ may be complex and $\rho \in \mathbb{C}^d$.*

(i) $c_q^\nu = \sum_{\mathbf{n}}(-1)^{|\mathbf{n}|}\prod_{e\in\mathcal{E}}\Gamma_1\!\begin{bmatrix}\nu_e + (t\mathbf{w})_e\\ \nu_e\end{bmatrix}\mathsf{Z}_{\nu+t\mathbf{w};t}(\boldsymbol{\xi}^{(0)})\prod_{l\neq0,\,k}\frac{(\xi_k^{(l)})^{n_{l,k}}}{n_{l,k}!}$, *the sum over the arrays $\mathbf{n} = (n_{l,k})_{l\neq0,\,k}$ in $\mathbb{N}$ with $\sum_{l,k} l\,n_{l,k} = q$, where $\mathbf{w} = (\sum_l n_{l,k})_k$; at the unit configuration the factor $\prod_e\Gamma_1\!\begin{bmatrix}\nu_e + (t\mathbf{w})_e\\ \nu_e\end{bmatrix}$ is the polynomial $\prod_e(\nu_e)_{w_e}$, and away from it each product $\prod_e\Gamma_1\!\begin{bmatrix}\nu_e + (t\mathbf{w})_e\\ \nu_e\end{bmatrix}\mathsf{Z}_{\nu+t\mathbf{w};t}(\boldsymbol{\xi}^{(0)})$ is $\mathsf{G}_{\nu+t\mathbf{w};t}(\boldsymbol{\xi}^{(0)})/\prod_e\Gamma(\nu_e)$.*

(ii) *At one unit exponent, $t = (1)$, with $\boldsymbol{\xi}(\rho) = L(\rho)$ and the index λ: for every i, $\sum_l L^{(l)}\,(q_i - l_i + 1 + \lambda l_i)\,c^{\lambda}_{q-l+\mathbf{e}_i} = 0$, coefficients with a negative index being 0.*

(iii) $\partial_{\xi_k^{(l)}} c^{\nu}_q = -\prod_e \Gamma_1\begin{bmatrix}\nu_e + t_{k,e}\\ \nu_e\end{bmatrix} c^{\nu+t_k}_{q-l}$, *read in the same way.*

(iv) *For a configuration t, an index $\nu \in \mathbb{C}^{\mathcal{E}}$ and coefficients $\xi_k(\rho)$ depending smoothly on ρ (Proposition 2.13(iii) and the chain rule),*

$$\rho_i \partial_{\rho_i} \mathsf{Z}_{\nu;t}(\boldsymbol{\xi}(\rho)) = -\sum_k \prod_e \Gamma_1\begin{bmatrix}\nu_e + t_{k,e}\\ \nu_e\end{bmatrix} \big(\rho_i \partial_{\rho_i} \xi_k\big) \mathsf{Z}_{\nu+t_k;t}(\boldsymbol{\xi}(\rho)).$$

Chapter 3

The Breta

3.1 Definition and the tower

Definition 3.1 (Breta)**.** The data of a Breta are:

- a finite set $\mathcal{E}$ of scales and a partition $\mathcal{P}$ of $\mathcal{E}$ into *bunches* Q; each bunch is read in scale and shape, $x_Q = \rho_Q u_Q$ with $\rho_Q > 0$ and $u_Q \in \Delta_Q$;
- a *shape index* $\mathbf{m} \in \mathbb{C}^{\mathcal{E}}$ and a *scale index* $\boldsymbol{\nu} = (\nu_Q)_{Q\in\mathcal{P}}$;
- terms $k = 1, \dots, N$, each with a *shape exponent* $\pi_k \in \mathbb{R}^{\mathcal{E}}$, a *level* $\ell_k = (\ell_{k,Q})_Q \in \mathbb{R}^{\mathcal{P}}$ and a coefficient $\xi_k > 0$.

With $u^{\pi_k} = \prod_Q u_Q^{\pi_k|_Q}$ and $d\omega = \prod_Q d\omega_Q$, the *Breta* is

$$\mathsf{B}^{\mathcal{P}}_{\mathbf{m},\boldsymbol{\nu};(\pi,\ell)}(\boldsymbol{\xi}) := \int_{\prod_Q \Delta_Q} u^{\mathbf{m}-\mathbf{1}}\ \mathsf{Z}_{\boldsymbol{\nu};\ell}\big((u^{\pi_k}\xi_k)_k\big)\, d\omega(u),$$

the Zamma on the bunch scales with configuration ℓ, wherever the integral converges. The data are *homogeneous* when every level is the degree of its shape exponent on each bunch, $\ell_{k,Q} = \langle \pi_k, \mathbf{1}_Q\rangle$; then the shape exponents form a configuration $t = (\pi_k)_k$ on $\mathcal{E}$ and the Breta is written $\mathsf{B}^{\mathcal{P}}_{\mathbf{m},\boldsymbol{\nu};t}(\boldsymbol{\xi})$. When $\mathcal{P} = \{B\}$ has one bunch, the scale index has one entry and is written as a number, $\mathsf{B}^{\{B\}}_{\mathbf{m},\nu;t}(\boldsymbol{\xi})$.

The Breta has five slots: the partition, the shape index, the scale index, the terms and the coefficients. It is the Gramma read in scale and shape on every bunch at once (Theorem 2.8), with the scale integrals closed into a Zamma and the shapes left as an integral; the scale index is free, and for homogeneous data fixing it at the bunch totals of the shape index, $\nu_Q = m_Q$, makes the Breta the Gramma itself up to Gammas.

Theorem 3.2 (The tower)**.** *Let the data be homogeneous and* $\mathbf{m} \in \mathcal{T}_t$*. For every partition* $\mathcal{P}$ *of the scales,*

$$\mathsf{G}_{\mathbf{m};t}(\boldsymbol{\xi}) = \prod_{Q\in\mathcal{P}} \Gamma(m_Q)\ \mathsf{B}^{\mathcal{P}}_{\mathbf{m},(m_Q)_Q;t}(\boldsymbol{\xi}).$$

With the finest partition the Breta is $\mathsf{Z}_{\mathbf{m};t}(\boldsymbol{\xi})$*; with the coarsest,* $\Gamma(m_{\mathcal{E}})$ *times the Breta is the integral of Theorem 2.8 with* $R = \varnothing$*. At the unit configuration* I_B *of a bunch* B *and the coarsest partition* $\{B\}$*, the Zamma inside is* $\big(\sum_e \xi_e u_e\big)^{-m_B}$*, and*

$$\prod_{e\in B} \Gamma(m_e)\, \xi_e^{-m_e} = \Gamma(m_B)\, \mathsf{B}^{\{B\}}_{\mathbf{m},m_B;I_B}(\boldsymbol{\xi}) \qquad (\operatorname{Re} m_e > 0).$$

Corollary 3.3 (Coarsening)**.** *Let the data be homogeneous, and let $\mathcal{P}$ refine $\mathcal{Q}$. Then*

$$\mathsf{B}^{\mathcal{Q}}_{\mathbf{m},(m_Q)_Q;t}(\boldsymbol{\xi}) = \prod_{Q\in\mathcal{Q}} \Gamma_{1}^{k_Q}\begin{bmatrix}(m_P)_{P\subseteq Q}\\ m_Q\end{bmatrix}\ \mathsf{B}^{\mathcal{P}}_{\mathbf{m},(m_P)_P;t}(\boldsymbol{\xi}),$$

with k_Q the number of bunches of $\mathcal{P}$ inside Q.

Proposition 3.4 (The Breta on the orthant)**.** *For any data,*

$$\mathsf{B}^{\mathcal{P}}_{\mathbf{m},\boldsymbol{\nu};(\pi,\ell)}(\boldsymbol{\xi}) = \frac{1}{\prod_Q \Gamma(\nu_Q)} \int_{\mathbb{R}^{\mathcal{E}}_{>0}} x^{\mathbf{m}-\mathbf{1}} \prod_Q |x_Q|^{\nu_Q - m_Q} \exp\Big(-\sum_k \xi_k\, x^{\pi_k} \prod_Q |x_Q|^{\ell_{k,Q}-\langle \pi_k,\mathbf{1}_Q\rangle}\Big)\, dx,$$

either side converging when the other does: a free scale index is one more power of each bunch's total, a level that is not the degree of its shape exponent on a bunch is one more power of that bunch's total inside its term, and for homogeneous data at $\nu_Q = m_Q$ this is Theorem 3.2.

Theorem 3.5 (Relations of the Breta)**.** *Each identity holds wherever every Breta in it converges. The terms are (π,ℓ); homogeneous data have $t_k = \pi_k$ and $\ell_{k,Q} = \langle t_k, \mathbf{1}_Q\rangle$. In this statement write $g_k = \prod_Q \Gamma_1\begin{bmatrix}\nu_Q+\ell_{k,Q}\\ \nu_Q\end{bmatrix}$.*

(i) Shape split*, per bunch Q:*

$$\mathsf{B}^{\mathcal{P}}_{\mathbf{m},\boldsymbol{\nu};(\pi,\ell)}(\boldsymbol{\xi}) = \sum_{e\in Q} \mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\mathbf{e}_e,\boldsymbol{\nu};(\pi,\ell)}(\boldsymbol{\xi}).$$

(ii) Ladder*, per term k:*

$$\partial_{\xi_k} \mathsf{B}^{\mathcal{P}}_{\mathbf{m},\boldsymbol{\nu};(\pi,\ell)}(\boldsymbol{\xi}) = -g_k\, \mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\pi_k,\boldsymbol{\nu}+\ell_k;(\pi,\ell)}(\boldsymbol{\xi}).$$

(iii) Scale exchange*, per bunch Q:*

$$\mathsf{B}^{\mathcal{P}}_{\mathbf{m},\boldsymbol{\nu};(\pi,\ell)}(\boldsymbol{\xi}) = \sum_k \ell_{k,Q}\,\xi_k\,\Gamma_1\begin{bmatrix}\nu_Q+\ell_{k,Q}\\ \nu_Q+1\end{bmatrix} \prod_{Q'\neq Q} \Gamma_1\begin{bmatrix}\nu_{Q'}+\ell_{k,Q'}\\ \nu_{Q'}\end{bmatrix}\ \mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\pi_k,\boldsymbol{\nu}+\ell_k;(\pi,\ell)}(\boldsymbol{\xi}).$$

(iv) Shape exchange*, for scales $e\neq f$ of one bunch, with $\operatorname{Re} m_e, \operatorname{Re} m_f > 0$:*

$$m_e\, \mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\mathbf{e}_f,\boldsymbol{\nu};(\pi,\ell)}(\boldsymbol{\xi}) - m_f\, \mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\mathbf{e}_e,\boldsymbol{\nu};(\pi,\ell)}(\boldsymbol{\xi}) = \sum_k \xi_k\, g_k \Big[\pi_{k,e}\, \mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\pi_k+\mathbf{e}_f,\boldsymbol{\nu}+\ell_k;(\pi,\ell)}(\boldsymbol{\xi}) - \pi_{k,f}\, \mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\pi_k+\mathbf{e}_e,\boldsymbol{\nu}+\ell_k;(\pi,\ell)}(\boldsymbol{\xi})\Big].$$

(v) Shape exchange on the orthant*, for scales $e\neq f$ of one bunch Q:*

$$\begin{aligned}(m_e - m_f)\, \mathsf{B}^{\mathcal{P}}_{\mathbf{m},\boldsymbol{\nu};(\pi,\ell)}(\boldsymbol{\xi}) + (\nu_Q - m_Q)\Big(\mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\mathbf{e}_e,\boldsymbol{\nu};(\pi,\ell)}(\boldsymbol{\xi}) - \mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\mathbf{e}_f,\boldsymbol{\nu};(\pi,\ell)}(\boldsymbol{\xi})\Big)\\ = \sum_k \xi_k\, g_k \Big[(\pi_{k,e}-\pi_{k,f})\, \mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\pi_k,\boldsymbol{\nu}+\ell_k;(\pi,\ell)}(\boldsymbol{\xi})\\ + \big(\ell_{k,Q} - \langle \pi_k,\mathbf{1}_Q\rangle\big)\Big(\mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\pi_k+\mathbf{e}_e,\boldsymbol{\nu}+\ell_k;(\pi,\ell)}(\boldsymbol{\xi}) - \mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\pi_k+\mathbf{e}_f,\boldsymbol{\nu}+\ell_k;(\pi,\ell)}(\boldsymbol{\xi})\Big)\Big];\end{aligned}$$

for homogeneous data the second line of the right side is absent.

For homogeneous data a term raises the shape total of each bunch and its scale index by the same level, so the ladder, the scale exchange and the shape exchange (v) keep the condition $\nu_Q = m_Q$; in (v) the shifts of the shape index alone carry the factor $\nu_Q - m_Q$, which vanishes there. The shape split and the shape exchange (iv) shift the shape index alone.

3.2 Letters

A *letter* is a function that enters an integrand through a power P^{-s}, s its *letter exponent*. On bunches read in scale and shape, a polynomial letter with positive coefficients is a sum of patterns, each a monomial in the scales and the shapes; the letter presentation writes the integral of a kernel against a product of letters as one Breta, by giving every letter a scale of its own.

Proposition 3.6 (Letter presentation)**.** *Let the scales B carry a partition $\mathcal{Q}$ into bunches, each read in scale and shape, $x_Q = \rho_Q u_Q$, with $\rho = (\rho_Q)_{Q\in\mathcal{Q}}$ and $u = (u_Q)_{Q\in\mathcal{Q}}$; let* kernel terms *$g_j \rho^{\lambda_j} u^{\pi_j}$ ($g_j > 0$, $\lambda_j \in \mathbb{R}^{\mathcal{Q}}$, $\pi_j \in \mathbb{R}^B$) and letters*

$$P_i(\rho, u) = \sum_p C_{i,p}\, \rho^{\ell_{i,p}} u^{\pi_{i,p}}, \qquad C_{i,p} > 0, \qquad i = 1, \dots, N,$$

be given, the sum over the patterns *p of the letter P_i, with $\ell_{i,p} \in \mathbb{R}^{\mathcal{Q}}$, $\pi_{i,p} \in \mathbb{R}^B$ and letter exponents s_i, $\operatorname{Re} s_i > 0$. The array $(C_{i,p})$ lists the coefficients of the patterns. Introduce one scale v_i per letter, put $V = \{v_1, \dots, v_N\}$, and take the partition of the scales $B \sqcup V$*

$$\mathcal{P} = \mathcal{Q} \cup \{\{v_1\}, \dots, \{v_N\}\}.$$

On $B \sqcup V$ the shape index is $(\mathbf{m}, \mathbf{s})$, and on the bunches the scale index is $(\boldsymbol{\nu}, \mathbf{s})$, $\boldsymbol{\nu} \in \mathbb{C}^{\mathcal{Q}}$. The term arrays $(\widetilde{\pi}, \widetilde{\ell})$ have one column per kernel term and one per pattern:

column	*shape exponent on $B \sqcup V$*	*level on $\mathcal{P}$*	*coefficient*
j	$(\pi_j, 0_V)$	$(\lambda_j, 0_V)$	g_j
(i,p)	$(\pi_{i,p}, \mathbf{e}_i)$	$(\ell_{i,p}, \mathbf{e}_i)$	$C_{i,p}$

with $\mathbf{e}_i$ the unit vector at v_i in the shape column and at the singleton bunch $\{v_i\}$ in the level column, and $\mathbf{g} \oplus \mathbf{C}$ lists the coefficients in this column order. Then

$$\int_{\prod_Q \Delta_Q} u^{\mathbf{m}-\mathbf{1}} \int_{\mathbb{R}^{\mathcal{Q}}_{>0}} \rho^{\boldsymbol{\nu}-\mathbf{1}} \exp\Big(-\sum_j g_j \rho^{\lambda_j} u^{\pi_j}\Big) \prod_i P_i(\rho, u)^{-s_i}\, d\rho\, d\omega(u) = \prod_{Q\in\mathcal{Q}} \Gamma(\nu_Q)\, \mathsf{B}^{\mathcal{P}}_{(\mathbf{m},\mathbf{s}),(\boldsymbol{\nu},\mathbf{s});(\widetilde{\pi},\widetilde{\ell})}(\mathbf{g} \oplus \mathbf{C}).$$

The shapes of the singleton bunches are points, so the entries of the shape index on V do not enter the integral; they move with the scale entries on V, which keeps the relations of Theorem 3.5 literal. In the rest of this statement the partition, the term arrays and the coefficients are fixed, and

$$b(\mathbf{m}, \boldsymbol{\nu}; \mathbf{s}) \quad \textit{stands for} \quad \mathsf{B}^{\mathcal{P}}_{(\mathbf{m},\mathbf{s}),(\boldsymbol{\nu},\mathbf{s});(\widetilde{\pi},\widetilde{\ell})}(\mathbf{g} \oplus \mathbf{C}).$$

The relations of Theorem 3.5 read: the scale exchange at $\{v_i\}$ is the letter split

$$b(\mathbf{m}, \boldsymbol{\nu}; \mathbf{s}) = \sum_p C_{i,p} \prod_{Q\in\mathcal{Q}} \Gamma_1\begin{bmatrix} \nu_Q + \ell_{i,p,Q} \\ \nu_Q \end{bmatrix} b(\mathbf{m} + \pi_{i,p}, \boldsymbol{\nu} + \ell_{i,p}; \mathbf{s} + \mathbf{e}_i);$$

the ladders are

$$\partial_{g_j} b(\mathbf{m}, \boldsymbol{\nu}; \mathbf{s}) = -\prod_{Q\in\mathcal{Q}} \Gamma_1\begin{bmatrix} \nu_Q + \lambda_{j,Q} \\ \nu_Q \end{bmatrix} b(\mathbf{m} + \pi_j, \boldsymbol{\nu} + \lambda_j; \mathbf{s}),$$

$$\partial_{C_{i,p}} b(\mathbf{m},\boldsymbol{\nu};\mathbf{s}) = -s_i \prod_{Q\in\mathcal{Q}} \Gamma_1\!\begin{bmatrix}\nu_Q+\ell_{i,p,Q}\\ \nu_Q\end{bmatrix}\, b(\mathbf{m}+\pi_{i,p},\boldsymbol{\nu}+\ell_{i,p};\mathbf{s}+\mathbf{e}_i);$$

and the scale exchange on each $Q\in\mathcal{Q}$ is

$$\begin{aligned}\nu_Q\, b(\mathbf{m},\boldsymbol{\nu};\mathbf{s}) = \sum_j \lambda_{j,Q}\, g_j \prod_{Q'\in\mathcal{Q}} \Gamma_1\!\begin{bmatrix}\nu_{Q'}+\lambda_{j,Q'}\\ \nu_{Q'}\end{bmatrix}\, b(\mathbf{m}+\pi_j,\boldsymbol{\nu}+\lambda_j;\mathbf{s})\\ + \sum_{i,p} s_i\, \ell_{i,p,Q}\, C_{i,p} \prod_{Q'\in\mathcal{Q}} \Gamma_1\!\begin{bmatrix}\nu_{Q'}+\ell_{i,p,Q'}\\ \nu_{Q'}\end{bmatrix}\, b(\mathbf{m}+\pi_{i,p},\boldsymbol{\nu}+\ell_{i,p};\mathbf{s}+\mathbf{e}_i).\end{aligned}$$

Proposition 3.7 (Letter data on the orthant)**.** *Use the partition and the term arrays of Proposition 3.6, and for $\alpha\in\mathbb{R}^B_{>0}$ write $P_i(\alpha)$ for the letter at $\rho_Q=|\alpha_Q|$, $u_Q=\alpha_Q/|\alpha_Q|$:*

$$P_i(\alpha) = \sum_p C_{i,p}\,\alpha^{\pi_{i,p}} \prod_{Q\in\mathcal{Q}} |\alpha_Q|^{\ell_{i,p,Q}-\langle\pi_{i,p},\mathbf{1}_Q\rangle}.$$

Then, either side converging when the other does,

$$\begin{aligned}&\prod_{Q\in\mathcal{Q}} \Gamma(\nu_Q)\, \mathsf{B}^{\mathcal{P}}_{(\mathbf{m},\mathbf{s}),(\boldsymbol{\nu},\mathbf{s});(\widetilde{\pi},\widetilde{\ell})}(\mathbf{g}\oplus\mathbf{C})\\ &\qquad = \int_{\mathbb{R}^B_{>0}} \alpha^{\mathbf{m}-\mathbf{1}} \prod_{Q\in\mathcal{Q}} |\alpha_Q|^{\nu_Q-m_Q} \exp\Big(-\sum_j g_j\,\alpha^{\pi_j} \prod_{Q\in\mathcal{Q}} |\alpha_Q|^{\lambda_{j,Q}-\langle\pi_j,\mathbf{1}_Q\rangle}\Big) \prod_i P_i(\alpha)^{-s_i}\, d\alpha :\end{aligned}$$

each bunch total $|\alpha_Q|$ is one more letter, at the exponent $m_Q-\nu_Q$, and it enters every kernel term and pattern whose level on Q is not its degree there. For homogeneous letter data, $\lambda_{j,Q}=\langle\pi_j,\mathbf{1}_Q\rangle$ and $\ell_{i,p,Q}=\langle\pi_{i,p},\mathbf{1}_Q\rangle$, the letters are $P_i(\alpha)=\sum_p C_{i,p}\alpha^{\pi_{i,p}}$, and at $\nu_Q=m_Q$ the totals are absent.

Proposition 3.8 (Equal levels collapse)**.** *In a Breta the dressed coefficients of all terms with one level add: the Zamma inside has one term per distinct level, whose coefficient is that level's polynomial in the shape. For homogeneous letters of a bunch the level of a pattern is its degree.*

3.3 The shape integral

Theorem 3.9 (The shape integral)**.** *For $\operatorname{Re} m_e>0$ ($e\in B$),*

$$\int_{\Delta_B} u^{\mathbf{m}-\mathbf{1}}\, d\omega_B(u) = \mathsf{B}^{\{B\}}_{\mathbf{m},m_B;I_B}(\mathbf{1}) = \Gamma_{|B|}\!\begin{bmatrix}\mathbf{m}\\ m_B\end{bmatrix} :$$

the tower (Theorem 3.2) at the unit configuration I_B with unit coefficients, where the Zamma inside the Breta is $\big(\sum_e u_e\big)^{-m_B}=1$.

The stacked Gamma of the masses over their total is therefore the integral of the shape density $u^{\mathbf{m}-\mathbf{1}}$ on the simplex, and the Dirichlet law is that density normalised.

Definition 3.10 (Dirichlet law)**.** For $\mathbf{m}\in\mathbb{R}^B_{>0}$, $\operatorname{Dir}_{\mathbf{m}}(du) := u^{\mathbf{m}-\mathbf{1}}\, d\omega_B(u)/\Gamma_{|B|}\!\begin{bmatrix}\mathbf{m}\\ m_B\end{bmatrix}$, a probability measure on Δ_B.

Theorem 3.11 (Moments and steps)**.** *For* $\mathbf{m} \in \mathbb{R}^B_{>0}$ *and* $\mathbf{k} \in \mathbb{C}^B$ *with* $\mathrm{Re}(m_e + k_e) > 0$ *for every* $e \in B$*,*

$$\mathbb{E}_{U\sim \mathrm{Dir}_{\mathbf{m}}}\big[U^{\mathbf{k}}\big] = \frac{\Gamma_{\substack{|B|\\1}}\left[\begin{matrix}\mathbf{m}+\mathbf{k}\\ m_B+|\mathbf{k}|\end{matrix}\right]}{\Gamma_{\substack{|B|\\1}}\left[\begin{matrix}\mathbf{m}\\ m_B\end{matrix}\right]},$$

which for $\mathbf{k} \in \mathbb{N}^B$ *is* $\prod_e (m_e)_{k_e}/(m_B)_{|\mathbf{k}|}$*. For every* $\mathbf{m} \in \mathbb{C}^B$ *off the poles the stacked Gamma* $\Gamma_{\substack{|B|\\1}}\left[\begin{matrix}\mathbf{m}\\ m_B\end{matrix}\right]$ *satisfies the shape split and the shape exchange of its Breta* $\mathsf{B}^{\{B\}}_{\mathbf{m},m_B;I_B}(\mathbf{1})$*:*

$$\Gamma_{\substack{|B|\\1}}\left[\begin{matrix}\mathbf{m}\\ m_B\end{matrix}\right] = \sum_{e\in B}\Gamma_{\substack{|B|\\1}}\left[\begin{matrix}\mathbf{m}+\mathbf{e}_e\\ m_B+1\end{matrix}\right], \qquad m_e\Gamma_{\substack{|B|\\1}}\left[\begin{matrix}\mathbf{m}+\mathbf{e}_f\\ m_B+1\end{matrix}\right] = m_f\Gamma_{\substack{|B|\\1}}\left[\begin{matrix}\mathbf{m}+\mathbf{e}_e\\ m_B+1\end{matrix}\right],$$

$$\Gamma_{\substack{|B|\\1}}\left[\begin{matrix}\mathbf{m}+\mathbf{e}_e\\ m_B+1\end{matrix}\right] = \frac{m_e}{m_B}\Gamma_{\substack{|B|\\1}}\left[\begin{matrix}\mathbf{m}\\ m_B\end{matrix}\right].$$

Theorem 3.12 (Aggregation)**.** *Let* $B = B_1 \sqcup \cdots \sqcup B_q$ *with nonempty blocks and* $J = \{1, \dots, q\}$*. The map* $(w, v^{(1)}, \dots, v^{(q)}) \mapsto u$*,* $u|_{B_j} = w_j v^{(j)}$*, is a bijection* $\Delta_J \times \prod_j \Delta_{B_j} \to \Delta_B$*, and*

$$u^{\mathbf{m}-\mathbf{1}}d\omega_B = \prod_j w_j^{m_{B_j}-1}\, d\omega_J(w) \prod_j (v^{(j)})^{\mathbf{m}|_{B_j}-\mathbf{1}} d\omega_{B_j}(v^{(j)}).$$

Consequently $\Gamma_{\substack{|B|\\1}}\left[\begin{matrix}\mathbf{m}\\ m_B\end{matrix}\right] = \Gamma_{\substack{q\\1}}\left[\begin{matrix}(m_{B_j})_j\\ m_B\end{matrix}\right]\prod_j \Gamma_{\substack{|B_j|\\1}}\left[\begin{matrix}\mathbf{m}|_{B_j}\\ m_{B_j}\end{matrix}\right]$*, and under* $\mathrm{Dir}_{\mathbf{m}}$ *the block totals and the block shapes are independent, with laws* $\mathrm{Dir}_{(m_{B_j})_j}$ *and* $\mathrm{Dir}_{\mathbf{m}|_{B_j}}$*.*

3.4 Products of shape integrals

Theorem 3.13 (The Shruffle)**.** *For a bunch* Q *and a total order* ς *on* Q *let* $\Delta^{\varsigma}_Q = \{u \in \Delta_Q : u_{\varsigma(1)} > u_{\varsigma(2)} > \cdots\}$ *and* $I^{\varsigma}_Q(f;\mathbf{m}) = \int_{\Delta^{\varsigma}_Q} u^{\mathbf{m}-\mathbf{1}} f(u)\, d\omega_Q$*. For pairwise disjoint bunches* $A_1, \dots, A_q$ *with total orders* ς_i *on* A_i*, functions* f_i *on* Δ_{A_i}*,* $A = A_1 \sqcup \cdots \sqcup A_q$ *and* $\bigotimes_i f_i(w) = \prod_i f_i(w_{A_i}/|w_{A_i}|)$ *on* Δ_A*, with* $\mathrm{Re}\, m_{A_i} > 0$ *and the integrals absolutely convergent,*

$$\prod_{i=1}^{q} I^{\varsigma_i}_{A_i}(f_i;\mathbf{m}|_{A_i}) = \Gamma_{\substack{1\\q}}\left[\begin{matrix} & m_A & \\ m_{A_1},\ & \dots,\ & m_{A_q}\end{matrix}\right]\sum_{\varsigma} I^{\varsigma}_A\Big(\bigotimes_i f_i;\mathbf{m}\Big),$$

the sum over the orders ς *of* A *that restrict to every* ς_i*.*

The product of shape integrals on disjoint bunches $A_1, \dots, A_q$ is $\Gamma_{\substack{1\\q}}\left[\begin{matrix} & m_A & \\ m_{A_1},\ & \dots,\ & m_{A_q}\end{matrix}\right]$ times the sum of the shape integrals on the joined bunch over the interleavings of their orders: this is the Shruffle, the product rule of the shape side, whose counterpart for Trailmoments at a common cut is the Struffle (Theorem 5.25).

3.5 The Beta port

Definition 3.14 (Beta port)**.** For $q \in \mathbb{N}$ and $a, b \in \mathbb{C}$,

$$\Pi^{a,b}_q(x) = \frac{(-1)^q x^{1-a}(1-x)^{1-b}}{q!}\,\partial^q_x\big[x^{a+q-1}(1-x)^{b+q-1}\big]$$

$$= \sum_{k=0}^{q} (-1)^{q+k} \binom{a+q-1}{q-k} \binom{b+q-1}{k} x^k (1-x)^{q-k},$$

a polynomial of degree at most q. For positive integers a, b its coefficients are integers; for fixed q and a, b affine in an integer parameter, its coefficients are integers of polynomial growth in that parameter.

Theorem 3.15 (Relations of the Beta port)**.** *(i)* Action on a monomial. *For* $\operatorname{Re} c > 0$ *and* $\operatorname{Re} b > 0$*:* $\int_0^1 x^{c-1}(1-x)^{b-1}\,\Pi_q^{a,b}(x)\,dx = \binom{c-a}{q}\Gamma\,{}_2{}_1\!\left[\begin{matrix} c,\ b+q \\ c+b+q \end{matrix}\right]$*. With* $c = a + j$*,* $j \in \mathbb{N}$*, the binomial vanishes for* $j < q$*: the Beta port is orthogonal, for the density* $x^{a-1}(1-x)^{b-1}$*, to every polynomial of degree below* q*.*

(ii) Integration by parts. *For* $\operatorname{Re} a, \operatorname{Re} b > 0$ *and* g *with* q *continuous derivatives on* $[0,1]$*,*

$$\int_0^1 x^{a-1}(1-x)^{b-1}\,\Pi_q^{a,b}(x)\,g(x)\,dx = \frac{1}{q!}\int_0^1 x^{a+q-1}(1-x)^{b+q-1}\,g^{(q)}(x)\,dx;$$

with one Beta port per scale, of orders $\mathbf{n} = (n_e)_{e\in\mathcal{E}}$*,*

$$\int_{[0,1]^{\mathcal{E}}} \prod_e x_e^{a_e-1}(1-x_e)^{b_e-1}\Pi_{n_e}^{a_e,b_e}(x_e)\,g(\mathbf{x})\,d\mathbf{x} \\ = \frac{1}{\prod_e n_e!}\int_{[0,1]^{\mathcal{E}}} \prod_e x_e^{a_e+n_e-1}(1-x_e)^{b_e+n_e-1}\,\partial^{\mathbf{n}} g(\mathbf{x})\,d\mathbf{x}.$$

(iii) Letter ladder. *For letters* $L_i = c_i + d_i x$ *positive on* $[0,1]$ *(*$c_i > 0$ *and* $c_i + d_i > 0$*) and exponents* $w_i \in \mathbb{C}$*,*

$$\frac{(-1)^q}{q!}\,\partial_x^q \prod_i L_i^{-w_i} = \prod_i L_i^{-w_i} \sum_{|v|=q} \prod_i \frac{(w_i)_{v_i}}{v_i!}\Big(\frac{d_i}{L_i}\Big)^{v_i},$$

so that, for $\operatorname{Re} a, \operatorname{Re} b > 0$*,*

$$\int_0^1 x^{a-1}(1-x)^{b-1}\,(-1)^q \Pi_q^{a,b} \prod_i L_i^{-w_i}\,dx \\ = \sum_{|v|=q} \prod_i \frac{(w_i)_{v_i}}{v_i!}\int_0^1 x^{a-1}(1-x)^{b-1}\prod_i L_i^{-w_i}\prod_i \Big(\frac{x(1-x)d_i}{L_i}\Big)^{v_i}dx.$$

Let $a, b > 0$ *and every* $w_i \geq 0$*. (iv) Reflection. $\Pi_q^{a,b}(1-x) = (-1)^q \Pi_q^{b,a}(x)$*.*

(v) Three-term and derivative relations. *For* $q \geq 1$ *and* $a, b \in \mathbb{C}$ *with* $a + b + 2q - i \neq 0$ *for* $i = 0, 1, 2$*,*

$$x\,\Pi_q^{a,b} = \frac{(q+1)(a+b+q-1)}{(a+b+2q)(a+b+2q-1)}\,\Pi_{q+1}^{a,b} + \Big(\frac{(q+1)(a+q)}{a+b+2q} - \frac{q(a+q-1)}{a+b+2q-2}\Big)\Pi_q^{a,b}$$

$$+\frac{(a+q-1)(b+q-1)}{(a+b+2q-1)(a+b+2q-2)}\,\Pi^{a,b}_{q-1},$$

$$x(1-x)\,\partial_x\Pi^{a,b}_q=\Big(\frac{q(b+q-1)}{a+b+2q-2}-q\,x\Big)\Pi^{a,b}_q+\frac{(a+q-1)(b+q-1)}{a+b+2q-2}\,\Pi^{a,b}_{q-1};$$

for every $q\in\mathbb{N}$ the coefficient of x^j in $\Pi^{a,b}_q$ is $(-1)^{q+j}\binom{a+q-1}{q-j}\binom{a+b+q+j-2}{j}$, and that of x^q is $\binom{a+b+2q-2}{q}$.

The Beta port moves derivatives of an integrand onto its shape density: integrating against $\Pi^{a,b}_q$ is integrating the q-th derivative against the density with both exponents raised by q. Against a product of linear letters whose slopes have one sign it keeps the sign of the integrand, up to $(-1)^q$ when the slopes are negative, which is what the arithmetic of Part VI uses. The Beta port of order q is orthogonal, for the density $x^{a-1}(1-x)^{b-1}$, to every polynomial of lower degree (Theorem 3.15(i)), and at every pair of exponents multiplication by x and the operator $x(1-x)\partial_x$ move each Beta port by at most one step in its order (Theorem 3.15(v)): finite coefficient rules, which is what turns a mark relation (Theorem 35.10) into a recurrence of bounded width.

Chapter 4

Fibre integrals and closing

Definition 4.1 (Fibre integral)**.** Let $\mathbf{b} \in \mathbb{C}^N$ be *shares*, pinned by $P\mathbf{b} = \boldsymbol{\pi}$ with P a real $q \times N$ matrix with linearly independent rows and $\boldsymbol{\pi} \in \mathbb{C}^q$. Let f be holomorphic on a tube $\{\operatorname{Re}\mathbf{b} \in U\}$, and let $\mathbf{c} \in U$ be an *admissible real point*, $P\mathbf{c} = \operatorname{Re}\boldsymbol{\pi}$. The *fibre integral* is

$$\int_{P\mathbf{b}=\boldsymbol{\pi}} f := (2\pi)^{q-N} \int_{\mathbb{R}^N} f(\mathbf{c}+i\mathbf{y})\,\delta^q\big(P\mathbf{y} - \operatorname{Im}\boldsymbol{\pi}\big)\,d\mathbf{y} = \frac{(2\pi)^{q-N}}{\sqrt{\det PP^{\mathsf{T}}}} \int_{P\mathbf{y}=\operatorname{Im}\boldsymbol{\pi}} f(\mathbf{c}+i\mathbf{y})\,d\mathrm{vol}_{N-q}(\mathbf{y})$$

whenever it converges, vol_{N-q} being the $(N-q)$-dimensional volume on the affine subspace; by Cauchy's theorem it does not depend on $\mathbf{c}$ within one connected set of admissible real points. Its *dimension* is $N-q$. With one pin, $P = (1,\dots,1)$ and $\boldsymbol{\pi} = s$, it is the *share integral*

$$\int_{a_1+\cdots+a_k=s} f(\mathbf{a}) = \frac{1}{(2\pi i)^{k-1}} \int_{c_1+i\mathbb{R}} \cdots \int_{c_{k-1}+i\mathbb{R}} f\Big(a_1,\dots,a_{k-1},\, s - \sum_{i<k} a_i\Big)\,da_1\cdots da_{k-1}.$$

At dimension zero, $q = N$, the value is $|\det P|^{-1} f(P^{-1}\boldsymbol{\pi})$. When $\boldsymbol{\pi}$ is real, with $V = \{\mathbf{y} :\ P\mathbf{y} = 0\}$ and the measure $d\boldsymbol{\vartheta} = (\det PP^{\mathsf{T}})^{-1/2}\,d\mathrm{vol}_{N-q}$ on it, the fibre integral is written $\int_{\mathbf{c}+iV} f = (2\pi)^{q-N}\int_V f(\mathbf{c}+i\boldsymbol{\vartheta})\,d\boldsymbol{\vartheta}$, its admissible real point shown.

Proposition 4.2 (The share side of the Gramma)**.** *For $\nu \in \mathcal{T}_t$,*

$$\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = \int_{t\mathbf{b}=\nu} \prod_{k=1}^{N} \Gamma(b_k)\,\xi_k^{-b_k},$$

the fibre integral with one share per term, pinned by the configuration ($|\mathcal{E}|$ pins), of dimension $N - |\mathcal{E}|$; its admissible real points are the $\mathbf{c} \in (0,\infty)^N$ with $t\mathbf{c} = \operatorname{Re}\nu$, and they exist exactly on the domain. At dimension zero it is the value of Corollary 2.6.

On the share side the configuration is the matrix of the pins and the index their values, one pin per scale; each term carries one share, with its Gamma and its coefficient's power as factors.

Theorem 4.3 (The native gauge of a configuration)**.** *Let the t_k span $\mathbb{R}^{\mathcal{E}}$, $\nu \in \operatorname{int}\operatorname{cone}(t)$ real and $\boldsymbol{\xi} > 0$.*

(i) $\Phi_{\boldsymbol{\xi}}(y) = \sum_k \xi_k e^{\langle t_k, y\rangle} - \langle \nu, y\rangle$ is strictly convex and tends to $+\infty$ along every ray; its unique critical point $y^\star$ solves $\sum_k \xi_k e^{\langle t_k, y^\star\rangle} t_k = \nu$, and $e^{y^\star}$ is the native gauge *of the configuration.*

(ii) The shares $w_k^\star = \xi_k e^{\langle t_k, y^\star\rangle}$ are an admissible real point of the share side (Proposition 4.2). On the real fibre $\{\mathbf{w} > 0 :\ t\mathbf{w} = \nu\}$ the function $S(\mathbf{w}) = \sum_k \big(w_k - w_k \log(w_k/\xi_k)\big)$ is strictly concave with unique critical point $\mathbf{w}^\star$, and $S(\mathbf{w}^\star) = \Phi_{\boldsymbol{\xi}}(y^\star)$.

(iii) For $\nu' \in \mathbb{C}^{\mathcal{E}}$, as $\lambda \to \infty$,

$$\mathsf{G}_{\lambda\nu+\nu';t}(\lambda\boldsymbol{\xi}) = e^{\langle \nu', y^\star\rangle}\, e^{-\lambda\Phi_{\boldsymbol{\xi}}(y^\star)} \Big(\frac{2\pi}{\lambda}\Big)^{|\mathcal{E}|/2} \det\Big(\sum_k w_k^\star t_k t_k^{\mathsf{T}}\Big)^{-1/2} \big(1 + O(\lambda^{-1})\big).$$

The native gauge of a configuration is read on both of its sides at once: on the orthant side its logarithmic coordinate $y^\star$ minimizes the convex function $\Phi_{\boldsymbol{\xi}}$, on the share side the shares $\mathbf{w}^\star$ it determines maximize the entropy-like function S on the real fibre, and the minimum equals the maximum.

Corollary 4.4 (Splitting a coefficient)**.** *Let $k \geq 2$, $X \in (0,\infty)^k$, $\operatorname{Re} s > 0$ and $\mathbf{c} \in (0,\infty)^{k-1}$ with $\sum_i c_i < \operatorname{Re} s$. On this contour, every share having positive real part,*

$$\mathsf{Z}_{s;(1)}(X_1 + \cdots + X_k) = \Big(\sum_{i=1}^k X_i\Big)^{-s} = \int_{a_1+\cdots+a_k=s} {}_1\Gamma_k\begin{bmatrix}\mathbf{a}\\ s\end{bmatrix} \prod_{i=1}^k X_i^{-a_i},$$

equivalently $\Gamma(s)(X_1+\cdots+X_k)^{-s} = \int_{|\mathbf{a}|=s} \prod_i \Gamma(a_i) X_i^{-a_i}$: the share side of the one-scale Gamma $\mathsf{G}_{s;(1,\dots,1)}(X)$ (Proposition 4.2). The stacked Gamma ${}_1\Gamma_k\begin{bmatrix}\mathbf{a}\\ s\end{bmatrix}$ is the share kernel *of the letter $X_1 + \cdots + X_k$ at the exponent s.*

Theorem 4.5 (Closing)**.** *Let a fibre integral have the form $\int_{P\mathbf{b}=\boldsymbol{\pi}} \Gamma\big(\ell(\mathbf{b})\big) G(\mathbf{b})$ with ℓ affine and not constant on the fibre. Suppose that, moving the contour along a direction of the fibre in which ℓ decreases, $\Gamma(\ell)$ is the only factor with poles crossed, and the shifted contour's contribution tends to zero. Then*

$$\int_{P\mathbf{b}=\boldsymbol{\pi}} \Gamma\big(\ell(\mathbf{b})\big)\, G(\mathbf{b}) = \sum_{j\geq 0} \frac{(-1)^j}{j!} \int_{P\mathbf{b}=\boldsymbol{\pi},\ \ell(\mathbf{b})=-j} G(\mathbf{b}),$$

each term a fibre integral with one more pin. When several factors have poles crossed, each contributes its own lattice; where several share a pole hyperplane, the residue is a Laurent coefficient of the Gamma factors (Chapter 5).

Closing trades one dimension of the fibre for a sum over the poles crossed: the Gamma whose argument falls is replaced by its residues. Where closing can be repeated until the fibre has dimension zero, every term is the value $|\det P|^{-1} G(P^{-1}\boldsymbol{\pi})$ of the remaining factors at one point.

Theorem 4.6 (The share kernels form a semigroup)**.** *For a letter $\sum_{i=1}^k X_i$, shares $\mathbf{a}, \mathbf{b}, \mathbf{g} \in \mathbb{C}^k$ and $|\mathbf{g}| = s + s'$, on admissible contours,*

$$\int_{\mathbf{a}+\mathbf{b}=\mathbf{g},\ |\mathbf{a}|=s} {}_1\Gamma_k\begin{bmatrix}\mathbf{a}\\ s\end{bmatrix}\, {}_1\Gamma_k\begin{bmatrix}\mathbf{b}\\ s'\end{bmatrix} = {}_1\Gamma_k\begin{bmatrix}\mathbf{g}\\ s+s'\end{bmatrix}.$$

Splitting the letter at the exponent s and at the exponent s' and merging the shares is splitting it at $s + s'$: the share kernels of Corollary 4.4 compose like the powers they open.

Corollary 4.7 (Four Gammas on a line)**.** *On a contour separating the poles of $\Gamma(a+z)\Gamma(b+z)$ from those of $\Gamma(c-z)\Gamma(d-z)$,*

$$\frac{1}{2\pi i}\int \Gamma(a+z)\,\Gamma(b+z)\,\Gamma(c-z)\,\Gamma(d-z)\,dz = {}_1\Gamma_4\begin{bmatrix} a+c,\ b+d,\ a+d,\ b+c \\ a+b+c+d \end{bmatrix}:$$

Theorem 4.6 at $k = 2$, multiplied by $\Gamma(a+c)\Gamma(b+d)$, with the shares $(a+z,\ c-z)$ at the exponent $a+c$ and $(d-z,\ b+z)$ at the exponent $b+d$, merged to $(a+d,\ b+c)$.

The four Gammas are the Gamma factors of the four shares of a Gramma on three scales, pinned by the three scales, and the one free share is the contour variable; integrating the orthant side scale by scale leaves $\Gamma(a+c)\Gamma(b+d)$ times the Beta corner ${}_{2}\Gamma_{1}\left[\begin{matrix} a+d,\ b+c \\ a+b+c+d \end{matrix}\right]$, the shape integral of two scales (Theorem 3.9).

Chapter 5

The Trailmoment

5.1 Definition

Definition 5.1 (Trailmoment)**.** The data of a Trailmoment are an index ν and a configuration t, those of a Zamma; a measure ϕ, the *input*, on a space Y, the *source*; a measurable *coefficient function* $\mathbf{c} : Y \to (0,\infty)^N$; and a measurable *cut region* $Y' \subseteq Y$. The *Trailmoment* is

$$(\mathsf{T}_{\nu;t}[\mathbf{c}]\,\phi)(Y') = \int_{Y'} \mathsf{Z}_{\nu;t}\big(\mathbf{c}(y)\big)\,\phi(dy)$$

wherever it converges: a normalized Zamma kernel read against the input over the cut region.

The Trailmoment has five slots: its index and configuration, which are the kernel's, its coefficient function, its input and its cut region. On a line, $Y = \mathbb{R}$, the cut region (N,∞) is the *cut* at N, and the region $(N, N']$ between two cuts is a *head*; on $\mathbb{R}^d$ the region $X_N = \{N < y_1 < \cdots < y_d\}$ is a *trail region*, the nested tails that give the Trailmoment its name; the trails of Section 5.8 are read over it. The input is written as a density with its domain marked by an indicator, so that the measure is part of the data.

Definition 5.2 (Lattice inputs; the index-one value)**.** The *lattice input* on the coset $b+q\mathbb{Z}$, $b \in \mathbb{R}$, of step $q > 0$ and frequency $a \in \mathbb{C}$ is $e^{2\pi i a x}\,\mathbb{I}_{b+q\mathbb{Z}} = \sum_{m\in b+q\mathbb{Z}} e^{2\pi i a m}\,\delta_m$; at frequency 0 it is counting measure on $b+q\mathbb{Z}$, written $\mathbb{I}_{b+q\mathbb{Z}}$, and for $\operatorname{Im} a > 0$ the values $e^{2\pi i a m}$ decay geometrically toward $+\infty$. The input $f\,\mathbb{I}_{b+q\mathbb{Z}}$ has the density f on the lattice, and $\mathbb{I}_{\mathbb{Z}}$ is the *counting input*. At one unit exponent and the coefficient function x the kernel is $\mathsf{Z}_{\nu;(1)}(x) = x^{-\nu}$, so at a cut beyond which every lattice point is positive

$$(\mathsf{T}_{\nu;(1)}[x]\,f\,\mathbb{I}_{b+\mathbb{Z}})((N,\infty)) = \sum_{m\in b+\mathbb{Z},\ m>N} f(m)\,m^{-\nu}.$$

At index one the lattice input is regularized at its upper end:

$$(\mathsf{T}_{1;(1)}[x]\,\mathbb{I}_{b+\mathbb{Z}})((N,\infty)) := \lim_{M\to\infty}\Big((\mathsf{T}_{1;(1)}[x]\,\mathbb{I}_{b+\mathbb{Z}})((N,N+M]) - \log M\Big),$$

which exists, the heads being $\log M + (\mathsf{T}_{1;(1)}[x]\,\mathbb{I}_{b+\mathbb{Z}})((N,\infty)) + O(M^{-1})$: the regularized value is the coefficient of $M^0 \log^0 M$ in the heads.

Proposition 5.3 (The cut relation)**.** *The Trailmoment is additive in its cut region: for disjoint measurable $Y_1', Y_2' \subseteq Y$, $(\mathsf{T}_{\nu;t}[\mathbf{c}]\,\phi)(Y_1' \sqcup Y_2') = (\mathsf{T}_{\nu;t}[\mathbf{c}]\,\phi)(Y_1') + (\mathsf{T}_{\nu;t}[\mathbf{c}]\,\phi)(Y_2')$, either side converging when the other does; on a line, for $N < N'$,*

$$(\mathsf{T}_{\nu;t}[\mathbf{c}]\,\phi)((N,\infty)) = (\mathsf{T}_{\nu;t}[\mathbf{c}]\,\phi)((N,N']) + (\mathsf{T}_{\nu;t}[\mathbf{c}]\,\phi)((N',\infty)),$$

and for a lattice input at index one it holds with the regularized values.

Definition 5.4 (Inputs)**.** An input is a nonnegative σ-finite measure μ, or such a measure with a complex density, $\phi = f\mu$ with $|\phi| = |f|\mu$; a Trailmoment converges when $\int |\mathsf{Z}_{\nu;t}(\mathbf{c})|\, d|\phi|$ over the cut region is finite. The image $\tau_*\phi$ of an input with a complex density under a measurable map τ is used only in integrals $\int g\, d(\tau_*\phi) := \int g \circ \tau\, d\phi$ with $\int |g \circ \tau|\, d|\phi| < \infty$; $|\tau_*\phi|$ denotes $\tau_*|\phi|$, and tameness and convergence of $\tau_*\phi$ are meant with it. The *Lebesgue input* $\mathbb{I}_{\mathbb{R}}$ is Lebesgue measure on $\mathbb{R}$, $f\,\mathbb{I}_{\mathbb{R}}$ is the input with density f, $\mathbb{I}_D$ is Lebesgue measure on an interval D, and $\mathbb{I}_{\mathbb{R}^{\mathcal{E}}}$ is Lebesgue measure on $\mathbb{R}^{\mathcal{E}}$; the lattice inputs are those of Definition 5.2, and at integer frequency the lattice input on $\mathbb{Z}$ is the counting input.

An input is *tame beyond the cut N* when its part beyond N is carried by $[x_0,\infty)$ for some $x_0 > 0$ and $\int_{(N,\infty)} x^{-\beta}\, |\phi|(dx) < \infty$ for some real β. Its Laplace transform beyond the cut is

$$\mathcal{F}_N(u) = \int_{(N,\infty)} e^{-ux}\, \phi(dx),$$

which converges for $\operatorname{Re} u > 0$, with $|\mathcal{F}_N(u)| \le e^{-(u-1)x_0} \int_{(N,\infty)} e^{-x}\, |\phi|(dx)$ for $u \ge 1$. When $\mathcal{F}_N$ is moreover meromorphic at $u = 0$, $(\mathsf{T}_{\nu;(1)}[x]\,\phi)((N,\infty))$ denotes, for every ν off its poles, the continuation in which $\Gamma(\nu)\,(\mathsf{T}_{\nu;(1)}[x]\,\phi)((N,\infty))$ is the meromorphic continuation of $\int_0^\infty u^{\nu-1}\mathcal{F}_N(u)\, du$, the Laplace side of Theorem 5.11 below at one unit exponent. At index one on a lattice input it is the regularized value of Definition 5.2, which is the constant term of the continuation at $\nu = 1$.

Proposition 5.5 (The continued Trailmoment on a line)**.** *Let ϕ be tame beyond the cut N with $\mathcal{F}_N(u) = \sum_{k \ge -k_0} c_k u^k$ near $u = 0$. Then $\Gamma(\nu)\,(\mathsf{T}_{\nu;(1)}[x]\,\phi)((N,\infty))$ is meromorphic in ν with at most simple poles, at $\nu = -k$, $k \ge -k_0$, with residue c_k, and at the nonpositive integers*

$$(\mathsf{T}_{-j;(1)}[x]\,\phi)((N,\infty)) = (-1)^j j!\, c_j \qquad (j \in \mathbb{N}).$$

At a nonpositive integer index the Trailmoment of a tame input is a Taylor coefficient of its Laplace transform, so a cut that releases a head changes these values by the head read at the same index.

5.2 Slots, corners and heights

Definition 5.6 (Slots, corners, height)**.** A *slot* is a place of a symbol of the serif family where one of its data stands. A Gramma or a Zamma has three slots: its index, its configuration and its coefficients. A Breta has five: its partition into bunches, its shape index, its scale index, its terms (shape exponents and levels) and its coefficients. A Trailmoment has five: its index ν, its configuration t, its coefficient function $\mathbf{c}$, its input ϕ and its cut region. A *corner* of a member of the serif family is that member with some of its slots given particular values. A *relation* is an identity between members of the serif family. Its *height* is the set of values of the slots on which one proof establishes it; a slot is *free* in a relation when the height does not restrict it and *pinned* otherwise. For a pinned slot, the *mechanism* is the step of the proof that uses the pinned value.

A relation recited at a corner is understood once its height is known: which slots the proof leaves free, which it uses, and at which step. A relation whose height is every value of every slot is a property of the operator. A pin records what a proof uses; it does not say that the relation fails at the other values of the slot, and where the converse is proved, so that the relation is a property of the pinned value, it is stated with the relation.

5.3 Relations at free slots

Theorem 5.7 (The gauge of the coefficient function)**.** *Let $(\nu, t, \mathbf{c}, \phi, Y')$ be the data of a Trailmoment on a source Y and let $\ell : Y \to (0,\infty)^{\mathcal{E}}$ be measurable. Then*

$$\big(\mathsf{T}_{\nu;t}[(\ell^{t_k} c_k)_k]\,\phi\big)(Y') = \big(\mathsf{T}_{\nu;t}[\mathbf{c}]\,\ell^{-\nu}\phi\big)(Y'),$$

either side converging when the other does. If the columns t_k, $k \in S$, form a basis of $\mathbb{R}^{\mathcal{E}}$, the choice $\log \ell = -(t_S^{\mathsf{T}})^{-1} \log \mathbf{c}_S$ makes $\ell^{t_k} c_k = 1$ for every $k \in S$: the gauge moves $|\mathcal{E}|$ of the N coefficient functions into the input, and the kernel then depends on the source point only through the $N - |\mathcal{E}|$ functions $\ell^{t_k} c_k$, $k \notin S$. At the unit configuration, $(\mathsf{T}_{\nu;I_{\mathcal{E}}}[\mathbf{c}]\,\phi)(Y') = \int_{Y'} \mathbf{c}^{-\nu}\, d\phi$.

At the unit configuration the kernel is a density on the input: index, coefficient function and input enter only through the measure $\mathbf{c}^{-\nu}\phi$. With $N > |\mathcal{E}|$ terms the kernel depends on the source point through $N - |\mathcal{E}|$ gauge-invariant functions as well as through a density, and this count is the dimension of the share side (Theorem 5.10).

Theorem 5.8 (Exchange and ladder of the Trailmoment)**.** *Each identity holds wherever every Trailmoment in it converges.*

(i) Exchange, one relation per scale. *For each $e \in \mathcal{E}$,*

$$(\mathsf{T}_{\nu;t}[\mathbf{c}]\,\phi)(Y') = \sum_{k=1}^{N} t_{k,e}\ \Gamma_1^{\,1}\begin{bmatrix}\nu_e + t_{k,e}\\ \nu_e + 1\end{bmatrix} \prod_{f \neq e} \Gamma_1^{\,1}\begin{bmatrix}\nu_f + t_{k,f}\\ \nu_f\end{bmatrix}\ \big(\mathsf{T}_{\nu + t_k;t}[\mathbf{c}]\,c_k\phi\big)(Y').$$

(ii) Ladder. *If $\mathbf{c} = \mathbf{c}_\zeta$ depends differentiably on a real parameter ζ and the differentiated integrand is dominated by an integrable function locally uniformly in ζ,*

$$\partial_\zeta(\mathsf{T}_{\nu;t}[\mathbf{c}_\zeta]\,\phi)(Y') = -\sum_{k=1}^{N} \prod_{e} \Gamma_1^{\,1}\begin{bmatrix}\nu_e + t_{k,e}\\ \nu_e\end{bmatrix}\ \big(\mathsf{T}_{\nu + t_k;t}[\mathbf{c}_\zeta]\,(\partial_\zeta c_k)\,\phi\big)(Y').$$

(iii) The unit configuration. *At $t = I_{\mathcal{E}}$ the exchange relation at each scale has one term, and on the interior of the set of indices where the Trailmoment converges the index is differentiated through the input: for every $e \in \mathcal{E}$,*

$$(\mathsf{T}_{\nu;I_{\mathcal{E}}}[\mathbf{c}]\,\phi)(Y') = (\mathsf{T}_{\nu + \mathbf{e}_e;I_{\mathcal{E}}}[\mathbf{c}]\,c_e\phi)(Y'), \qquad \partial_{\nu_e}(\mathsf{T}_{\nu;I_{\mathcal{E}}}[\mathbf{c}]\,\phi)(Y') = -(\mathsf{T}_{\nu;I_{\mathcal{E}}}[\mathbf{c}]\,(\log c_e)\,\phi)(Y').$$

At the unit configuration a step of the index at a scale is a factor of that coordinate of the coefficient function on the input, in both directions. With several terms on a scale the exchange relation is linear in $N + 1$ Trailmoments whose inputs differ by the factors c_k, one relation per scale, and a step of the index is no longer a density.

Theorem 5.9 (Transport)**.** *For a measurable map $\tau : Y \to Y_2$, an input ϕ on Y, a coefficient function $\mathbf{c}$ on Y_2 and a cut region $Y_2' \subseteq Y_2$,*

$$(\mathsf{T}_{\nu;t}[\mathbf{c}]\,\tau_*\phi)(Y_2') = (\mathsf{T}_{\nu;t}[\mathbf{c}\circ\tau]\,\phi)(\tau^{-1}Y_2'),$$

whenever the right side converges; for a nonnegative input either side converges when the other does. In particular, transporting by the coefficient function itself, a convergent Trailmoment is

$$(\mathsf{T}_{\nu;t}[\mathbf{c}]\,\phi)(Y') = \big(\mathsf{T}_{\nu;t}[\mathrm{id}]\,\mathbf{c}_*(\phi|_{Y'})\big)\big((0,\infty)^N\big)\,:$$

coefficient function, input and cut region enter only through the image $\mathbf{c}_*(\phi|_{Y'})$ of the input on the orthant of coefficients.

A Trailmoment of a nonnegative input is therefore a function of three things: an index, a configuration, and a measure on the orthant of coefficients. Two descriptions of that measure, by different coefficient functions, inputs and cut regions, give the same member of the serif family. An increasing bijection of the line carries half-lines to half-lines: with $\tau(x) = x + h$ it is the *shift* of the cut, and with $\tau(x) = qx$ at one unit exponent it gives $(\mathsf{T}_{\nu;(1)}[x]\,\tau_*\phi)((qN,\infty)) = q^{-\nu}(\mathsf{T}_{\nu;(1)}[x]\,\phi)((N,\infty))$.

Theorem 5.10 (The share side of the Trailmoment)**.** *Let $\operatorname{Re}\nu \in \operatorname{int}\operatorname{cone}(t)$, and let $\mathbf{s} \in (0,\infty)^N$ be an admissible real point, $t\mathbf{s} = \operatorname{Re}\nu$, with $\int_{Y'}\prod_k c_k(y)^{-s_k}\,|\phi|(dy) < \infty$. On the contour through $\mathbf{s}$,*

$$\prod_{e\in\mathcal{E}}\Gamma(\nu_e)\ (\mathsf{T}_{\nu;t}[\mathbf{c}]\,\phi)(Y') = \int_{t\mathbf{b}=\nu}\ \prod_{k=1}^{N}\Gamma(b_k)\ (\mathsf{T}_{\mathbf{b};I_N}[\mathbf{c}]\,\phi)(Y'),$$

$$(\mathsf{T}_{\mathbf{b};I_N}[\mathbf{c}]\,\phi)(Y') = \int_{Y'}\prod_{k=1}^{N} c_k(y)^{-b_k}\,\phi(dy),$$

a fibre integral of dimension $N - |\mathcal{E}|$ of Trailmoments at the unit configuration I_N, with one scale per term of t. Where some ν_e lies in $-\mathbb{N}$ the left side is read as $\int_{Y'}\mathsf{G}_{\nu;t}(\mathbf{c})\,d\phi$.

Every configuration is written through the unit configuration: a Trailmoment at any configuration is a superposition of Trailmoments at the unit configuration over the fibre of its configuration, each multiplied by the Gammas of its shares. Closing the fibre integral (Theorem 4.5) replaces the superposition by residues, and the residues are Trailmoments at the unit configuration at shifted indices; that is why their values appear in the closings of every configuration.

Theorem 5.11 (The Laplace side of the Trailmoment)**.** *The joint Laplace transform of the data $(\mathbf{c},\phi,Y')$ is $\mathcal{F}(v) = \int_{Y'} e^{-\langle v,\mathbf{c}(y)\rangle}\,\phi(dy)$ for $v \in (0,\infty)^N$. For $\nu \in \mathcal{T}_t$, wherever the double integral converges,*

$$\prod_{e\in\mathcal{E}}\Gamma(\nu_e)\ (\mathsf{T}_{\nu;t}[\mathbf{c}]\,\phi)(Y') = \int_{\mathbb{R}^{\mathcal{E}}_{>0}} x^{\nu-\mathbf{1}}\,\mathcal{F}\big(x^{t_1},\dots,x^{t_N}\big)\,dx = \big(\mathsf{T}_{\mathbf{1}-\nu;I_{\mathcal{E}}}[x]\ \mathcal{F}(x^t)\,\mathbb{I}_{\mathbb{R}^{\mathcal{E}}}\big)\big(\mathbb{R}^{\mathcal{E}}_{>0}\big),$$

where $\mathcal{F}(x^t) = \mathcal{F}(x^{t_1},\dots,x^{t_N})$ and the kernel of the last Trailmoment is $\prod_e x_e^{\nu_e-1}$, the Zamma of the unit configuration at the index $\mathbf{1}-\nu$; where some ν_e lies in $-\mathbb{N}$ the left side is read as $\int_{Y'}\mathsf{G}_{\nu;t}(\mathbf{c})\,d\phi$. The exponential is the Zamma of a term at exponent zero, $\mathsf{Z}_{1;(1,0)}(1,\xi) = e^{-\xi}$, so the joint Laplace transform is a Trailmoment of the same input: $\mathcal{F}(v) = (\mathsf{T}_{1;(1,0)}[(1,\langle v,\mathbf{c}\rangle)]\,\phi)(Y')$.

Index ν on the input side is index $\mathbf{1}-\nu$ on the Laplace side. Besides the input itself, a Trailmoment has two sides: the share side, which resolves the configuration into unit configurations, and the Laplace side, which replaces the input by its Laplace transform; the reflections of the index (Theorems 5.18 and 5.19), the Shruffle (Theorem 5.26) and the Cremona (Theorem 5.29) are read on the Laplace side, and the lattice relations and the Struffle on the input itself.

5.4 Lattices

Theorem 5.12 (The lattice relations)**.** *Let $b\in\mathbb{R}$, let $q\geq 1$ be an integer, let $(\nu,t,\mathbf{c})$ be the data of a kernel on $\mathbb{R}$, f a density and N a cut.*

(i) Cosets. *Wherever the right side converges,*

$$\sum_{r=0}^{q-1}\big(\mathsf{T}_{\nu;t}[\mathbf{c}]\,f\,\mathbb{I}_{\frac{b+r}{q}+\mathbb{Z}}\big)((N,\infty))=\big(\mathsf{T}_{\nu;t}[\mathbf{c}(\,\cdot\,/q)]\,f(\,\cdot\,/q)\,\mathbb{I}_{b+\mathbb{Z}}\big)((qN,\infty)).$$

(ii) Frequencies. *For $a\in\mathbb{R}$, wherever the Trailmoments on the left converge,*

$$\sum_{r=0}^{q-1}\big(\mathsf{T}_{\nu;t}[\mathbf{c}]\,e^{2\pi i(a+\frac{r}{q})(x-b)}f\,\mathbb{I}_{b+\mathbb{Z}}\big)((N,\infty))=q\,\big(\mathsf{T}_{\nu;t}[\mathbf{c}]\,e^{2\pi ia(x-b)}f\,\mathbb{I}_{b+q\mathbb{Z}}\big)((N,\infty)),$$

the right side summing over the lattice of step q.

A lattice is assembled from a sublattice in two ways: by cosets, the q cosets of $\mathbb{Z}$ in $q^{-1}\mathbb{Z}$; by frequencies, the q exponentials $e^{2\pi irx/q}$, $0\leq r<q$. Both statements are free in the index, the configuration, the coefficient function, the density, the coset and the cut. At one unit exponent with the coefficient function x the rescaled coefficient function of (i) multiplies the kernel by the scalar q^{ν}, $\mathsf{Z}_{\nu;(1)}(x/q)=q^{\nu}x^{-\nu}$; at index one, with the regularized values, the same assembly carries the further term $q\log q$, the finite part read in two coordinates (Lemma 1.9).

5.5 The Gamma read by Trailmoments

Proposition 5.13 (Heads and higher orders at lattice data)**.** *For real $b>-1$ and $|z|<1+b$,*

$$\log\Gamma(1+b-z)=\log\Gamma(1+b)+\sum_{i\geq 1}\frac{z^i}{i}\,(\mathsf{T}_{i;(1)}[x]\,\mathbb{I}_{b+\mathbb{Z}})((b,\infty)),$$

the index-one Trailmoment regularized; equivalently, for $j\in\mathbb{N}$,

$$(\log\Gamma)^{(j+1)}(1+b)=(-1)^{j+1}j!\,(\mathsf{T}_{j+1;(1)}[x]\,\mathbb{I}_{b+\mathbb{Z}})((b,\infty)).$$

Further $\Gamma(-k+z)=\dfrac{(-1)^k\,\Gamma(1+z)\,\Gamma(1-z)}{z\,\Gamma(k+1-z)}$ for $k\in\mathbb{N}$. In this statement write $h=\prod_a\Gamma(1+b_a-z_a)/\prod_c\Gamma(1+b'_c-z'_c)$, a stacked Gamma whose constants b_a,b'_c lie in one translate $b_0+\mathbb{N}$ with $b_0>-1$, with $\sum_a z_a=\sum_c z'_c$, $|z_a|<1+b_a$ and $|z'_c|<1+b'_c$. Then

$$\log\frac{h}{h|_{z=0}}=\sum_c z'_c\,(\mathsf{T}_{1;(1)}[x]\,\mathbb{I}_{b_0+\mathbb{Z}})((b_0,b'_c])$$

$$- \sum_a z_a \, (\mathsf{T}_{1;(1)}[x]\, \mathbb{I}_{b_0+\mathbb{Z}})((b_0, b_a])$$
$$+ \sum_{i\geq 2} \frac{1}{i} \Big(\sum_a z_a^i \, (\mathsf{T}_{i;(1)}[x]\, \mathbb{I}_{b_0+\mathbb{Z}})((b_a, \infty))$$
$$- \sum_c z_c'^i \, (\mathsf{T}_{i;(1)}[x]\, \mathbb{I}_{b_0+\mathbb{Z}})((b_c', \infty))\Big) :$$

the regularized index-one values cancel, the first order is a finite sum over a head of the lattice, rational when b_0 is, and the orders $i \geq 2$ are Trailmoments of the lattice input cut at the data. At integer data, $b_0 = 0$, the first order is rational and the higher orders are Trailmoments of the counting input.

Proposition 5.14 (Laurent data of the Gamma at its poles)**.** *Let $j \in \mathbb{N}$. For $|\varepsilon| < 1$, with $(-1)^j \varepsilon\, \Gamma(-j+\varepsilon) = \Gamma(1+\varepsilon)\, \Gamma(1-\varepsilon)/\Gamma(1+j-\varepsilon)$,*

$$\log\big((-1)^j \varepsilon\, \Gamma(-j+\varepsilon)\big) = -\log j! - (\mathsf{T}_{1;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((j,\infty))\, \varepsilon$$
$$- \sum_{k\geq 2} \frac{(\mathsf{T}_{k;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((j,\infty))}{k}\, \varepsilon^k + \sum_{k\geq 1} \frac{(\mathsf{T}_{2k;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((0,\infty))}{k}\, \varepsilon^{2k},$$

and $(\log\Gamma)'(j+1) = -(\mathsf{T}_{1;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((j,\infty))$. Let h be holomorphic near $b = -j$, and let $k_1, \ldots, k_p$ be integers with $j_i = j - k_i \in \mathbb{N}$, so that every $\Gamma(b+k_i)$ has a pole at $-j$. Then

$$\operatorname*{Res}_{b=-j} \Big(h(b) \prod_{i=1}^{p} \Gamma(b+k_i) \Big) = (-1)^{j_1+\cdots+j_p} \sum_{l=0}^{p-1} \frac{h^{(l)}(-j)}{l!}\, [\varepsilon^{p-1-l}] \prod_{i=1}^{p} \big((-1)^{j_i} \varepsilon\, \Gamma(-j_i+\varepsilon)\big),$$

each factor of the product being the exponential of the display at j_i; at $p = 2$ and $k_1 = k_2 = 0$ it is $\frac{1}{(j!)^2}\big(h'(-j) + 2\,(\log\Gamma)'(j+1)\, h(-j)\big)$. Every Laurent coefficient of $\prod_i \Gamma(b+k_i)$ at $-j$ is $\prod_i (j_i!)^{-1}$ times a polynomial in Trailmoments of the counting input cut at the j_i and at 0.

Proposition 5.15 (Selecting an index inside a word)**.** *Let $w \geq 2$ be an integer and $h(z) = \prod_i \Gamma(1 + b_i - a_i z)^{n_i}$, a finite product with real $b_i > -1$, $a_i \in \mathbb{C}$ and $n_i \in \mathbb{Z}$. Its w-th multiplicative difference satisfies*

$$\prod_{j=0}^{w} h(jz)^{(-1)^{w-j}\binom{w}{j}} = 1 + (w-1)! \Big[\sum_i n_i a_i^w \, (\mathsf{T}_{w;(1)}[x]\, \mathbb{I}_{b_i+\mathbb{Z}})((b_i,\infty)) \Big] z^w + O(z^{w+1}).$$

At integer values $b_i = k_i \in \mathbb{N}$ with rational a_i, an integer $\ell \geq 1$ with every $\ell a_i \in \mathbb{Z}$ and $k_* = \max_i k_i$, the coefficient of z^w is $A\,(\mathsf{T}_{w;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((0,\infty)) - B$ with $A = (w-1)! \sum_i n_i a_i^w$ and $B = (w-1)! \sum_i n_i a_i^w \, (\mathsf{T}_{w;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((0,k_i])$, both cleared by $\ell^w d_{k_*}^w$. For the one factor $\Gamma(k+1-z)$, the coefficient of z^w in $\prod_{j=0}^{w} \Gamma(k+1-jz)^{(-1)^{w-j}\binom{w}{j}}$ is $(w-1)!\, (\mathsf{T}_{w;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((k,\infty))$, and passing from k to $k+1$ multiplies this product by $\prod_{j=0}^{w} (k+1-jz)^{(-1)^{w-j}\binom{w}{j}}$. The difference acts multiplicatively on one word, not on the sums of a closing; along a ray from the origin whose law of $[1]$ is reflexive of order two, the coefficient of the coordinate is read without any sum, from the closings of the ray (Chapter 43).

The w-th difference annihilates every power of z below the w-th in the logarithm of a Gamma word, so it removes the regularized index-one values together with all Trailmoments of lower index and keeps exactly those of index w: from a word in the Gammas of the data it selects one Trailmoment index, with a rational head.

Lemma 5.16 (Two Gammas and their reflections). *The stacked Gamma* $\Gamma_{\substack{4\\0}}\big[a,\ a,\ 1-a,\ 1-a\big] = \pi^2/\sin^2\pi a$ *has at every integer* m *the principal part* $(a-m)^{-2}$ *and no simple part, it equals* $\sum_{m\in\mathbb{Z}}(a+m)^{-2}$*, and on the line* $a=\frac12+iy$ *it equals* $4\pi^2/(e^{\pi y}+e^{-\pi y})^2$*.*

(i) Right closing. *For* $0<c<1$ *and* g *rational, holomorphic on* $\{\operatorname{Re} a\ge c\}$*, with* $g(a)=O(|a|^{-2})$*:* $\dfrac{1}{2\pi i}\displaystyle\int_{(c)}\Gamma_{\substack{4\\0}}\big[a,\ a,\ 1-a,\ 1-a\big]\ g(a)\,da=-\sum_{m\ge1}g'(m)$.

(ii) Left closing. *For* $0<X<1$*:* $\dfrac{1}{2\pi i}\displaystyle\int_{(1/2)}\Gamma_{\substack{4\\0}}\big[a,\ a,\ 1-a,\ 1-a\big]\ X^{-a}\,da=\frac{\log X}{X-1}$.

(iii) Fourier read. *For real* t*,*

$$\frac{1}{2\pi}\int_{\mathbb{R}}\Gamma_{\substack{4\\0}}\big[\tfrac12+iy,\ \tfrac12+iy,\ \tfrac12-iy,\ \tfrac12-iy\big]\ e^{ity}\,dy=\Gamma_{\substack{2\\0}}\big[1+\tfrac{it}{2\pi},\ 1-\tfrac{it}{2\pi}\big]=\frac{t}{e^{t/2}-e^{-t/2}}.$$

A closing whose poles coincide (Theorem 4.5) takes Laurent coefficients of its Gammas, and a balanced word near lattice data has heads and higher orders (Proposition 5.13): in both cases the Gammas contribute words in Trailmoments of lattice inputs, read at the cuts that the data set. The stacked Gamma of Lemma 5.16 is the simplest coincidence, two Gammas and their two reflections meeting at every integer: its double poles have no simple parts, so its right closing reads the derivative of the rest of the integrand at the positive integers, and on the line $\operatorname{Re} a=\frac12$ it is 2π times the density of the critical-line law (Chapter 36).

Theorem 5.17 (Reflected pairs and matched parity). *(i)* Cosets. *For* $0<b<1$ *and every integer* $n\ge1$*,*

$$(\mathsf{T}_{n;(1)}[x]\,\mathbb{I}_{b+\mathbb{Z}})((b-1,\infty))+(-1)^n\,(\mathsf{T}_{n;(1)}[x]\,\mathbb{I}_{-b+\mathbb{Z}})((-b,\infty))=\frac{(-1)^{n-1}}{(n-1)!}\,\partial_b^{n-1}\big(\pi\cot\pi b\big),$$

the index-one values regularized. The left side is $\sum_{m\in b+\mathbb{Z}}m^{-n}$ *over the whole lattice, in symmetric order at* $n=1$*, and the right side is* π^n *times a polynomial of degree* n *in* $\cot\pi b$ *with rational coefficients.*

(ii) Frequencies. *For* $0<b\le1$ *and every integer* $n\ge2$*, the Trailmoment* $(\mathsf{T}_{n;(1)}[x]\,\sin\big(2\pi bx-\frac{\pi(n-1)}{2}\big)\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$ *is* $\frac{(-1)^{n-1}(2\pi)^n}{2}$ *times the coefficient of* u^{n-1} *in* $e^{-bu}/(1-e^{-u})$*. The density is* $(-1)^{n/2}\cos(2\pi bx)$ *at even* n *and* $(-1)^{(n-1)/2}\sin(2\pi bx)$ *at odd* n*, and the value is* π^n *times a polynomial of degree* n *in* b *with rational coefficients.*

(iii) Periodic densities. *For integers* $0<r<q$ *and* $n\ge1$*,*

$$(\mathsf{T}_{n;(1)}[x]\,\big(\mathbb{I}_{r+q\mathbb{Z}}+(-1)^n\,\mathbb{I}_{-r+q\mathbb{Z}}\big))((0,\infty))=\frac{(-1)^{n-1}}{q^n(n-1)!}\,\partial_b^{n-1}\big(\pi\cot\pi b\big)\Big|_{b=r/q},$$

at $n=1$ *with the points of the two lattices taken in increasing order.*

(iv) Folding. *At* $b=\frac12$ *the two lattices of (i) are one, and (i) reads*

$$\big(1+(-1)^n\big)(\mathsf{T}_{n;(1)}[x]\,\mathbb{I}_{\frac12+\mathbb{Z}})((0,\infty))=\frac{(-1)^{n-1}}{(n-1)!}\,\partial_b^{n-1}(\pi\cot\pi b)\Big|_{b=1/2}:$$

at odd n *both sides vanish, and at even* $n=2j$*, with the lattice relation at the step* 2 *(Theorem 5.12(i)),*

$$(\mathsf{T}_{2j;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))=\frac{-1}{2\,(2^{2j}-1)\,(2j-1)!}\ \partial_b^{2j-1}\big(\pi\cot\pi b\big)\Big|_{b=1/2}.$$

At $b = 1$, (ii) gives $(\mathsf{T}_{2j;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty)) = (-1)^{j+1}\frac{(2\pi)^{2j}}{2}$ times the coefficient of u^{2j-1} in $1/(e^u-1)$, and the identity $0=0$ at odd n.

At an integer index n the kernel $\mathsf{Z}_{n;(1)}(x) = x^{-n}$ has the parity of n under $x \mapsto -x$. What closes, for every coset $b+\mathbb{Z}$ and every integer index, is the value of the whole coset, points of both signs: the reflection of the Gamma evaluates it, and at $n=2$ and $0<b<1$ it is $\Gamma_{\substack{4\\0}}\big[b,\ b,\ 1-b,\ 1-b\big]$ (Lemma 5.16). A Trailmoment reads the points beyond its cut only, so this relation gives it when the input, continued to the whole lattice, has the parity of the index: an even periodic density closes at even indices and an odd one at odd indices, by (iii), and on the coset $q\mathbb{Z}$ by (iv). On a lattice equal to its own reflection the pair of (i) folds onto one Trailmoment with the factor $1+(-1)^n$; at even n that Trailmoment closes, and at odd n the relation is the identity $0=0$ and carries no information. Statement (ii) is the same rule read on frequencies. The mismatched parities, the sine at an even index and the cosine at an odd index, are reached by neither statement on any coset or at any frequency; the counting input at an odd index is the cosine at frequency zero, and its Trailmoments are the ones that the positive words of Part VI carry.

5.6 Reflections of the index

Theorem 5.18 (Reflection through the poles of the Laplace transform)**.** *Let $\mathcal{F}$ be a function on $(0,\infty)$ that extends to a meromorphic function on $\mathbb{C}$ with no pole on $(0,\infty)$, such that*

(a) its poles other than $u=0$ are simple, with residue r_p at the pole p, and its pole at 0 has order $k_0 \geq 0$, with $k_0 = 0$ when there is none;

(b) there are radii $R_m \to \infty$ and a real A with $\sup_{|u|=R_m} |\mathcal{F}(u)| = O(R_m^A)$.

Write $\Sigma_m(\nu) = \sum_{0<|p|<R_m} r_p\,(-p)^{\nu-1}$, with $(-p)^{\nu-1} = \exp\big((\nu-1)\log(-p)\big)$ and $|\arg(-p)| < \pi$.

(i) On the strip. *If moreover $\mathcal{F}(u) = O(u^A)$ as $u \to +\infty$, then for $k_0 < \operatorname{Re}\nu < -A$ with $\nu \notin \mathbb{Z}$,*

$$\int_0^\infty u^{\nu-1}\mathcal{F}(u)\,du = \frac{\pi}{\sin\pi\nu}\lim_{m\to\infty}\Sigma_m(\nu).$$

(ii) Beyond the strip. *If $\mathcal{F} = \mathcal{F}_N$ is the Laplace transform of an input ϕ tame beyond the cut N, its poles lie in $\operatorname{Re} u \leq 0$, and for $\operatorname{Re}\nu < -A$ with $\nu \notin \{1,2,3,\dots\}$,*

$$(\mathsf{T}_{\nu;(1)}[x]\,\phi)((N,\infty)) = \Gamma(1-\nu)\lim_{m\to\infty}\Sigma_m(\nu).$$

Reflection of the index replaces an input by the poles of its Laplace transform: each simple pole p becomes the point measure $r_p\,\delta_{-p}$, read by the kernel $\mathsf{Z}_{1-\nu;(1)}$. The relation is free in the input within (a) and (b), and pinned at one unit exponent with the coefficient function x; the mechanism is the Laplace side of the kernel $\mathsf{Z}_{\nu;(1)}$, where the index is the exponent of the scale and a full turn of the scale multiplies the integrand by $e^{2\pi i\nu}$. For the input $e^{-x}\,\mathbb{I}_{\mathbb{R}}$ cut at 0, whose Laplace transform $1/(1+u)$ has the one pole -1, statement (i) is the reflection of the Gamma (Proposition 1.3(v)); for a lattice input the strip of (i) is empty, and the reflection is a statement about the continued Trailmoment, which is (ii).

Theorem 5.19 (Reflection by inversion of the Laplace transform)**.** *Let ϕ and ψ be tame beyond the cut 0, with Laplace transforms $\mathcal{F}$ and $\mathcal{G}$, and suppose that for some $k \in \mathbb{R}$, $\lambda > 0$, $C \neq 0$ and $f_0, g_0 \in \mathbb{C}$,*

$$\mathcal{F}(u) + f_0 = C\,u^{-k}\Big(\mathcal{G}\big(\tfrac{\lambda}{u}\big) + g_0\Big) \qquad (u>0).$$

Then $\Gamma(\nu)\,(\mathsf{T}_{\nu;(1)}[x]\,\phi)((0,\infty))$*, defined for large* $\operatorname{Re}\nu$ *by the Laplace side, continues meromorphically to* $\mathbb{C}$*,*

$$\Gamma(\nu)\,(\mathsf{T}_{\nu;(1)}[x]\,\phi)((0,\infty)) = \int_{\sqrt{\lambda}}^{\infty} u^{\nu-1}\mathcal{F}(u)\,du + C\lambda^{\nu-k}\int_{\sqrt{\lambda}}^{\infty} u^{k-\nu-1}\mathcal{G}(u)\,du + \frac{C\,g_0\,\lambda^{(\nu-k)/2}}{\nu-k} - \frac{f_0\,\lambda^{\nu/2}}{\nu},$$

whose only possible poles are simple, at $\nu = k$ *and* $\nu = 0$*. The same holds with* ψ *in the place of* ϕ*, and*

$$\Gamma(\nu)\,(\mathsf{T}_{\nu;(1)}[x]\,\phi)((0,\infty)) = C\,\lambda^{\nu-k}\,\Gamma(k-\nu)\,(\mathsf{T}_{k-\nu;(1)}[x]\,\psi)((0,\infty)).$$

The inversion $u \mapsto \lambda/u$ of the scale is the reflection of the Gramma (Proposition 2.3) on the Laplace side. The relation is free in the two inputs, which need not be lattices and whose Laplace transforms need not be meromorphic; it uses one property of the pair, that the inversion of the scale carries the Laplace transform of one to that of the other. The constants f_0 and g_0 are the multiples of δ_0 that the two inputs would carry at the origin, where the kernel $\mathsf{Z}_{\nu;(1)}$ is not defined, and for $k \neq 0$ they give the residues of the continuation, $-f_0$ at $\nu = 0$ and Cg_0 at $\nu = k$.

Theorem 5.20 (Reflection at the coefficient function $x+\mu$)**.** *Let* ϕ*,* ψ*,* $\mathcal{F}$*,* $\mathcal{G}$*,* k*,* λ*,* C*,* f_0 *and* g_0 *be as in Theorem 5.19, and let* $\mu > 0$*. For* $\operatorname{Re} s > \max(k,0)$ *with* $\int_{(0,\infty)}(x+\mu)^{-\operatorname{Re} s}\,|\phi|(dx) < \infty$*,*

$$\Gamma(s)\Big[(\mathsf{T}_{s;(1)}[x+\mu]\,\phi)((0,\infty)) + f_0\,\mu^{-s}\Big] = C\,\lambda^{s-k}\int_{(0,\infty)}\mathsf{G}_{k-s;(1,-1)}(y,\lambda\mu)\,\psi(dy) + C\,g_0\,\Gamma(s-k)\,\mu^{k-s}.$$

The integral on the right converges for every $s \in \mathbb{C}$ *and is entire in* s*.*

5.7 Joint sources

Theorem 5.21 (Closure with the source kept joint)**.** *(i)* $\mathsf{Z}_{\nu;t}(\mathbf{c})\,\mathsf{Z}_{\eta;s}(\mathbf{d}) = \mathsf{Z}_{(\nu,\eta);\,t\oplus s}(\mathbf{c}\oplus\mathbf{d})$*, the configuration* $t \oplus s$ *acting on the disjoint union of the two sets of scales.*

(ii) A finite expression built from Zammas with positive indices by products and by nested reads against nonnegative measures is one Trailmoment on a source: its configuration is the concatenation $\oplus$ *of the factors' configurations, and its input is the joint measure* $\phi(dy)\,\psi_y(dw)$ *of the source variables, every shared variable, conditional dependence and cut retained. The same holds for complex data where every integral converges absolutely.*

Proposition 5.22 (The joint Laplace transform of Dirichlet inputs)**.** *Let* $U = (U_Q)_{Q\in\mathcal{P}}$ *have independent blocks* $U_Q \sim \operatorname{Dir}_{\mathbf{m}|_Q}$ *on a partition* $\mathcal{P}$ *of the scales, let* $P_1,\dots,P_q$ *be finite sums* $P_i(u) = \sum_{\mathbf{a}}[u^{\mathbf{a}}]P_i\,u^{\mathbf{a}}$ *over exponents* $\mathbf{a} \in [0,\infty)^{\mathcal{E}}$*, polynomials when the exponents are integers, and let* t *be a configuration of* q *columns on* d *scales and* $\nu \in \mathbb{C}^d$*. Then* $\mathcal{F}(v) = \mathbb{E}_{U\sim\bigotimes_Q \operatorname{Dir}_{\mathbf{m}|_Q}}\big[\exp\big(-\sum_i v_i P_i(U)\big)\big]$ *is entire and*

$$\mathcal{F}(v) = \sum_{\mathbf{k}\in\mathbb{N}^q}\frac{(-v)^{\mathbf{k}}}{\mathbf{k}!}M(\mathbf{k}),$$

$$M(\mathbf{k}) = \sum_{\mathbf{a}}\big[u^{\mathbf{a}}\big]\big(P_1(u)^{k_1}\cdots P_q(u)^{k_q}\big)\prod_e \Gamma_1\begin{bmatrix} m_e + a_e \\ m_e\end{bmatrix}\prod_Q \Gamma_1\begin{bmatrix} m_Q \\ m_Q + a_Q\end{bmatrix}, \qquad a_Q = \sum_{e\in Q} a_e;$$

for integer exponents the stacked Gammas are $\prod_e (m_e)_{a_e} / \prod_Q (m_Q)_{a_Q}$. *If every* P_i *is positive on the interior of the source and* $\operatorname{Re}\nu_j > 0$, *then, wherever the read converges,*

$$\mathbb{E}_{U\sim\bigotimes_Q \mathrm{Dir}_{\mathbf{m}|_Q}}\big[\mathsf{Z}_{\nu;t}\big(P_1(U),\dots,P_q(U)\big)\big] = \frac{1}{\prod_j \Gamma(\nu_j)} \int_{(0,\infty)^d} x^{\nu-\mathbf{1}}\, \mathcal{F}\big(x^{t_1},\dots,x^{t_q}\big)\, dx,$$

the Laplace side of the Trailmoment $(\mathsf{T}_{\nu;t}[(P_i)_i] \otimes_Q \mathrm{Dir}_{\mathbf{m}|_Q})\big(\prod_Q \Delta_Q\big)$. *For real coefficients, two choices of the data with equal joint moment arrays* M *give the vectors* $(P_i(U))_i$ *equal laws, hence equal reads of every kernel.*

5.8 Trails

Definition 5.23 (Trail data)**.** Take d scales, an index $\boldsymbol{\nu} \in \mathbb{C}^d$, the *trail columns* $I_d = (\mathbf{e}_1,\dots,\mathbf{e}_d)$, and *constant columns* $(t_k)_{k\in C}$ with constant coefficients $\lambda_k > 0$ (a constant column of coefficient zero is absent). Put

$$t = I_d \oplus (t_k)_{k\in C}, \qquad \mathbf{c}(y) = (y_1,\dots,y_d,(\lambda_k)_{k\in C}), \qquad X_N = \{N < y_1 < \cdots < y_d\}.$$

The *trail* at the cut N of an input ϕ on $\mathbb{R}^d$, carried where every trail coefficient is positive, is the Trailmoment of Definition 5.1 with this coefficient function and cut region,

$$(\mathsf{T}_{\boldsymbol{\nu};\, I_d\oplus(t_k)_{k\in C}}[(y_1,\dots,y_d,(\lambda_k)_{k\in C})]\,\phi)(X_N);$$

with no constant columns it is $(\mathsf{T}_{\boldsymbol{\nu};I_d}[y]\,\phi)(X_N)$. For lattices $\mathbb{L}_1,\dots,\mathbb{L}_d \subset \mathbb{R}$ the input $\mathbb{I}_{\mathbb{L}_1\times\cdots\times\mathbb{L}_d}$ is counting measure on their product, of which the cut region selects the points in X_N. The input is *given by increments* $\psi_1,\dots,\psi_d$, measures on $(0,\infty)$, when it is the image ϕ_N of $\bigotimes_j \psi_j$ under $s \mapsto y$, $y_i = N + s_1 + \cdots + s_i$; their Laplace transforms are $L_j(U) = \int e^{-sU}\psi_j(ds)$. By transport (Theorem 5.9) the trail of such an input is the Trailmoment on the increment source $(0,\infty)^d$ with the input $\bigotimes_j \psi_j$ and the coefficient function $s \mapsto (N+s_1,\dots,N+s_1+\cdots+s_d,(\lambda_k)_{k\in C})$, over the whole source: there the cut N is carried by the coefficient function.

Theorem 5.24 (The trail by its increments)**.** *Let the input be given by increments, put* $t = I_d \oplus (t_k)_{k\in C}$, *and let* $U_i = x_i + \cdots + x_d$ *be the sums of the scales from the* i*-th on,* $U_{d+1} = 0$. *Wherever the right side converges absolutely, with* $x_i = U_i - U_{i+1}$,

$$\begin{aligned}&(\mathsf{T}_{\boldsymbol{\nu};t}[(y,(\lambda_k)_{k\in C})]\,\phi_N)(X_N)\\ &\qquad = \int_{U_1>\cdots>U_d>0} \prod_{i=1}^{d} \frac{(U_i-U_{i+1})^{\nu_i-1}}{\Gamma(\nu_i)}\, \exp\Big(-\sum_{k\in C}\lambda_k x^{t_k}\Big) e^{-NU_1} \prod_{j=1}^{d} L_j(U_j)\, dU.\end{aligned}$$

Its relations hold wherever the reads in them converge, the derivatives under the integral being dominated:

(i) Moving the cut, *with the increments fixed:*

$$\partial_N(\mathsf{T}_{\boldsymbol{\nu};t}[(y,(\lambda_k)_{k\in C})]\,\phi_N)(X_N) = -\sum_i \nu_i\,(\mathsf{T}_{\boldsymbol{\nu}+\mathbf{e}_i;t}[(y,(\lambda_k)_{k\in C})]\,\phi_N)(X_N).$$

(ii) Ladder.

$$\partial_{\lambda_k}(\mathsf{T}_{\boldsymbol{\nu};t}[(y,(\lambda_h)_{h\in C})]\,\phi_N)(X_N) = -\Gamma_d\begin{bmatrix}\boldsymbol{\nu}+t_k\\ \boldsymbol{\nu}\end{bmatrix}\,(\mathsf{T}_{\boldsymbol{\nu}+t_k;t}[(y,(\lambda_h)_{h\in C})]\,\phi_N)(X_N).$$

(iii) Exchange, per scale.

$$(\mathsf{T}_{\boldsymbol{\nu};t}[(y,(\lambda_k)_{k\in C})]\,\phi_N)(X_N) = (\mathsf{T}_{\boldsymbol{\nu}+\mathbf{e}_i;t}[(y,(\lambda_k)_{k\in C})]\,y_i\phi_N)(X_N) + \frac{1}{\nu_i}\sum_{k\in C} t_{k,i}\lambda_k \Gamma_d{}_d\begin{bmatrix}\boldsymbol{\nu}+t_k\\ \boldsymbol{\nu}\end{bmatrix}\,(\mathsf{T}_{\boldsymbol{\nu}+t_k;t}[(y,(\lambda_h)_{h\in C})]\,\phi_N)(X_N).$$

(iv) Composition. *If every constant column is supported on one scale, partition C into sets C_i with $\mathrm{supp}(t_k)\subseteq\{i\}$ for $k\in C_i$, assigning every zero column to one scale, and put $t^{(i)} = (1)\oplus(t_{k,i})_{k\in C_i}$. Then*

$$\mathsf{Z}_{\boldsymbol{\nu};t}(y,(\lambda_k)_{k\in C}) = \prod_i \mathsf{Z}_{\nu_i;t^{(i)}}(y_i,(\lambda_k)_{k\in C_i}),$$

and the trail is the iterated read over $s_1,\dots,s_d>0$, in that order, of $\prod_i \mathsf{Z}_{\nu_i;t^{(i)}}(N+s_1+\cdots+s_i,(\lambda_k)_{k\in C_i})$ against $\bigotimes_i\psi_i$: each one-scale Trailmoment has the next read in its input. With counting increments, every ψ_j the counting input on the positive integers, no constant columns and $N\in b+\mathbb{Z}$, this is the nest of one-scale Trailmoments at successive running cuts, with indices $\nu_1,\dots,\nu_d$ and lattice input $\mathbb{I}_{b+\mathbb{Z}}$, and the trail is $(\mathsf{T}_{\boldsymbol{\nu};I_d}[y]\,\mathbb{I}_{(b+\mathbb{Z})^d})(\{N<y_1<\cdots<y_d\})$.

5.9 Products of Trailmoments

Theorem 5.25 (The Struffle)**.** *(i) Let ϕ,ψ be inputs on $\mathbb{R}$ with any indices, configurations and coefficient functions. If the product below converges with $|\phi|$, $|\psi|$ and the moduli of the kernels, then*

$$\begin{aligned}&(\mathsf{T}_{\nu;t}[\mathbf{c}]\,\phi)((N,\infty))\,(\mathsf{T}_{\nu';t'}[\mathbf{c}']\,\psi)((N,\infty))\\ &\quad=\Big(\mathsf{T}_{\nu;t}[\mathbf{c}]\,\big[x\mapsto(\mathsf{T}_{\nu';t'}[\mathbf{c}']\,\psi)((x,\infty))\big]\phi\Big)((N,\infty))\\ &\qquad+\Big(\mathsf{T}_{\nu';t'}[\mathbf{c}']\,\big[x\mapsto(\mathsf{T}_{\nu;t}[\mathbf{c}]\,\phi)((x,\infty))\big]\psi\Big)((N,\infty))\\ &\qquad+\big(\mathsf{T}_{(\nu,\nu');\,t\oplus t'}[\mathbf{c}\oplus\mathbf{c}']\,\phi\wedge\psi\big)((N,\infty)),\end{aligned}$$

where the diagonal input *is $\phi\wedge\psi=\sum_x\phi(\{x\})\psi(\{x\})\delta_x$, the sum over the points that both inputs charge, and the diagonal kernel is the Zamma of the concatenation $t\oplus t'$ (Theorem 5.21(i)).*

(ii) For inputs $\phi_1,\dots,\phi_r$ on $\mathbb{R}$ with kernel data $(\nu_i,t_i,\mathbf{c}_i)$, if $\prod_i(\mathsf{T}_{\nu_i;t_i}[\mathbf{c}_i]\,\phi_i)((N,\infty))$ converges with the total variations and the moduli of the kernels, it is the sum over the ordered partitions $(B_1,\dots,B_s)$ of $\{1,\dots,r\}$ into nonempty blocks of

$$\int_{N<x_1<\cdots<x_s}\prod_{j=1}^{s}\Big(\prod_{i\in B_j}\mathsf{Z}_{\nu_i;t_i}(\mathbf{c}_i(x_j))\Big)\Big(\bigwedge_{i\in B_j}\phi_i\Big)(dx_j),$$

with $\bigwedge_{i\in B}\phi_i=\sum_x\prod_{i\in B}\phi_i(\{x\})\delta_x$ for a block of at least two elements and ϕ_i for the block $\{i\}$.

The Struffle orders the points of the inputs along the line; the diagonal is there exactly when the inputs charge common points beyond the cut. It is free in the index, the configuration and

the coefficient function of both factors and in their inputs on the line; the cut region is pinned at one common cut. At one unit exponent with one coefficient function on both factors the diagonal kernel is $\mathsf{Z}_{\nu+\nu';(1)}$.

Theorem 5.26 (The Shruffle on a line)**.** *For a string $w = (w_1, \dots, w_n)$ of measurable functions on $(0,\infty)$ put* $\operatorname{chain}(w) = \int_{x_1>\cdots>x_n>0} \prod_i w_i(x_i)\,dx$*, defined when* $\operatorname{chain}(|w|) < \infty$*.*

(i) If $\operatorname{chain}(|w^{(1)}|), \dots, \operatorname{chain}(|w^{(r)}|)$ *are finite,* $\prod_{i=1}^{r} \operatorname{chain}(w^{(i)}) = \sum_{\varsigma} \operatorname{chain}(\varsigma)$*, the sum over the $(n_1 + \cdots + n_r)!/(n_1! \cdots n_r!)$ interleavings of the r strings, n_i the length of $w^{(i)}$.*

(ii) Let a trail have its input given by nonnegative increments, with Laplace transforms $L_1, \dots, L_d$, and a cut $N \in \mathbb{R}$ such that the image of the first increment ψ_1 under $s \mapsto s + N$ is carried by $(0,\infty)$, as it is when $N \geq 0$; let it have no constant columns and positive integer indices $a_1, \dots, a_d$. Then, both sides finite or infinite together, with 1^a for a copies of the constant function 1, the trail is the chain integral of its string:

$$(\mathsf{T}_{\mathbf{a};I_d}[y]\,\phi_N)(X_N) = \operatorname{chain}\big(e^{-N\cdot}L_1,\ 1^{a_1-1},\ L_2,\ 1^{a_2-1},\ \dots,\ L_d,\ 1^{a_d-1}\big).$$

(iii) The product of finitely many such trails is the sum, over the interleavings of their strings, of trails of the same kind at the cut 0: every interleaving begins with a Laplace transform and is the string of the trail whose increments have the Laplace transforms of the interleaving in their order, each index being one more than the number of constant functions 1 that follow its Laplace transform, $e^{-N\cdot}L$ being the Laplace transform of the increment moved by N.

The Shruffle orders the scales on the Laplace side. It is free in the nonnegative increments, in the number of scales, and in the cut as long as the first point beyond it is positive; it is pinned at positive integer indices without constant columns, where $(U_i - U_{i+1})^{a-1}/\Gamma(a)$ is the volume of a chain of points. Where a nest of Trailmoments on the input side is a trail given by increments all equal to one measure at the cut 0, as for the counting input cut at 0, the Struffle and the Shruffle expand one product into the same members, and comparing the two expansions gives linear relations among the trails.

Theorem 5.27 (Trails at frequencies are iterated integrals)**.** *Let $d \geq 1$, $\boldsymbol{\nu} \in \{1, 2, \dots\}^d$ and $\mathbf{a} \in \mathbb{R}^d$, put $\zeta_i = e^{2\pi i a_i}$, and let $\zeta_d \neq 1$ when $\nu_d = 1$. Put $c_i = \zeta_i\zeta_{i+1}\cdots\zeta_d$, $w = |\boldsymbol{\nu}|$, and let $(\ell_1, \dots, \ell_w)$ be the word $c_1^{-1}, 0^{\nu_1-1}, c_2^{-1}, 0^{\nu_2-1}, \dots, c_d^{-1}, 0^{\nu_d-1}$, 0^r standing for r letters 0. Then the heads of the trail over $\{0 < y_1 < \cdots < y_d \leq N\}$ of the lattice input $e^{2\pi i\langle \mathbf{a}, y\rangle}\,\mathbb{I}_{\mathbb{Z}^d}$ at the indices $\boldsymbol{\nu}$ converge as $N \to \infty$, to the trail itself when $\nu_d \geq 2$, and with the trail read as this limit*

$$\big(\mathsf{T}_{\boldsymbol{\nu};I_d}[y]\ e^{2\pi i\langle \mathbf{a}, y\rangle}\,\mathbb{I}_{\mathbb{Z}^d}\big)\big(\{0 < y_1 < \cdots < y_d\}\big) = (-1)^d \int_{0<t_1<\cdots<t_w<1} \prod_{j=1}^{w} \frac{dt_j}{t_j - \ell_j},$$

an absolutely convergent integral. For $|z| < 1$ the trail with the factor z^{y_d} in its density is $(-1)^d$ times the same integral over $0 < t_1 < \cdots < t_w < z$ along the segment from 0 to z.

On the Laplace side the input of the trail, given by its increments, has the letters $c_i z/(1 - c_i z)$ in the variable $z = e^{-U}$, singular at the c_i^{-1}, and the index of each scale adds the letters 0 of the factor 1^{ν_i-1} of the Shruffle (Theorem 5.26(ii)): the theorem is the chain integral of that string, read in z, for inputs with complex densities.

Theorem 5.28 (The sum over the splittings of an index)**.** *Let $b \in \mathbb{R}$, let N be a cut, and let $m_0 > 0$ be the first point of $b + \mathbb{Z}$ beyond N. For an integer $w \geq 3$,*

$$\sum_{a=1}^{w-2} (\mathsf{T}_{(a,w-a);I_2}[y]\, \mathbb{I}_{(b+\mathbb{Z})^2})(\{N < y_1 < \cdots < y_2\}) = (\mathsf{T}_{w-1;(1)}[x]\, \eta\, \mathbb{I}_{b+\mathbb{Z}})((N,\infty)),$$

$$\eta(m) = (\mathsf{T}_{1;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((m-m_0,\infty)) - (\mathsf{T}_{1;(1)}[x]\, \mathbb{I}_{b+\mathbb{Z}})((m,\infty)) = \sum_{k\geq 1} \Big(\frac{1}{m-m_0+k} - \frac{1}{m+k}\Big),$$

the index-one values regularized. At every point m of the lattice beyond the cut,

$$\eta(m) - \frac{1}{m} = (\log\Gamma)'(m) - (\log\Gamma)'(m-m_0+1),$$

which is positive for $m_0 > 1$, zero for $m_0 = 1$ and negative for $m_0 < 1$. So the sum over the splittings is $(\mathsf{T}_{w;(1)}[x]\, \mathbb{I}_{b+\mathbb{Z}})((N,\infty))$ if and only if $m_0 = 1$, that is, for the counting input at a cut in $[0,1)$; it is larger for $m_0 > 1$ and smaller for $m_0 < 1$. For the counting input cut at an integer $c \geq 0$, $m_0 = c+1$ and $\eta(m) = (\mathsf{T}_{1;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((m-c-1,m])$, a head of $c+1$ terms. For a lattice $b + q\mathbb{Z}$ of step $q > 0$ with a positive first point m_0 beyond the cut, the sum over $1 \leq a \leq w-2$ of the trails with the indices $(a, w-a)$ on its points is $(\mathsf{T}_{w;(1)}[x]\, \mathbb{I}_{b+q\mathbb{Z}})((N,\infty))$ if and only if $m_0 = q$.

Summing the trails on two scales over the splittings of an index telescopes in the inner variable, and what is left is one Trailmoment of index one less, with the density η. The index rises back by one exactly when $\eta(m) = \frac{1}{m}$ at every point, which is exactly when the first point beyond the cut is 1.

Theorem 5.29 (The Cremona of an increment)**.** *Let $L > 0$ be continuous on $(0,\infty)$ with $\int_x^\infty L < \infty$ for $x > 0$ and $\int_0^\infty L = \infty$, and let $\mathrm{tail}_L(x) = \int_x^\infty L(u)\, du$, the* tail function*, a decreasing bijection of $(0,\infty)$. For a string w whose entries are $L(x)\, dx$ or dx, let $\mathrm{chain}_L(w)$ be its chain integral over $x_1 > \cdots > x_n > 0$, largest variable first, and w^* the reversed string with $L(x)\, dx$ and dx swapped. Then $\mathrm{tail}_L \circ \mathrm{tail}_L = \mathrm{id}$ if and only if $L(\mathrm{tail}_L(x))\, L(x) = 1$ for every x, and in that case $\mathrm{chain}_L(w) = \mathrm{chain}_L(w^*)$ for every string, finite or infinite together.*

The Cremona uses one property of the increment: its tail function tail_L is an involution of the scale, so that the substitution $y = \mathrm{tail}_L(x)$ carries dx to $L(y)\, dy$ as well as $L(x)\, dx$ to dy. For the counting increments, $L(u) = 1/(e^u - 1)$ and the involution is the curve $e^{-x} + e^{-y} = 1$.

5.10 Convolutions of inputs

Definition 5.30 (The two convolutions)**.** Let ϕ and ψ be inputs carried by $[0,\infty)$, and $\phi \otimes \psi$ their product on $[0,\infty)^2$. The *additive convolution* $\phi \boxplus \psi$ is the image of $\phi \otimes \psi$ under $(x,y) \mapsto x + y$. When both inputs are carried by $(0,\infty)$, the *multiplicative convolution* $\phi \boxtimes \psi$ is the image of $\phi \otimes \psi$ under $(x,y) \mapsto xy$. Both are images in the sense of Definition 5.4: for inputs with complex densities they are used only in integrals that converge absolutely on the product $\phi \otimes \psi$. The multiplicative convolution of two σ-finite measures need not be σ-finite; it is used only where an integral of Theorem 5.31(ii) below converges absolutely, and there it is σ-finite, its kernel being positive and finite on $(0,\infty)$. For lattice inputs with densities, $(f\, \mathbb{I}_{\mathbb{Z}}) \boxplus (g\, \mathbb{I}_{\mathbb{Z}})$ and $(f\, \mathbb{I}_{\mathbb{Z}}) \boxtimes (g\, \mathbb{I}_{\mathbb{Z}})$ denote the convolutions of the parts beyond the cut 0: for densities f and g on the positive integers, the first has the density $\sum_{j+k=n} f(j)g(k)$ at n and the second the density $\sum_{jk=n} f(j)g(k)$; likewise for lattice inputs on other cosets. For an input carried by $[0,\infty)$ write $\mathcal{F}_\phi(u) = \int_{[0,\infty)} e^{-ux}\, \phi(dx)$, the kernel being 1 at the point $x = 0$: it is the Laplace transform beyond every cut $N < 0$, and for an input carried by $(0,\infty)$ the Laplace transform beyond the cut 0.

Theorem 5.31 (Two convolutions)**.** *Let ϕ on Y_1 and ψ on Y_2 be inputs with coefficient functions c and c' and cut regions Y_1' and Y_2', and write $c+c'$ and $c\,c'$ for the functions $(y_1, y_2) \mapsto c(y_1)+c'(y_2)$ and $(y_1, y_2) \mapsto c(y_1)\,c'(y_2)$ on $Y_1 \times Y_2$.*

(i) The kernel $\mathsf{Z}_{1;(1,0)}(1, \cdot)$ on a sum. *If the two Trailmoments on the right converge,*

$$\big(\mathsf{T}_{1;(1,0)}[(1, c+c')]\ \phi \otimes \psi\big)(Y_1' \times Y_2') = (\mathsf{T}_{1;(1,0)}[(1, c)]\,\phi)(Y_1')\ (\mathsf{T}_{1;(1,0)}[(1, c')]\,\psi)(Y_2').$$

For inputs carried by $[0, \infty)$ and $u \in \mathbb{C}$ such that $e^{-x \operatorname{Re} u}$ is integrable for $|\phi|$ and for $|\psi|$, $\mathcal{F}_{\phi \boxplus \psi}(u) = \mathcal{F}_\phi(u)\,\mathcal{F}_\psi(u)$.

(ii) The kernel $\mathsf{Z}_{\nu;I_\mathcal{E}}$ on a product. *For coefficient functions $\mathbf{c}$ and $\mathbf{c}'$ with values in $(0, \infty)^\mathcal{E}$, $\mathbf{c}\,\mathbf{c}'$ their coordinatewise product and $\nu \in \mathbb{C}^\mathcal{E}$, if the two Trailmoments on the right converge,*

$$\big(\mathsf{T}_{\nu;I_\mathcal{E}}[\mathbf{c}\,\mathbf{c}']\ \phi \otimes \psi\big)(Y_1' \times Y_2') = (\mathsf{T}_{\nu;I_\mathcal{E}}[\mathbf{c}]\,\phi)(Y_1')\ (\mathsf{T}_{\nu;I_\mathcal{E}}[\mathbf{c}']\,\psi)(Y_2').$$

For inputs carried by $(0, \infty)$,

$$(\mathsf{T}_{\nu;(1)}[x]\,\phi \boxtimes \psi)((0,\infty)) = (\mathsf{T}_{\nu;(1)}[x]\,\phi)((0,\infty))\ (\mathsf{T}_{\nu;(1)}[x]\,\psi)((0,\infty)),$$
$$\mathcal{F}_{\phi \boxtimes \psi}(u) = \int_{(0,\infty)} \mathcal{F}_\psi(ux)\,\phi(dx),$$

the first when its right side converges and the second when $\iint e^{-xy \operatorname{Re} u}\,|\phi|(dx)\,|\psi|(dy) < \infty$.

(iii) Converses. *Let g be a continuous complex-valued function on $(0, \infty)^\mathcal{E}$, not identically zero, with $g(s+s') = g(s)\,g(s')$ for all $s, s' \in (0, \infty)^\mathcal{E}$. Then $g(s) = e^{-\langle u, s\rangle}$ for one $u \in \mathbb{C}^\mathcal{E}$. Let h be a continuous complex-valued function on $(0, \infty)^\mathcal{E}$, not identically zero, with $h(x\,x') = h(x)\,h(x')$ for the coordinatewise product. Then $h = \mathsf{Z}_{\nu;I_\mathcal{E}}$ for one $\nu \in \mathbb{C}^\mathcal{E}$. The two hypotheses are the product relations of (i) and of (ii), for a kernel g or h in the place of the kernel there, on every pair of Dirac measures.*

The two convolutions add and multiply the points of two inputs, and each has one kernel that turns it into a product: on sums the kernel $\mathsf{Z}_{1;(1,0)}(1, \cdot)$ of a term at exponent zero beside a unit term, which is e^{-c}; on products the kernel $\mathsf{Z}_{\nu;I_\mathcal{E}}$ of the unit configuration, the power $\mathbf{c} \mapsto \mathbf{c}^{-\nu}$. Both statements are free in the two inputs, the two coefficient functions and the two cut regions, and each is pinned in its kernel; (iii) is the converse of that pin.

Chapter 6

Rational words and live inputs

A rational word acting on a Trailmoment through its input is moved, by partial fractions and the shift of the cut, onto Trailmoments of shifted inputs at the unit configuration; the pole columns of the word then separate what is a Trailmoment from what is a finite difference. An input is *live* when the values of its density are themselves read from the serif family, a Breta or a Gramma at a shifting slot, and the relations of that member give the input a recurrence of finite order. Every identity for rational words and live inputs is a finite identity first, at finite cuts; its infinite form uses the displayed convergence, or the common finite upper cut of the closing it comes from.

Definition 6.1 (Rational words and their transport)**.** A *rational word* is a function

$$R(x) = \sum_{k=0}^{k_{\max}} \sum_{j=1}^{J_k} c_{k,j}(x+k)^{-j},$$

kept with its partial-fraction presentation. For the data $(\nu, t, \mathbf{c}, \phi)$ of a Trailmoment on a line and the cut region (N, ∞), the rational word acts through the input,

$$(\mathsf{T}_{\nu;t}[\mathbf{c}]\,(R\phi))((N,\infty)) = \int_{(N,\infty)} R(x)\,\mathsf{Z}_{\nu;t}(\mathbf{c}(x))\,\phi(dx).$$

Write $(\mathrm{Sh}^h f)(m) = f(m+h)$, $\Delta H(m) = H(m+1) - H(m)$, $\tau_k(x) = x + k$ and $\phi_k = (\tau_k)_*\phi$. On the counting input at index zero, where $\mathsf{Z}_{0;(1)}(x) = 1$, this is $(\mathsf{T}_{0;(1)}[x]\,Rf\,\mathbb{I}_{\mathbb{Z}})((N,\infty)) = \sum_{m>N} R(m)f(m)$ for an integer cut $N \geq 0$.

Theorem 6.2 (Shifted inputs)**.** *With* $g_k(y) = \mathsf{Z}_{\nu;t}(\mathbf{c}(y-k))f(y-k)$,

$$(\mathsf{T}_{\nu;t}[\mathbf{c}]\,(Rf\phi))((N,\infty)) = \sum_{k,j} c_{k,j}\,(\mathsf{T}_{j;(1)}[x]\,(g_k\phi_k))((N+k,\infty)).$$

On the counting input at integer cuts $M > N \geq 0$*,*

$$(\mathsf{T}_{0;(1)}[x]\,Rf\,\mathbb{I}_{\mathbb{Z}})((N,M]) = \sum_{k,j} c_{k,j}\,(\mathsf{T}_{j;(1)}[x]\,(\mathrm{Sh}^{-k} f)\,\mathbb{I}_{\mathbb{Z}})((N+k,M+k]),$$

and when the Trailmoments converge individually

$$(\mathsf{T}_{0;(1)}[x]\,Rf\,\mathbb{I}_{\mathbb{Z}})((N,\infty)) = \sum_{k,j} c_{k,j}\,(\mathsf{T}_{j;(1)}[x]\,(\mathrm{Sh}^{-k} f)\,\mathbb{I}_{\mathbb{Z}})((N+k,\infty)).$$

When only the combination converges, the common finite upper cut is kept and the limit is taken in the combination. For $f = \mathbf{1}$, $\sum_k c_{k,1} = 0$ and an integer $m_0 \geq 1$, with the index-one Trailmoments regularized,

$$\begin{aligned}(\mathsf{T}_{0;(1)}[x]\, R\, \mathbb{I}_{\mathbb{Z}})((m_0-1,\infty)) &= \sum_{k,s} c_{k,s}\, (\mathsf{T}_{s;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((m_0-1+k,\infty)) \\ &= \sum_{s\geq 2}\sum_{k} c_{k,s}\, (\mathsf{T}_{s;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((m_0-1+k,\infty)) - \sum_{k} c_{k,1}\, (\mathsf{T}_{1;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((0, m_0-1+k]) \\ &= \int_0^\infty \Big[\sum_{k,s} \frac{c_{k,s}}{\Gamma(s)} u^{s-1} e^{-ku}\Big] \frac{e^{-(m_0-1)u}}{e^u-1}\, du.\end{aligned}$$

Theorem 6.3 (Common cut and heads)**.** *For a common cut $N' \geq N + k_{\max}$,*

$$\begin{aligned}(\mathsf{T}_{j;(1)}[x]\, (\mathrm{Sh}^{-k} f)\mathbb{I}_{\mathbb{Z}})((N+k,\infty)) &= (\mathsf{T}_{j;(1)}[x]\, (\mathrm{Sh}^{-k} f)\mathbb{I}_{\mathbb{Z}})((N',\infty)) \\ &\quad + (\mathsf{T}_{j;(1)}[x]\, (\mathrm{Sh}^{-k} f)\mathbb{I}_{\mathbb{Z}})((N+k,N']),\end{aligned}$$

the head being $\sum_{N+k<\ell\leq N'} \ell^{-j} f(\ell-k)$ (Proposition 5.3). For $R = -g'$ with $g(a) = \sum_{h,s} c_{h,s}(a+h)^{-s} = O(a^{-2})$ and $C_s = \sum_h c_{h,s}$, under individual convergence,

$$\begin{aligned}(\mathsf{T}_{0;(1)}[x]\, (-g')f\, \mathbb{I}_{\mathbb{Z}})((N,\infty)) &= \sum_{s} s\, C_s\, (\mathsf{T}_{s+1;(1)}[x]\, f\, \mathbb{I}_{\mathbb{Z}})((N',\infty)) \\ &\quad + \sum_{h,s} s\, c_{h,s}\, (\mathsf{T}_{s+1;(1)}[x]\, (\mathrm{Sh}^{-h} f - f)\, \mathbb{I}_{\mathbb{Z}})((N',\infty)) \\ &\quad + \sum_{h,s} s\, c_{h,s}\, (\mathsf{T}_{s+1;(1)}[x]\, (\mathrm{Sh}^{-h} f)\, \mathbb{I}_{\mathbb{Z}})((N+h,N']).\end{aligned}$$

Theorem 6.4 (Pole columns are a rational difference quotient)**.** *Let $R(t) = \sum_{k=0}^{k_{\max}} \sum_{s=1}^{w} c_{k,s}(t+k)^{-s}$ with coefficients in a subfield $\mathbb{K}$ of $\mathbb{C}$, $C_s = \sum_k c_{k,s}$, and $H(t) = \sum_{k,s} c_{k,s} \sum_{j=0}^{k-1} (t+j)^{-s}$, a rational function with coefficients in $\mathbb{K}$. Then*

$$R(t) = \sum_{s=1}^{w} C_s t^{-s} + \Delta H(t),$$

and $R(t) = O(t^{-2})$ exactly when $C_1 = 0$. Conversely a difference ΔH of a proper rational function with poles on the nonpositive integer lattice has every column sum zero; modulo such differences, the rational words of maximum order w have the basis $t^{-1}, \ldots, t^{-w}$, and those that are $O(t^{-2})$ the basis $t^{-2}, \ldots, t^{-w}$. If the poles fall in several cosets of $\mathbb{Z}$, each coset has its own columns.

Theorem 6.5 (Summation by parts with a live input)**.** *Let H be a function on the integers above N and f a density on them.*

(i) $\Delta(Hf)(m) = \Delta H(m) f(m) + H(m+1)\Delta f(m)$, *so at finite cuts $M > N$*

$$\sum_{N<m\leq M} \Delta H(m) f(m) = H(M+1)f(M+1) - H(N+1)f(N+1) - \sum_{N<m\leq M} H(m+1)\Delta f(m).$$

(ii) If the upper boundary vanishes and the series converges, $\sum_{m>N} \Delta H(m) f(m) = -H(N+1)f(N+1) - \sum_{m>N} H(m+1)\Delta f(m)$.

(iii) For a Trailmoment read as a function of its cut, $\Delta\,(\mathsf{T}_{p;(1)}[x]\,g\,\mathbb{I}_{\mathbb{Z}})((m,\infty)) = -(m+1)^{-p}g(m+1)$ *(Proposition 5.3), and hence*

$$\sum_{m>N}\Delta H(m)\,(\mathsf{T}_{p;(1)}[x]\,g\,\mathbb{I}_{\mathbb{Z}})((m,\infty)) \\ = -H(N+1)\,(\mathsf{T}_{p;(1)}[x]\,g\,\mathbb{I}_{\mathbb{Z}})((N+1,\infty)) + (\mathsf{T}_{p;(1)}[x]\,Hg\,\mathbb{I}_{\mathbb{Z}})((N+1,\infty)),$$

with one fewer Trailmoment in the input.

(iv) With R, C_s, H *as in Theorem 6.4 and the index-one Trailmoment regularized (Definition 5.2),*

$$\lim_{M\to\infty}\Big((\mathsf{T}_{0;(1)}[x]\,R\,\mathbb{I}_{\mathbb{Z}})((N,N+M]) - C_1\log M\Big) = \sum_{s=1}^{w} C_s\,(\mathsf{T}_{s;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((N,\infty)) - H(N+1);$$

when $C_1 = 0$*, that is when* $R = O(t^{-2})$*, the left side is* $(\mathsf{T}_{0;(1)}[x]\,R\,\mathbb{I}_{\mathbb{Z}})((N,\infty))$ *and the sum starts at* $s = 2$*. For a general density* f*, when the terms converge and the upper boundary vanishes,*

$$(\mathsf{T}_{0;(1)}[x]\,Rf\,\mathbb{I}_{\mathbb{Z}})((N,\infty)) = \sum_{s=1}^{w} C_s\,(\mathsf{T}_{s;(1)}[x]\,f\,\mathbb{I}_{\mathbb{Z}})((N,\infty)) \\ - H(N+1)f(N+1) - \sum_{m>N} H(m+1)\Delta f(m).$$

Theorem 6.6 (Translation and the terminating descent)**.** *For the counting input, each inner Trailmoment below is read at its displayed running cut.*

(i) $(\mathsf{T}_{p;(1)}[x]\,g\,\mathbb{I}_{\mathbb{Z}})((y-k,\infty)) = (\mathsf{T}_{p;(1)}[x]\,g\,\mathbb{I}_{\mathbb{Z}})((y,\infty)) + (\mathsf{T}_{p;(1)}[x]\,g\,\mathbb{I}_{\mathbb{Z}})((y-k,y])$*, the head being* $\sum_{a=0}^{k-1}(y-a)^{-p}g(y-a)$ *(Proposition 5.3).*

(ii)

$$(\mathsf{T}_{j;(1)}[x]\,\big[x\mapsto(\mathsf{T}_{p;(1)}[x]\,g\,\mathbb{I}_{\mathbb{Z}})((x-k,\infty))\big]\,\mathbb{I}_{\mathbb{Z}})((N+k,\infty)) \\ = (\mathsf{T}_{j;(1)}[x]\,\big[x\mapsto(\mathsf{T}_{p;(1)}[x]\,g\,\mathbb{I}_{\mathbb{Z}})((x,\infty))\big]\,\mathbb{I}_{\mathbb{Z}})((N+k,\infty)) \\ + \sum_{a=0}^{k-1}(\mathsf{T}_{p;(1)}[x]\,(x+a)^{-j}g\,\mathbb{I}_{\mathbb{Z}})((N+k-a,\infty)).$$

(iii) For positive integers p, j*, each product* $z^{-p}(z+a)^{-j}$ *has finite rational partial fractions with poles at* 0 *and* $-a$ *only. The recursion therefore terminates on every finite nest of Trailmoments of the counting input, each taking the next as a function of its cut: it returns finitely many such nests, finite shifted copies of* g *and their heads, keeps the selected cuts, lowers at each correction the number of Trailmoments nested in the remaining input, and uses only rational operations on the pole data.*

(iv) If $R(-L-t) = -R(t)$*, then* $\sum_k c_{k,j} = 0$ *for every even* j*, and for a density* f *that is a nest of* d *Trailmoments of the counting input, at a common cut* C*,*

$$(\mathsf{T}_{0;(1)}[x]\,Rf\,\mathbb{I}_{\mathbb{Z}})((N,\infty)) = \sum_{j}\Big(\sum_{k} c_{k,j}\Big)(\mathsf{T}_{j;(1)}[x]\,f\,\mathbb{I}_{\mathbb{Z}})((C,\infty)) + E_d,$$

with E_d a sum of terms with at most d nested Trailmoments, so the terms with $d+1$ nested Trailmoments carry only odd outer indices, starting at three when $\sum_k c_{k,1} = 0$. For $f = \mathbf{1}$, an integer $m_0 \geq 1$ and $R(-k_{\max} - t) = -R(t)$, $c_{k_{\max}-k,s} = -(-1)^s c_{k,s}$, and at every even index s the Trailmoments combine into the finite sum

$$\sum_k c_{k,s}\Big[(\mathsf{T}_{s;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((m_0 - 1 + k, \infty)) - (\mathsf{T}_{s;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((m_0 - 1, \infty))\Big] \\ = -\sum_k c_{k,s}\,(\mathsf{T}_{s;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((m_0 - 1, m_0 - 1 + k]).$$

Proposition 6.7 (Zamma kernels and general measures)**.** *For counting measure the product rule applies to the kernel times the density, $g(m) = \mathsf{Z}_{\nu;t}(\mathbf{c}(m))f(m)$, with $\Delta g(m) = \mathsf{Z}_{\nu;t}(\mathbf{c}(m+1))\Delta f(m) + f(m)\Delta[\mathsf{Z}_{\nu;t}(\mathbf{c}(m))]$. For a general measure μ restricted to $(N, M]$, $\int \Delta H\, g\, d\mu_{N,M} = \int H\, d\big((\tau_1)_*(g\mu_{N,M}) - g\mu_{N,M}\big)$.*

6.1 Live inputs

Theorem 6.8 (A Breta input with a recurrence of finite order)**.** *For $\operatorname{Re} a, \operatorname{Re} b > 0$, real $q_i < 1$ with $q_i \neq 0$, and $s_i \in \mathbb{C}$, let*

$$f(m) = \int_0^1 x^{m+a-1}(1-x)^{b-1} \prod_{i=1}^{r} (1 - q_i x)^{-s_i}\, dx \qquad (m \geq 0).$$

For $\operatorname{Re} s_i > 0$ this is a Breta in which m sits in the shape index: on the bunch $\{1, 2\}$ with the shape $u = (x, 1-x)$, the kernel terms ρu_1 and ρu_2 with unit coefficients and the letters $P_i(\rho, u) = \rho\big((1-q_i)u_1 + u_2\big)$, Proposition 3.6 at the scale index $1 + |\mathbf{s}|$ gives

$$f(m) = \Gamma(1 + |\mathbf{s}|)\, \mathsf{B}^{\mathcal{P}}_{((m+a,\,b),\,\mathbf{s}),\,(1+|\mathbf{s}|,\,\mathbf{s});\,(\widetilde{\pi},\widetilde{\ell})}(\mathbf{g} \oplus \mathbf{C}).$$

Then $f(m) = O(m^{-\operatorname{Re} b})$, and with $Q = \prod_i (1 - q_i x)$, $Q_i = Q/(1 - q_i x)$ and

$$B_m(x) = \big[(m+a)(1-x) - bx\big]Q(x) + x(1-x)\sum_i (s_i - 1) q_i Q_i(x) = \sum_{\ell=0}^{r+1} B_\ell(m) x^\ell,$$

the density obeys $\sum_{\ell=0}^{r+1} B_\ell(m) f(m+\ell) = 0$, with $B_0(m) = m + a$ and $B_{r+1}(m) = (-1)^{r+1}(\prod_i q_i)(m + a + b + r - \sum_i s_i)$. If $a + b + r - \sum_i s_i \notin -\mathbb{N}$, both extreme coefficients are nonzero for every $m \geq 0$, and all shifts reduce to $(f(m), \ldots, f(m+r))$ with coefficients rational in m.

Theorem 6.9 (A fixed set of input-dependent evaluations)**.** *With f, a, b, r, q_i and s_i as in Theorem 6.8, write in this statement $Q(x) = \prod_i (1 - q_i x)$, $C(x) = (1-x)Q(x)$, $\eta(x) = x^{a-1}(1-x)^{b-1}\prod_i (1 - q_i x)^{-s_i}$ and*

$$B(x) = \big[a(1-x) - bx\big]Q(x) + x(1-x)\sum_i (s_i - 1)\, q_i\, \frac{Q(x)}{1 - q_i x},$$

so that $(xC\eta)' = B\eta$; let B_ℓ, C_ℓ and Q_ℓ be the coefficients of x^ℓ.

(i) For each maximum index A, every shift reduces to $f(N+1),\dots,f(N+r+1)$ and the Trailmoments $(\mathsf{T}_{p;(1)}[x+k]\,f\,\mathbb{I}_{\mathbb{Z}})((N,\infty)) = \sum_{m>N} f(m)(m+k)^{-p}$, $1\le p\le A$, $0\le k\le r$, together with $(\mathsf{T}_{p;(1)}[x+a]\,f\,\mathbb{I}_{\mathbb{Z}})((N,\infty))$ when a is an integer at least $r+1$.

(ii) For $k\ge r+1$ and $p\ge 2$,

$$\sum_{\ell=0}^{r+1}(B_\ell - kC_\ell)\,(\mathsf{T}_{p;(1)}[x+k-\ell]\,f\,\mathbb{I}_{\mathbb{Z}})((N,\infty)) + \sum_{\ell=0}^{r+1} C_\ell\,(\mathsf{T}_{p-1;(1)}[x+k-\ell]\,f\,\mathbb{I}_{\mathbb{Z}})((N,\infty))$$
$$= \sum_{\ell=0}^{r+1}\sum_{v=1}^{\ell}\Big[\frac{B_\ell - kC_\ell}{(N+v+k-\ell)^p} + \frac{C_\ell}{(N+v+k-\ell)^{p-1}}\Big]f(N+v),$$

and at $p=1$,

$$\sum_{\ell=0}^{r+1}(B_\ell - kC_\ell)\,(\mathsf{T}_{1;(1)}[x+k-\ell]\,f\,\mathbb{I}_{\mathbb{Z}})((N,\infty))$$
$$= \sum_{\ell=0}^{r+1}\sum_{v=1}^{\ell}\frac{B_\ell - kC_\ell}{N+v+k-\ell}f(N+v) - \sum_{\ell=0}^{r} Q_\ell f(N+1+\ell).$$

(iii) Cuts move by $(\mathsf{T}_{p;(1)}[x+k]\,f\,\mathbb{I}_{\mathbb{Z}})((N+1,\infty)) = (\mathsf{T}_{p;(1)}[x+k]\,f\,\mathbb{I}_{\mathbb{Z}})((N,\infty)) - f(N+1)/(N+1+k)^p$ (Proposition 5.3).

(iv) For rational data, if c_* clears the coefficients of B, C and Q, then $d^A_{N+J}\prod_{r+1\le k\le J,\ k\ne a}|c_*(a-k)|^A$ clears all shifts through J and indices through A.

Theorem 6.10 (The row of a rational function against an input with a recurrence)**.** *Let f be a density on the integers $m>N$, $N\in\mathbb{Z}$, with $\sum_{m>N}|f(m)|(1+|m|)^d<\infty$, that satisfies $\sum_{i=0}^{\tau} p_i(m)\,f(m+i)=0$ for every integer $m>N$, with $\tau\ge 1$ and $p_i\in\mathbb{Z}[m]$ of degree at most d. Let $u\ge 1$ be an integer and $h_*\in\frac{1}{u}\mathbb{Z}$ with $N+1+h_*>0$. In this statement write, for integers $s\ge 1$, $r\ge 0$ and $h\in h_*+\mathbb{N}$,*

$$T_s(h) = (\mathsf{T}_{s;(1)}[x+h]\,f\,\mathbb{I}_{\mathbb{Z}})((N,\infty)) = \sum_{m>N}\frac{f(m)}{(m+h)^s},$$
$$M_r = (\mathsf{T}_{-r;(1)}[x]\,f\,\mathbb{I}_{\mathbb{Z}})((N,\infty)) = \sum_{m>N} m^r f(m).$$

(i) For a rational function $R(m) = P(m) + \sum_{h,s} c_{h,s}(m+h)^{-s}$, P a polynomial of degree at most d and finitely many $h\in h_*+\mathbb{N}$, $\sum_{m>N} R(m)f(m) = \sum_r([m^r]P)\,M_r + \sum_{h,s} c_{h,s}\,T_s(h)$: one coordinate for each index and shift.

(ii) Let $J\ge\tau$ with $p_0(-h_*-j)\ne 0$ for $\tau\le j\le J$. Then for $s\ge 1$ and $\tau\le j\le J$, $T_s(h_*+j)$ is a rational combination of the $T_{s'}(h_*+i)$, $1\le s'\le s$, $0\le i<\tau$, of the moments M_r, $0\le r\le d-1$, and of the values $f(N+1),\dots,f(N+\tau)$.

(iii) For every $w\ge 1$ the coefficients of (ii) of all the $T_s(h_*+j)$, $1\le s\le w$, $\tau\le j\le J$, are cleared by

$$d^w_{u(N+h_*+J)}\prod_{j=\tau}^{J}\big|u^d p_0(-h_*-j)\big|^w.$$

A rational function with poles in several cosets of $\mathbb{Z}$ takes one such reduction for each coset.

Theorem 6.9 is the case of the Breta input of Theorem 6.8, read through its differential equation; here the input is any density with a recurrence, the live inputs of the closings along a ray among them (Theorem 43.1). The clearing has two parts: the heads released by the moves of the cut, cleared by a power of d_n on the scale u of the coset, and the values of the first coefficient of the recurrence at the shifts used, raised to the power of the index, which along a ray is the frame of the recurrence (Proposition 38.11).

Theorem 6.11 (A Gramma input with a recurrence of finite order)**.** *Let a one-scale configuration t have positive integer exponents with greatest exponent L, the term at exponent L present. For $\lambda, c > 0$ put $g(m) = \mathsf{G}_{\lambda+m;t}(\boldsymbol{\xi})/\Gamma(c+m)$. Then*

$$(m+\lambda)g(m) = \sum_k t_k \xi_k (m+c)_{t_k}\, g(m+t_k),$$

a shift relation of order L, the exchange relation of the Gramma (Theorem 2.4(ii)) divided by $\Gamma(c+m)$; for $L \geq 2$, $\log g(m) \leq -(1-1/L)m\log m + O(m)$, so g decays faster than every inverse power.

Part II

Tables and families

Chapter 7

Tables

7.1 Characters, tables, lists

Definition 7.1 (Characters, tables, lists)**.** The *characters* are a finite set $\mathcal{E}$, whose elements are the *marks*; each mark e carries a positive variable α_e, and its name carries nothing. A *table* on $\mathcal{E}$ is a nonempty family $\mathcal{B}$ of r-element subsets of $\mathcal{E}$, the *bases*, with the *exchange property*: for bases T, T' and $a \in T \setminus T'$ there is $b \in T' \setminus T$ with $(T \setminus \{a\}) \cup \{b\}$ a basis. Each basis carries a weight $\theta_T > 0$; r is the *rank* and $r^* = n - r$ the *corank*. A *list* is a table whose weights are all 1; it is specified by its characters and its bases, $(\mathcal{E}, \mathcal{B})$, and by nothing else; for a set S and $0 \le k \le |S|$, $\binom{S}{k}$ is the list on S whose bases are the k-subsets of S. A mark in no basis is a *loop*, a mark in every basis a *coloop*. The *dual table* has the bases $\mathcal{E} \setminus T$ with the weights θ_T. The *Foreman polynomials* of a table are its basis and cobasis polynomials,

$$K(\alpha) = \sum_{T \in \mathcal{B}} \theta_T \, \alpha^T, \qquad \Psi(\alpha) = \sum_{T \in \mathcal{B}} \theta_T \, \alpha^{\mathcal{E} \setminus T} \qquad (\alpha \in \mathbb{R}^{\mathcal{E}}_{>0});$$

$K(\mathbf{1}) = \Psi(\mathbf{1}) = \sum_T \theta_T$ is the total weight. K and Ψ are the two letters of the table (Section 3.2): they enter a family word through powers (Chapter 8). The *table's gauge* is $\alpha = \mathbf{1}$.

A table carries two descriptors of one object, what is there (the bases, read by K) and what is not (their complements, read by Ψ), and the marks on which both sit; any two of these determine the third, and the theory keeps both polynomials at every step.

Proposition 7.2 (One function read twice)**.** *For every table, $\Psi(\alpha) = \alpha^{\mathcal{E}} K(\alpha^{-1})$, and the Foreman polynomials of the dual table are $K^* = \Psi$, $\Psi^* = K$. Inverting the gauge swaps K and Ψ up to the factor $\alpha^{\mathcal{E}}$, and up to scale the gauges fixed by $\alpha \mapsto \alpha^{-1}$ are $\alpha \propto \mathbf{1}$.*

Definition 7.3 (Deletion and contraction)**.** For a mark e and $R = \mathcal{E} \setminus \{e\}$, the *deletion* has the bases $T \not\ni e$ and the *contraction* the bases $T \setminus \{e\}$, $T \ni e$, both on R with the inherited weights; the deletion is a table when e is not a coloop, and the contraction when e is not a loop. With $K_{\setminus e}, \Psi_{\setminus e}$ and $K_{/e}, \Psi_{/e}$ the sums over these bases, a sum without terms being 0,

$$K = K_{\setminus e} + \alpha_e K_{/e}, \qquad \Psi = \alpha_e \Psi_{\setminus e} + \Psi_{/e}.$$

7.2 Circuits and molecules

Definition 7.4 (Independence, circuits, linking, molecules)**.** A set $S \subseteq \mathcal{E}$ is *independent* in a table if it lies in a basis; its *rank* $r(S)$ is the largest size of an independent subset. A *circuit* is a minimal

set that is not independent, and a *cocircuit* is a minimal set that meets every basis. Two marks are *linked* if they lie in a common circuit of some table of a family on $\mathcal{E}$, a finite sequence of tables on $\mathcal{E}$ (Chapter 8). The *molecules* are the smallest nonempty sets of marks that contain, with each mark, every mark linked to it; a molecule with one mark is a *unit*, and the set of molecules is the *polycule*. A family whose marks form more than one molecule is a *compound*.

Definition 7.5 (Minors, restriction, contraction)**.** For disjoint $A, D \subseteq \mathcal{E}$ such that some basis contains A and avoids D, the *minor* contracting A and deleting D is the table on $\mathcal{E} \setminus (A \cup D)$ with the bases $T \setminus A$, $T \supseteq A$, $T \cap D = \varnothing$, and the weights θ_T; deletion and contraction of one mark are the minors with $D = \{e\}$ and with $A = \{e\}$. For $X \subseteq \mathcal{E}$ the *restriction* $\mathcal{B}|X$ is the table on X with the bases $T \cap X$, $|T \cap X| = r(X)$, and the *contraction* $\mathcal{B}/X$ is the table on $\mathcal{E} \setminus X$ with the bases $T \setminus X$ of the same T; when the weights of these T factor as $\theta_T = \theta'_{T\cap X}\theta''_{T\setminus X}$, $\mathcal{B}|X$ and $\mathcal{B}/X$ carry θ' and θ''. When e is not a loop, $\mathcal{B}/\{e\}$ is the contraction of e (Definition 7.3); at a loop $\mathcal{B}/\{e\}$ is the deletion of e, while $K_{/e} = \Psi_{/e} = 0$.

Proposition 7.6 (Duality of minors)**.** *For a table $(\mathcal{B}, \theta)$ on $\mathcal{E}$ with the dual table $\mathcal{B}^*$ and $X \subseteq \mathcal{E}$, $X' = \mathcal{E} \setminus X$,*

$$(\mathcal{B}|X)^* = \mathcal{B}^*/X', \qquad (\mathcal{B}/X)^* = \mathcal{B}^*|X',$$

the duals taken on X and on X': a basis is at the top of X exactly when its complement is at the top of X' in the dual table. When the weights of the bases at the top of X factor, $\theta_T = \theta'_{T\cap X}\theta''_{T\setminus X}$, the minors of $\mathcal{B}^*$ carry the same weights, $\mathcal{B}^*/X'$ those of $\mathcal{B}|X$ and $\mathcal{B}^*|X'$ those of $\mathcal{B}/X$ on the complemented bases. So $K_{\mathcal{B}^*/X'} = \Psi_{\mathcal{B}|X}$, $\Psi_{\mathcal{B}^*/X'} = K_{\mathcal{B}|X}$, $K_{\mathcal{B}^*|X'} = \Psi_{\mathcal{B}/X}$ and $\Psi_{\mathcal{B}^*|X'} = K_{\mathcal{B}/X}$.

Lemma 7.7 (Linking read on the bases)**.** *Marks $e \neq f$ lie in a common circuit of a table exactly when some basis T has $e \in T$, $f \notin T$ and $(T \setminus \{e\}) \cup \{f\}$ a basis.*

Lemma 7.8 (The circuit lemma)**.** *If $w \in \mathbb{R}^{\mathcal{E}}$ has $\langle w, \mathbf{1}_T\rangle$ constant over the bases of a table, then $w_a = w_b$ for any two marks a, b linked by a circuit of that table. If $\langle w, \mathbf{1}_T\rangle$ is constant over the bases of every table of a family, w is constant on every molecule.*

Proposition 7.9 (Molecules split every table)**.** *Each molecule is a union of molecules of every table, those of a table being the molecules of that table alone, and every table is the* direct sum *of its restrictions to the molecules: its bases are exactly the unions of one basis of each restriction. When the weights factor across the molecules, $\theta_T = \prod_M \theta_M(T \cap \mathcal{E}_M)$, as they do for a list, the Foreman polynomials factor, $K(\alpha) = \prod_M K_M(\alpha_{\mathcal{E}_M})$ and $\Psi(\alpha) = \prod_M \Psi_M(\alpha_{\mathcal{E}_M})$.*

Lemma 7.10 (Unions of molecules)**.** *For a table on $\mathcal{E}$ of rank r and $S \subseteq \mathcal{E}$ the following are equivalent: (a) $r(S) + r(\mathcal{E} \setminus S) = r$; (b) every basis meets S in the same number of marks; (c) S is a union of molecules of the table (Definition 7.4).*

Theorem 7.11 (The Foreman polynomials of a linked table do not factor)**.** *If the circuits of a table link all of its $n \geq 2$ marks, then K and Ψ are irreducible polynomials.*

7.3 The Skeleton

Definition 7.12 (Skeleton counts)**.** The *cocircuit layer* of a table is its set of cocircuits and the *circuit layer* its set of circuits; the two layers together are the table's *Skeleton*. For $S \subseteq \mathcal{E}$, with $r^*(S) = |S| + r(\mathcal{E} \setminus S) - r$ the dual rank,

$$d(S) = |S| - r^*(S), \qquad d^*(S) = |S| - r(S), \qquad c(S) = |S| - d(S) - d^*(S), \qquad \varepsilon(S) = d(S) - d^*(S) :$$

$c(S)$ is the *width* and $\varepsilon(S)$ the *slant* of S.

Theorem 7.13 (The window)**.** *For every $S \subseteq \mathcal{E}$: $d(S) = \min_T |T \cap S|$, $d^*(S) = \min_T |S \setminus T|$, $r(S) = \max_T |T \cap S|$, and $\{|T \cap S| : T \in \mathcal{B}\} = \{d(S), d(S)+1, \dots, r(S)\}$. Hence $c(S) = r(S) - d(S)$ is the width of this window. Moreover $c(\mathcal{E} \setminus S) = c(S)$ and $\varepsilon(S) + \varepsilon(\mathcal{E} \setminus S) = 2r - n$.*

The number of marks of S that a basis occupies ranges over a window of consecutive integers; its floor is $d(S)$, its width is the width $c(S)$, and the same window read on the complements has the floor $d^*(S)$. Every count that the integrals of a family need is read from these two layers.

Definition 7.14 (Signed indicators and the centred polynomial)**.** For $T \subseteq \mathcal{E}$ the *signed indicator* is $\chi_T = \mathbf{1}_T - \mathbf{1}_{\mathcal{E}\setminus T}$. For $\alpha = e^{2z}$ the *centred polynomial* is

$$\Lambda(z) = \sum_{T \in \mathcal{B}} \theta_T \, e^{\langle z, \chi_T \rangle}.$$

Theorem 7.15 (One function, two Foreman polynomials)**.** *For $\alpha = e^{2z}$:*

(i) $K(\alpha) = e^{\langle \mathbf{1}, z \rangle} \Lambda(z)$ and $\Psi(\alpha) = e^{\langle \mathbf{1}, z \rangle} \Lambda(-z)$;

(ii) the dual table has the centred polynomial $\Lambda^*(z) = \Lambda(-z)$: duality and inversion of the gauge are $z \mapsto -z$;

(iii) for every $v \in \mathbb{R}^{\mathcal{E}}$ constant on each molecule of the table alone, with value v_M on the molecule M, $\langle v, \chi_T \rangle = \sum_M v_M (2r(M) - |M|)$ for every basis and

$$\Lambda(z + v) = \exp\Big(\sum_M v_M \big(2r(M) - |M|\big) \Big) \Lambda(z);$$

these are the only v for which $\Lambda(z + \lambda v)/\Lambda(z)$ does not depend on z for every λ, and at $v = \lambda \mathbf{1}$ the factor is $e^{\lambda(2r-n)}$.

Theorem 7.16 (The inner moment generating function)**.** *For a gauge $\alpha = e^{2z}$ the* basis law *and the* cobasis law *at α are the laws on $\mathcal{B}$*

$$\mathbb{P}_\alpha(T) = \frac{\theta_T \alpha^T}{K(\alpha)} = \frac{\theta_T e^{\langle z, \chi_T \rangle}}{\Lambda(z)}, \qquad \mathbb{P}^*_\alpha(T) = \frac{\theta_T \alpha^{\mathcal{E}\setminus T}}{\Psi(\alpha)} = \mathbb{P}_{\alpha^{-1}}(T).$$

Then

$$\frac{\Lambda(z+w)}{\Lambda(z)} = \mathbb{E}_{T \sim \mathbb{P}_\alpha}\big[e^{\langle w, \chi_T \rangle}\big], \qquad \nabla \log \Lambda(z) = \mathbb{E}_{T \sim \mathbb{P}_\alpha}[\chi_T] = 2R(\alpha) - \mathbf{1},$$

where $R_e(\alpha) = \alpha_e \partial_e \log K(\alpha) = \mathbb{P}_\alpha(e \in T)$ is the occupation*, and the derivatives of $\log \Lambda$ of order k at z are the joint cumulants of order k of χ_T under $\mathbb{P}_\alpha$. The* even *and* odd statistics *$E(z) = \log \Lambda(z) + \log \Lambda(-z)$ and $O(z) = \log \Lambda(z) - \log \Lambda(-z)$ satisfy $e^{E(z)} = K\Psi/\alpha^{\mathcal{E}}$, $e^{O(z)} = K/\Psi$, and, for every $w \in \mathbb{R}^{\mathcal{E}}$,*

$$e^{E(z+w)} = e^{E(z)} \, \mathbb{E}_{(T,T') \sim \mathbb{P}_\alpha \otimes \mathbb{P}^*_\alpha}\big[e^{\langle 2w, \mathbf{1}_T - \mathbf{1}_{T'} \rangle}\big] :$$

$E(z + \cdot) - E(z)$ is the cumulant generating function of $\chi_T - \chi_{T'}$ for independent $T \sim \mathbb{P}_\alpha$ and $T' \sim \mathbb{P}^*_\alpha$; at the table's gauge $e^{E(0)} = K(\mathbf{1})^2$. For table j of a family the two laws at α are $\mathbb{P}_{j,\alpha}$ and $\mathbb{P}^*_{j,\alpha} = \mathbb{P}_{j,\alpha^{-1}}$, the occupation is $R_j(\alpha)$, and the dual occupation *$R^*_j(\alpha)$, with $R^*_{j,e}(\alpha) = \mathbb{P}^*_{j,\alpha}(e \notin T) = 1 - R_{j,e}(\alpha^{-1})$, is the occupation of the dual table. At the table's gauge the two laws coincide, $\mathbb{P}^*_{j,\mathbf{1}} = \mathbb{P}_{j,\mathbf{1}}$.*

The centred polynomial is a moment generating function: its terms at z, divided by $\Lambda(z)$, are the law of a random basis, and its logarithm generates the cumulants of the signed indicator. The basis law and the cobasis law at a gauge are one law read at α and at α^{-1}, and at every gauge the product of the two evaluations generates the difference of a basis drawn from the basis law and an independent basis drawn from the cobasis law.

Definition 7.17 (Weight law, indicators, levels, cumulants)**.** The *weight law* of table j is its basis law at the table's gauge, $\mathbb{P}_{j,\mathbf{1}}(T) = \theta_{j,T}/K_j(\mathbf{1})$ on $\mathcal{B}_j$; for a list it is uniform. For a random basis T the *indicators* are $X_e = \mathbf{1}[e \in T]$, and for a set C of marks the *level* is $N_C = |T \cap C| = \sum_{e\in C} X_e$. For functions $Y_1, \dots, Y_k$ of T, $\kappa_{j,\alpha}(Y_1, \dots, Y_k)$ is their joint cumulant under $\mathbb{P}_{j,\alpha}$, and $Y^{\times a}$ in its argument lists Y a times; along a string $w = (e_1, \dots, e_k)$ of marks, $\kappa_{j,\alpha}(w) = \kappa_{j,\alpha}(X_{e_1}, \dots, X_{e_k}) = \partial_{y_{e_1}} \cdots \partial_{y_{e_k}} \log K_j(e^y)$ at $y = \log \alpha$. With one table the index j is dropped: $\mathbb{P}_\alpha$, $R(\alpha)$, κ_α.

Theorem 7.18 (The Skeleton is the Newton data of Λ)**.** *For every $S \subseteq \mathcal{E}$ the values $\langle \mathbf{1}_S, \chi_T \rangle$, $T \in \mathcal{B}$, fill $\{2j - |S| : \ d(S) \le j \le r(S)\}$. The Newton polytope of Λ is $2P - \mathbf{1}$ with $P = \operatorname{conv}\{\mathbf{1}_T\}$ the base polytope; its width in the direction $\mathbf{1}_S$ is $2c(S)$ and the midpoint of its extent in that direction is $\varepsilon(S)$.*

Proposition 7.19 (Loops and coloops)**.** *If e is a loop, $\Lambda(z) = e^{-z_e}\Lambda'(z|_{\mathcal{E}\setminus e})$ with Λ' the centred polynomial of the same bases on $\mathcal{E} \setminus e$; if e is a coloop, $\Lambda(z) = e^{z_e}\Lambda'(z|_{\mathcal{E}\setminus e})$ with Λ' that of the bases $T \setminus e$.*

7.4 Multivectors of any tensor rank

Definition 7.20 (Multivectors and tensor rank)**.** Let $\mathbb{F}$ be $\mathbb{R}$ or $\mathbb{C}$. A *multivector* of a table of rank r is an $\boldsymbol{\omega} \in \bigwedge^r \mathbb{F}^{\mathcal{E}}$ with $|\boldsymbol{\omega}_T|^2 = \theta_T$ for $T \in \mathcal{B}$ and $\boldsymbol{\omega}_T = 0$ otherwise; $\boldsymbol{\omega}_T = \sqrt{\theta_T}$ is one. Its *tensor rank* $\operatorname{rk}(\boldsymbol{\omega})$ is the least number of decomposable elements of $\bigwedge^r \mathbb{F}^{\mathcal{E}}$ with sum $\boldsymbol{\omega}$, written $\boldsymbol{\omega} = \sum_{k=1}^{\operatorname{rk}(\boldsymbol{\omega})} \boldsymbol{\omega}^{(k)}$, $\boldsymbol{\omega}^{(k)}_T = \det A^{(k)}_T$ with *slices* $A^{(k)} \in \mathbb{F}^{r\times n}$. The table is *tensorminental of tensor rank q* over $\mathbb{F}$ when q is the least tensor rank of its multivectors, and *determinantal* when $q = 1$. The *dual multivector* is the Hodge complement $\boldsymbol{\omega}^* \in \bigwedge^{n-r} \mathbb{F}^{\mathcal{E}}$, $|\boldsymbol{\omega}^*_{\mathcal{E}\setminus T}| = |\boldsymbol{\omega}_T|$, and $\operatorname{rk}(\boldsymbol{\omega}^*) = \operatorname{rk}(\boldsymbol{\omega})$.

Every table has multivectors, and every multivector has a tensor rank; tensor rank one, the determinantal case, is where a single matrix carries the table, and it is one case of the statements on multivectors, which hold at every tensor rank.

Proposition 7.21 (The letters of a tensorminental table)**.** *For a decomposition $\boldsymbol{\omega} = \sum_k \boldsymbol{\omega}^{(k)}$ into decomposable elements with slices $A^{(k)}$ and $D = \operatorname{diag}(\alpha)$,*

$$K(\alpha) = \sum_{k,l} \det\left(A^{(k)} D A^{(l)\mathsf{H}}\right) = \mathbf{1}^{\mathsf{H}} \mathbf{G}(\alpha) \mathbf{1}, \qquad \mathbf{G}_{kl}(\alpha) = \det\left(A^{(k)} D A^{(l)\mathsf{H}}\right),$$

and Ψ is the same expression for the slices of the dual multivector. $\mathbf{G}(\alpha)$ is the Gram matrix of the $\boldsymbol{\omega}^{(k)}$ for $\langle \eta, \xi \rangle_\alpha = \sum_T \alpha^T \eta_T \overline{\xi_T}$, Hermitian and positive semidefinite.

Theorem 7.22 (Tensor rank is hereditary)**.** *For disjoint $A, D \subseteq \mathcal{E}$ with A extending to a basis avoiding D, $\boldsymbol{\omega}_{A|D} := (\mathbf{e}_A \lrcorner \boldsymbol{\omega})|_{\mathcal{E}\setminus(A\cup D)}$, the restriction of the interior product of $\boldsymbol{\omega}$ with the wedge $\mathbf{e}_A$ of the unit vectors of the marks of A, $(\mathbf{e}_A \lrcorner \boldsymbol{\omega})_X = \pm \boldsymbol{\omega}_{X\cup A}$, is a multivector of the minor that contracts A and deletes D, with the weight $\theta_{X\cup A}$ on each basis X of the minor, and $\operatorname{rk}(\boldsymbol{\omega}_{A|D}) \le \operatorname{rk}(\boldsymbol{\omega})$.*

Theorem 7.23 (The pattern law of a tensorminental table is a finite interference)**.** *Let the table have a multivector of tensor rank q with slices $A^{(1)},\dots,A^{(q)}$, let $B\subseteq\mathcal{E}$ and $R=\mathcal{E}\setminus B$, and let α be a gauge at which every $M_{kl}=A^{(k)}D_\alpha A^{(l)\mathsf{H}}$, $D_\alpha=\operatorname{diag}(\alpha)$, with $\mathbf{G}_{kl}\not\equiv 0$ is invertible; pairs with $\mathbf{G}_{kl}\equiv 0$ as a polynomial in the gauge are omitted (Proposition 7.21). For $x\in\mathbb{C}^B$, with $x\circ\alpha_B=(x_e\alpha_e)_{e\in B}$,*

$$\mathbb{E}_{T\sim\mathbb{P}_\alpha}\Big[\prod_{e\in B}x_e^{\mathbf{1}[e\in T]}\Big]=\frac{K(x\circ\alpha_B,\alpha_R)}{K(\alpha)}=\sum_{k,l}w_{kl}\det\big(I+(D_x-I)\Pi^{(kl)}_{BB}\big),$$

where $\mathbb{P}_\alpha$ is the basis law at α, $D_x=\operatorname{diag}(x)$, $w_{kl}=\mathbf{G}_{kl}(\alpha)/K(\alpha)$ and $\Pi^{(kl)}=A^{(l)\mathsf{H}}M_{kl}^{-1}A^{(k)}D_\alpha$. Here $\sum_{k,l}w_{kl}=1$, $w_{lk}=\overline{w_{kl}}$, every $\Pi^{(kl)}$ is idempotent, and $\Pi^{(kk)}$ is the D_α-orthogonal projection onto the row space of $A^{(k)}$. The hypothesis holds off a proper algebraic set of gauges.

Corollary 7.24 (Moments and cumulants)**.** *In the setting of Theorem 7.23:*

(i) $\mathbb{P}_\alpha(S\subseteq T)=\sum_{k,l}w_{kl}\det\Pi^{(kl)}_{SS}$*;*

(ii) the law of $T\cap B$ is the w-mixture of q^2 determinantal components, whose cumulants are $\kappa^{(kl)}(e)=\Pi^{(kl)}_{ee}$ and, for $p\geq 2$ distinct marks,

$$\kappa^{(kl)}(e_1,\dots,e_p)=(-1)^{p-1}\sum_{\varsigma}\prod_{i=1}^{p}\Pi^{(kl)}_{e_{\varsigma(i)}e_{\varsigma(i+1)}},$$

the sum over the cyclic orders ς of $\{1,\dots,p\}$, with $\varsigma(p+1)=\varsigma(1)$; the joint cumulants κ_α of the indicators $X_e=\mathbf{1}[e\in T]$ under $\mathbb{P}_\alpha$ (Definition 7.17) are their total cumulants over the mixing index: for distinct marks $e_1,\dots,e_p$ of B,

$$\kappa_\alpha(e_1,\dots,e_p)=\sum_{\mathfrak{p}}\kappa_w\Big(\big(\kappa^{(kl)}(e_C)\big)_{C\in\mathfrak{p}}\Big),$$

the sum over the partitions $\mathfrak{p}$ of $\{1,\dots,p\}$ into nonempty blocks, $e_C=(e_c)_{c\in C}$, where for finitely many functions $(Y_i)_{i\in I}$ of the index (k,l)

$$\kappa_w\big((Y_i)_{i\in I}\big)=\sum_{\mathfrak{q}}(-1)^{|\mathfrak{q}|-1}(|\mathfrak{q}|-1)!\prod_{D\in\mathfrak{q}}\sum_{k,l}w_{kl}\prod_{i\in D}Y_i(k,l),$$

the sum over the partitions $\mathfrak{q}$ of I, is their joint cumulant over the index with the mixing coefficients w_{kl}; at one mark this is the occupation $R_e(\alpha)=\sum_{k,l}w_{kl}\Pi^{(kl)}_{ee}$. This is an identity of generating functions, valid for complex mixing coefficients summing to one.

A table with a multivector of tensor rank q reads the law of its patterns as an interference of q^2 determinantal components, mixed with complex coefficients that sum to one. At tensor rank one there is a single component and the mixture is a determinantal law; at every higher tensor rank the joint cumulants over the mixing index of the components' cumulants are the part that no single component carries.

Chapter 8

Families

8.1 The interest and its walls

Definition 8.1 (Family, interest, walls)**.** A *family* on $\mathcal{E}$ is a finite sequence $F = \big((\mathcal{B}_j, \theta_j);\, s_j, t_j\big)_{j=1}^{N}$ of tables on $\mathcal{E}$ with exponents $s_j, t_j \in \mathbb{C}$; $K_j, \Psi_j, \Lambda_j, E_j, O_j$, r_j and $d_j, d_j^*, c_j, \varepsilon_j$ belong to table j. A table is *active* when its exponents are not both zero, and a letter when its exponent is not zero. For *masses* $\mathbf{m} \in \mathbb{C}^{\mathcal{E}}$ the *interest* is

$$J_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \int_{\mathbb{R}^{\mathcal{E}}_{>0}} \alpha^{\mathbf{m}-\mathbf{1}} e^{-|\alpha|} \prod_j K_j(\alpha)^{-s_j} \Psi_j(\alpha)^{-t_j}\, d\alpha,$$

with its slots: the family's tables, the masses $\mathbf{m}$ and the exponents $\mathbf{s} = (s_j)_j$, $\mathbf{t} = (t_j)_j$. The *family word* $W = \prod_j K_j^{-s_j} \Psi_j^{-t_j}$ is homogeneous of degree $-\sum_j (s_j r_j + t_j r_j^*)$, and with the measure $d\alpha_{\mathbf{m}} = \alpha^{\mathbf{m}-\mathbf{1}} d\alpha$ (Definition 1.1(vii)), $J_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \int W\, e^{-|\alpha|} d\alpha_{\mathbf{m}}$. The *pair coordinates* are the *strengths* $\sigma_j = \frac{s_j + t_j}{2}$ and the *leans* $\delta_j = \frac{s_j - t_j}{2}$, with the total strength $\sigma = \sum_j \sigma_j$, so that $s_j = \sigma_j + \delta_j$ and $t_j = \sigma_j - \delta_j$; the *offsets* are $\boldsymbol{\mu} = \mathbf{m} - \sigma \mathbf{1}$. The *walls* and *top walls* are

$$\kappa_S = m_S - \sum_j \big(s_j d_j(S) + t_j d_j^*(S)\big),$$

$$\kappa_S^{\mathrm{top}} = \sum_j \big(s_j r_j(S) + t_j(|S| - d_j(S))\big) - m_S \qquad (\varnothing \neq S \subseteq \mathcal{E}).$$

The *imbalance* is $\kappa_{\mathcal{E}} = m_{\mathcal{E}} - \sum_j (s_j r_j + t_j r_j^*)$, and the *balance wall* is the hyperplane $\kappa_{\mathcal{E}} = 0$. On it the data are fixed by their pair coordinates $(\boldsymbol{\mu}_\perp; \boldsymbol{\sigma}, \boldsymbol{\delta})$, with $\boldsymbol{\mu}_\perp = \boldsymbol{\mu} - \frac{\mu_{\mathcal{E}}}{n}\mathbf{1}$ the projection of the offsets to $\mathbf{1}^\perp$: the exponents are $(\boldsymbol{\sigma} + \boldsymbol{\delta}, \boldsymbol{\sigma} - \boldsymbol{\delta})$ and the masses are the *balanced masses*

$$\mathbf{m}_F(\boldsymbol{\mu}_\perp; \boldsymbol{\sigma}, \boldsymbol{\delta}) = \boldsymbol{\mu}_\perp + \Big(\sigma + \frac{1}{n} \sum_j \delta_j (2r_j - n)\Big)\mathbf{1},$$

linear in $(\boldsymbol{\mu}_\perp; \boldsymbol{\sigma}, \boldsymbol{\delta})$. F is *connected* if every nonempty proper S has $c_j(S) > 0$ for some active table j. A family of one table is named by its table: for a table $\mathcal{A}$ with its weights $\theta^{\mathcal{A}}$, every object of the family $((\mathcal{A}, \theta^{\mathcal{A}}); s, t)$ carries $\mathcal{A}$ in place of F, as $J_{\mathcal{A}}(\mathbf{m}; s, t)$. A table may carry two systems of positive weights, θ^K for its letter K and θ^Ψ for its letter Ψ; at (s, t) it names the family of the two tables $((\mathcal{B}, \theta^K); s, 0)$ and $((\mathcal{B}, \theta^\Psi); 0, t)$, whose word is $K_{\theta^K}^{-s} \Psi_{\theta^\Psi}^{-t}$.

The exponents of a table enter in two coordinates: σ_j, how much the family weighs the table, and δ_j, which side it leans to, toward the bases (K) or toward their complements (Ψ). The pair $(K_j \Psi_j, K_j / \Psi_j)$ carries σ_j and δ_j separately, and the walls are read in either coordinates.

Theorem 8.2 (The interest is a partition function in the pair coordinates)**.** *(i) In the offsets,*

$$J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \int_{\mathbb{R}^{\mathcal{E}}_{>0}} \alpha^{\boldsymbol{\mu}-\mathbf{1}} e^{-|\alpha|} \prod_j \Lambda_j(\tfrac{1}{2}\log\alpha)^{-s_j} \Lambda_j(-\tfrac{1}{2}\log\alpha)^{-t_j}\, d\alpha.$$

(ii) In signed coordinates,

$$J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = 2^n \int_{\mathbb{R}^{\mathcal{E}}} \exp\Big(2\langle\boldsymbol{\mu}, z\rangle - \sum_j \big(\sigma_j E_j(z) + \delta_j O_j(z)\big) - \sum_e e^{2z_e}\Big)\, dz,$$

the partition function of the exponential family with natural parameters $(\boldsymbol{\mu};\sigma_j,\delta_j)$ and sufficient statistics $(2z;-E_j,-O_j)$.

(iii) $\kappa_S = \mu_S + \sum_j \big(\sigma_j\, c_j(S) - \delta_j\, \varepsilon_j(S)\big)$ *and* $\kappa_{\mathcal{E}} = \mu_{\mathcal{E}} - \sum_j \delta_j(2r_j - n)$.

Lemma 8.3 (Greedy bases on a sector)**.** *Let π be a total order of $\mathcal{E}$ with tails $U_k = \{\pi(k),\dots,\pi(n)\}$. There are bases $T^{\pm}_{\pi}$ with $|T^{+}_{\pi}\cap U_k| = d(U_k)$ and $|U_k \setminus T^{-}_{\pi}| = d^*(U_k)$ for all k, and on the sector $H_\pi = \{\alpha_{\pi(1)} \ge \cdots \ge \alpha_{\pi(n)}\}$ every basis has $\alpha^T \le \alpha^{T^+_\pi}$ and $\alpha^{\mathcal{E}\setminus T} \le \alpha^{\mathcal{E}\setminus T^-_\pi}$. For a nonempty set of r-element subsets of $\mathcal{E}$ this conclusion holds exactly when the set has the exchange property.*

The sectors are where the exchange property is used: on each sector one basis dominates every monomial of K and one cobasis every monomial of Ψ, and that is what gives the walls their form. What does not use the exchange property is the opening of every monomial by its shares (Corollary 4.4).

Lemma 8.4 (Cube integrals)**.** *Let $h(q,\lambda)$ be smooth in q near $[0,1]^m$, with every q-derivative continuous in (q,λ) and holomorphic in λ on an open set. Then* $\mathrm{cube}(x,\lambda;h) = \int_{[0,1]^m} \prod_k q_k^{x_k-1} h(q,\lambda)\, dq$*, defined for* $\operatorname{Re} x_k > 0$*, extends meromorphically to $\mathbb{C}^m$, jointly in λ, with poles on the hyperplanes $x_k = -j$, $j\in\mathbb{N}$: with $h = \sum_{j<M} h_j(q',\lambda) q_1^j + q_1^M r_M$,*

$$\mathrm{cube}(x,\lambda;h) = \sum_{j<M} \frac{\mathrm{cube}(x',\lambda;h_j)}{x_1 + j} + \mathrm{cube}\big((x_1+M,x'),\lambda;r_M\big),$$

repeated in each coordinate.

Theorem 8.5 (Existence and continuation)**.** *(i) $J_F(\mathbf{m};\mathbf{s},\mathbf{t})$ converges if and only if* $\operatorname{Re}\kappa_S > 0$ *for every nonempty $S\subseteq\mathcal{E}$, whatever $\mathbf{s},\mathbf{t}\in\mathbb{C}^N$; it is holomorphic there.*

(ii) On that region

$$J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \Gamma(\kappa_{\mathcal{E}}) \sum_\pi \int_{[0,1]^{n-1}} \prod_{k=2}^{n} q_k^{\kappa_{U_k}-1} h_\pi(q)\, dq, \qquad h_\pi = L_\pi^{-\kappa_{\mathcal{E}}} \prod_j k_{j,\pi}^{-s_j} \psi_{j,\pi}^{-t_j},$$

where in the sector coordinates $\alpha_{\pi(1)} = \rho$, $\alpha_{\pi(k)} = \rho q_2\cdots q_k$ one has

$$K_j = \rho^{r_j} \prod_k q_k^{d_j(U_k)} k_{j,\pi}(q), \qquad \Psi_j = \rho^{n-r_j} \prod_k q_k^{d^*_j(U_k)} \psi_{j,\pi}(q), \qquad |\alpha| = \rho L_\pi(q);$$

the sector letters *$k_{j,\pi},\psi_{j,\pi},L_\pi$ have nonnegative coefficients and positive constant terms $\theta_{j,T^+_{j,\pi}}$, $\theta_{j,T^-_{j,\pi}}$, $T^{\pm}_{j,\pi}$ the greedy bases of table j (Lemma 8.3), and* 1*, and $L_\pi \in [1,n]$.*

(iii) $J_F(\mathbf{m};\mathbf{s},\mathbf{t})$ *extends to a meromorphic function of* $(\mathbf{m},\mathbf{s},\mathbf{t})$ *with poles on the hyperplanes* $\kappa_S = -j$, $S \neq \varnothing$, $j \in \mathbb{N}$*; identities valid on an open subset of the region persist.*

Corollary 8.6 (Past several walls at once)**.** *For an order* π *write* $\kappa_k = \kappa_{U_k}$ *and let*

$$I_\pi = \int_{[0,1]^{n-1}} \prod_k q_k^{\kappa_k - 1} h_\pi(q)\, dq = \int_{[0,\infty)^{n-1}} e^{-\sum_k \kappa_k u_k} h_\pi(e^{-u})\, du$$

be the term of Theorem 8.5(ii), written also in the gaps $u_k = -\log q_k$*; in the log-ratios* $\eta_k = \log(\alpha_{\pi(1)}/\alpha_{\pi(k)}) = u_2 + \cdots + u_k$ *the sector is the trail region* $0 < \eta_2 < \cdots < \eta_n$*. Let no* κ_k *be a nonpositive integer and* $L_k \in \mathbb{N}$ *with* $\operatorname{Re}\kappa_k + L_k > 0$*. Then the continuation of* I_π *in the masses is*

$$\sum_{A \subseteq \{2,\dots,n\}} \sum_{\mathbf{l}:\ l_k < L_k\ (k \in A)} \prod_{k \in A} \frac{1}{\kappa_k + l_k} \int_{[0,1]^{A^c}} \prod_{k \notin A} q_k^{\kappa_k - 1} \Big[\prod_{k \notin A} (1 - \mathrm{Tay}_k)\, h_\pi^{(A,\mathbf{l})} \Big] dq_{A^c},$$

where $h_\pi^{(A,\mathbf{l})} = \partial_{q_A}^{\mathbf{l}} h_\pi / \mathbf{l}!$ *at* $q_A = 0$ *and* Tay_k *takes the Taylor polynomial in* q_k *of degree below* L_k*: the term* A *collapses the tails* U_k*,* $k \in A$*, together, at the levels* $\mathbf{l}$*.*

Theorem 8.7 (Projective form; the period)**.** *Put*

$$\begin{aligned} P_F(\mathbf{m};\mathbf{s},\mathbf{t}) &= \int_{\Delta_\mathcal{E}} u^{\boldsymbol{\mu}-\mathbf{1}} \prod_j \Lambda_j(\tfrac{1}{2}\log u)^{-s_j} \Lambda_j(-\tfrac{1}{2}\log u)^{-t_j}\, d\omega_\mathcal{E}(u) \\ &= \int_{\Delta_\mathcal{E}} u^{\mathbf{m}-\mathbf{1}} \prod_j K_j(u)^{-s_j} \Psi_j(u)^{-t_j}\, d\omega_\mathcal{E}(u). \end{aligned}$$

It converges if and only if $\operatorname{Re}\kappa_S > 0$ *for every nonempty proper* S*, and* $J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \Gamma(\kappa_\mathcal{E}) P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ *as meromorphic functions;* $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ *is the* period*. On the balance wall the period is the residue of* $J_F(\mathbf{m};\mathbf{s},\mathbf{t})$ *there; for every positive* h *homogeneous of degree one, the integral of* $\alpha^{\mathbf{m}-\mathbf{1}} \prod_j K_j^{-s_j} \Psi_j^{-t_j} d\alpha$ *over* $\{h = 1\}$ *(Definition 1.1(vii)) is the period.*

Definition 8.8 (The continued interest)**.** The continuation of Theorem 8.5(iii) keeps the symbol $J_F(\mathbf{m};\mathbf{s},\mathbf{t})$ away from its poles. Among them is the whole balance wall, where $J_F(\mathbf{m};\mathbf{s},\mathbf{t})$ has the residue $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ (Theorem 8.7). The factor $e^{-|\alpha|}$ damps the scaling mode, so no completion enters the continued interest.

Theorem 8.9 (The interest is a Gramma; its letter and mark relations)**.** *For* $\operatorname{Re} s_j, \operatorname{Re} t_j > 0$*, on the scales* $\mathcal{E} \sqcup \{v_j\} \sqcup \{w_j\}$ *let* t_F *be the configuration of the columns* $(\mathbf{e}_e; 0; 0)$ *with coefficient* 1*, and* $(\chi_T/2; \mathbf{e}_j; 0)$*,* $(-\chi_T/2; 0; \mathbf{e}_j)$ *with coefficient* $\theta_{j,T}$ *for* $T \in \mathcal{B}_j$*. Then*

$$\prod_j \Gamma(s_j)\Gamma(t_j)\, J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \mathsf{G}_{(\boldsymbol{\mu};\mathbf{s};\mathbf{t});t_F}(\mathbf{1} \oplus \boldsymbol{\theta} \oplus \boldsymbol{\theta}),$$

either side converging with the other. As identities of meromorphic functions:

(i) (letter relations) for each j*,*

$$J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \sum_{T \in \mathcal{B}_j} \theta_{j,T} J_F(\mathbf{m} + \mathbf{1}_T; \mathbf{s} + \mathbf{e}_j, \mathbf{t}) = \sum_{T \in \mathcal{B}_j} \theta_{j,T} J_F(\mathbf{m} + \mathbf{1}_{\mathcal{E}\setminus T}; \mathbf{s}, \mathbf{t} + \mathbf{e}_j);$$

(ii) (mark relations) for each e,

$$m_e J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = J_F(\mathbf{m}+\mathbf{e}_e;\mathbf{s},\mathbf{t}) + \sum_j s_j \sum_{T\ni e} \theta_{j,T} J_F(\mathbf{m}+\mathbf{1}_T;\mathbf{s}+\mathbf{e}_j,\mathbf{t}) + \sum_j t_j \sum_{T\not\ni e} \theta_{j,T} J_F(\mathbf{m}+\mathbf{1}_{\mathcal{E}\setminus T};\mathbf{s},\mathbf{t}+\mathbf{e}_j);$$

(iii) the same for the period $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ of Theorem 8.7, with $J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \Gamma(\kappa_{\mathcal{E}})P_F(\mathbf{m};\mathbf{s},\mathbf{t})$: the letter relations hold verbatim, and in the mark relation the pure mass shift carries the factor $\kappa_{\mathcal{E}}$, $m_e P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \kappa_{\mathcal{E}} P_F(\mathbf{m}+\mathbf{e}_e;\mathbf{s},\mathbf{t}) + \cdots$.

The interest is not a new kind of object: it is one Gramma, on the marks and one scale for each letter, and its relations are that Gramma's exchange relations. The letter relation is the exchange relation on a letter's scale, and the mark relation the exchange relation on a mark's scale, rewritten with the letter relations.

Definition 8.10 (Breta shape law; Breta law)**.** For real data with every proper wall positive, the *Breta shape law* $\mathrm{Breta}^{\circ}(F;\mathbf{m};\mathbf{s},\mathbf{t})$ is the probability measure

$$u^{\mathbf{m}-\mathbf{1}} \prod_j K_j(u)^{-s_j} \Psi_j(u)^{-t_j}\, d\omega_{\mathcal{E}}(u) / P_F(\mathbf{m};\mathbf{s},\mathbf{t}) \quad \text{on } \Delta_{\mathcal{E}}.$$

With every wall positive, the *Breta law* $\mathrm{Breta}(F;\mathbf{m};\mathbf{s},\mathbf{t})$ is the law on $\mathbb{R}^{\mathcal{E}}_{>0}$ with density $\alpha^{\mathbf{m}-\mathbf{1}} e^{-|\alpha|} \prod_j K_j(\alpha)^{-s_j} \Psi_j(\alpha)^{-t_j} / J_F(\mathbf{m};\mathbf{s},\mathbf{t})$.

Proposition 8.11 (The interest over latent vectors)**.** *Let every table j of a family be determinantal over $\mathbb{F}_j \in \{\mathbb{R},\mathbb{C}\}$ (Definition 7.20), put $\beta_j = \dim_{\mathbb{R}} \mathbb{F}_j$, and let $2s_j/\beta_j$ and $2t_j/\beta_j$ be nonnegative integers. Let $V_j \subseteq \mathbb{F}_j^{\mathcal{E}}$ be the row space of a slice of table j and $V_j^{\perp}$ its orthogonal complement, each with its Lebesgue measure, and for the* latent vectors *$x_{j,i} \in V_j$, $1 \le i \le 2s_j/\beta_j$, and $x^*_{j,i} \in V_j^{\perp}$, $1 \le i \le 2t_j/\beta_j$, put $\mathfrak{q}_e = \sum_j \big(\sum_i |(x_{j,i})_e|^2 + \sum_i |(x^*_{j,i})_e|^2 \big)$. Then*

$$J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \frac{\prod_e \Gamma(m_e)}{\prod_j K_j(\mathbf{1})^{s_j+t_j} \pi^{r_j s_j + r_j^* t_j}} \int \prod_{e\in\mathcal{E}} \big(1+\mathfrak{q}_e\big)^{-m_e} \prod_{j,i} dx_{j,i}\, dx^*_{j,i},$$

both sides finite or infinite together. Where they are finite, the Breta law $\mathrm{Breta}(F;\mathbf{m};\mathbf{s},\mathbf{t})$ (Definition 8.10) is the law of α under the joint law of α and the latent vectors with density proportional to $\alpha^{\mathbf{m}-\mathbf{1}} \exp\big(-\sum_e \alpha_e(1+\mathfrak{q}_e)\big)$, under which, given the latent vectors, the scales α_e are independent and $\alpha_e(1+\mathfrak{q}_e)$ has the law Gamma_{m_e}. Over $\mathbb{R}$ with $s_j = t_j$ the sums $u_{j,i} = x_{j,i} + x^*_{j,i}$ run over $\mathbb{R}^{\mathcal{E}}$, with $|(x_{j,i})_e|^2 + |(x^*_{j,i})_e|^2 = (\mathrm{pr}_j\, u_{j,i})_e^2 + \big((I-\mathrm{pr}_j)u_{j,i}\big)_e^2$, pr_j the orthogonal projection onto V_j.

The letters of a determinantal table open as Gaussian integrals: its basis polynomial is a Gram determinant, whose inverse powers are Gaussian integrals over the row space of its slice, real or complex, and its cobasis polynomial is the same over the orthogonal complement, each letter with as many latent vectors as its exponent asks; over $\mathbb{R}$ at equal exponents the two pair into Gaussian vectors on $\mathbb{R}^{\mathcal{E}}$ read through the two projections. The integrals over the scales are then Gamma integrals, and the interest becomes a rational integral in the latent vectors.

Proposition 8.12 (The interest under Gamma draws)**.** *Let the data be real with $\mathbf{m} > 0$.*

(i) Where every proper wall is positive, $P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}\,\mathbb{E}_{U\sim \mathrm{Dir}_{\mathbf{m}}}[W(U)]$. *With* $\phi_{\mathbf{m}}$ *the joint law of* $\big(K_1(U),\dots,K_N(U),\Psi_1(U),\dots,\Psi_N(U)\big)$ *for* $U\sim \mathrm{Dir}_{\mathbf{m}}$, *an input on the source* $(0,\infty)^{2N}$, $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ *is a Trailmoment at the unit configuration* I_{2N}*:*

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}\,\big(\mathsf{T}_{(\mathbf{s},\mathbf{t});I_{2N}}[\mathrm{id}]\,\phi_{\mathbf{m}}\big)\big((0,\infty)^{2N}\big).$$

(ii) Where moreover $\kappa_{\mathcal{E}}>0$, *so that every wall is positive, let* $\alpha\sim \mathrm{Gamma}_{\mathbf{m}}$, *with total* $|\alpha|$ *and shape* $U=\alpha/|\alpha|$. *The scale and the shape separate:* $|\alpha|\sim \mathrm{Gamma}_{m_{\mathcal{E}}}$ *and* $U\sim \mathrm{Dir}_{\mathbf{m}}$ *are independent, and*

$$J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \prod_e \Gamma(m_e)\,\mathbb{E}_{\alpha\sim\mathrm{Gamma}_{\mathbf{m}}}[W(\alpha)],$$

$$\mathbb{E}_{\alpha\sim\mathrm{Gamma}_{\mathbf{m}}}[W(\alpha)] = \frac{\Gamma(\kappa_{\mathcal{E}})}{\Gamma(m_{\mathcal{E}})}\,\mathbb{E}_{U\sim\mathrm{Dir}_{\mathbf{m}}}[W(U)].$$

(iii) In the exponents, $J_F(\mathbf{m};\mathbf{s},\mathbf{t})/\prod_e\Gamma(m_e)$ *is the moment generating function of the letters' logarithms* $-\log K_j(\alpha)$, $-\log\Psi_j(\alpha)$ *for* $\alpha\sim\mathrm{Gamma}_{\mathbf{m}}$, *and* $P_F(\mathbf{m};\mathbf{s},\mathbf{t})/\Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}$ *that of* $-\log K_j(U)$, $-\log\Psi_j(U)$ *for* $U\sim\mathrm{Dir}_{\mathbf{m}}$. *Their ratio* $\Gamma(\kappa_{\mathcal{E}})/\Gamma(m_{\mathcal{E}})$ *has its pole on the balance wall, where the moment generating function under* $\mathrm{Gamma}_{\mathbf{m}}$ *diverges and that under* $\mathrm{Dir}_{\mathbf{m}}$ *is the period over* $\Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}$.

Theorem 8.13 (Walls under Cremona)**.** *As functions of* $(\boldsymbol{\mu};\boldsymbol{\sigma},\boldsymbol{\delta})$: $\kappa_S^{\mathrm{top}}(\boldsymbol{\mu};\boldsymbol{\sigma},\boldsymbol{\delta}) = \kappa_S(-\boldsymbol{\mu};\boldsymbol{\sigma},-\boldsymbol{\delta})$, $\kappa_S+\kappa_S^{\mathrm{top}} = 2\sum_j\sigma_j c_j(S)$, *and* $\kappa_{\mathcal{E}\setminus S} = \kappa_{\mathcal{E}}+\kappa_S^{\mathrm{top}}$. *In pair coordinates* $\kappa_S^{\mathrm{top}} = \sum_j\big(\sigma_j c_j(S)+\delta_j\varepsilon_j(S)\big)-\mu_S$.

Theorem 8.14 (Cremona on the balance wall)**.** *For a connected family, on the hyperplane* $\kappa_{\mathcal{E}}=0$,

$$P_F(\boldsymbol{\mu}+\sigma\mathbf{1};\boldsymbol{\sigma}+\boldsymbol{\delta},\boldsymbol{\sigma}-\boldsymbol{\delta}) = P_F(-\boldsymbol{\mu}+\sigma\mathbf{1};\boldsymbol{\sigma}-\boldsymbol{\delta},\boldsymbol{\sigma}+\boldsymbol{\delta}),$$

the walls of the right side at S *being those of the left at* $\mathcal{E}\setminus S$*; the identity continues meromorphically along the hyperplane.*

On the balance wall the period is unchanged when the offsets and the leans change sign together: Cremona (Definition 9.1) swaps the two exponents of each table, $\delta_j\mapsto-\delta_j$, negates the offsets, and swaps every wall with the wall of the complement.

Proposition 8.15 (Dual tables)**.** *Replacing every table by its dual, with the same exponents, gives the interest at the exponents* (t_j,s_j)*: in pair coordinates* $\delta_j\mapsto-\delta_j$.

Proposition 8.16 (The wall of a compound)**.** *For every nonempty proper* S, $\kappa_S+\kappa_{\mathcal{E}\setminus S} = \kappa_{\mathcal{E}}+2\sum_j\sigma_j c_j(S)$. *So if* $c_j(S)=0$ *in every table with* $\sigma_j\neq0$, *then* $\kappa_S+\kappa_{\mathcal{E}\setminus S}=\kappa_{\mathcal{E}}$, *and on the balance wall a compound split along* S *has a wall with real part at most zero, and its period diverges.*

8.2 The native gauge

Definition 8.17 (Target; native gauge)**.** For data with $m_{\mathcal{E}} \neq 0$ the *target* is $\boldsymbol{\tau} = \frac{\sum_j (s_j r_j + t_j r_j^*)}{m_{\mathcal{E}}} \mathbf{m}$; on the balance wall it is $\mathbf{m}$. A point $\alpha^\star \in (\mathbb{C}^\times)^{\mathcal{E}}$ with $K_j(\alpha^\star)\Psi_j(\alpha^\star) \neq 0$ for every j is *native* when its *usage* equals the target,

$$\sum_j \big(s_j\, R_j(\alpha^\star) + t_j\, R_j^*(\alpha^\star)\big) = \boldsymbol{\tau},$$

where $R_{j,e} = \alpha_e \partial_e K_j / K_j$ is the occupation of table j and $R^*_{j,e} = \alpha_e \partial_e \Psi_j / \Psi_j$ that of its dual (Theorem 7.16), rational functions homogeneous of degree zero; so nativity is a property of the point up to scale. A native point in $\mathbb{R}^{\mathcal{E}}_{>0}$, written $\alpha^\star = e^{2z^\star}$, is a *native gauge*; the other native points are the *native gauges at complex points.*

Definition 8.18 (Potential; its even and odd parts)**.** In logarithmic coordinates the *potential* of a family with its exponent pairs is

$$\Phi(y) = \sum_j \Big(s_j \log K_j(e^y) + t_j \log \Psi_j(e^y)\Big) = \Phi_{\mathbf{E}}(y) + \Phi_{\mathbf{O}}(y),$$

$$\Phi_{\mathbf{E}}(y) = \sum_j \sigma_j \log \mathbf{E}_j(e^y), \qquad \Phi_{\mathbf{O}}(y) = \sum_j \delta_j \log \mathbf{O}_j(e^y), \qquad \mathbf{E}_j = K_j\Psi_j, \quad \mathbf{O}_j = K_j/\Psi_j,$$

the *even* and *odd letters* of table j, so that $\mathbf{E}_j(e^{2z}) = e^{2\langle \mathbf{1}, z\rangle} e^{E_j(z)}$ and $\mathbf{O}_j(e^{2z}) = e^{O_j(z)}$. The pair $(\Phi_{\mathbf{E}}, \Phi_{\mathbf{O}})$, either part written $\Phi_{\mathbf{X}}$ with $\mathbf{X} \in \{\mathbf{E}, \mathbf{O}\}$, is read whole: neither part is switched off at any lean, and the two are never added before they are read.

Theorem 8.19 (The native gauge is the saddle)**.** *The potential satisfies* $\partial_{y_e}\Phi = \sum_j \big(s_j R_{j,e} + t_j R^*_{j,e}\big)$*, the usage at* $\alpha = e^y$*, and the integrand of the interest is* $e^{\langle \mathbf{m}, y\rangle - \Phi(y) - |\alpha|}$ *in* y*. In the signed coordinates* $z = \frac{1}{2}y$*,* $\Phi(y) = \sigma\langle \mathbf{1}, y\rangle + \Phi^\circ(z)$ *with the* centred potential $\Phi^\circ(z) = \sum_j \big(s_j \log \Lambda_j(z) + t_j \log \Lambda_j(-z)\big) = \sum_j \big(\sigma_j E_j(z) + \delta_j O_j(z)\big)$*.*

(i) A gauge $\alpha^\star$ *is native iff* $\nabla\Phi(\log \alpha^\star) = \boldsymbol{\tau}$*; on the balance wall, iff* $\log \alpha^\star$ *is a critical point of* $\langle \mathbf{m}, y\rangle - \Phi(y)$*.*

(ii) For real data with $s_j, t_j \geq 0$*, not all zero, and* $\mathbf{m} > 0$*,* Φ *is convex, and a native gauge exists iff* $\boldsymbol{\tau}$ *lies in the relative interior of the Newton sum* $\mathcal{N}_F = \sum_j \big(s_j P_j + t_j P_j^*\big)$*, with* P_j *the base polytope of table* j *(Theorem 7.18) and* P_j^* *that of its dual; it is then unique modulo the space of directions along which* Φ *is affine.*

(iii) For such data $\mathcal{N}_F = \{x :\ x_{\mathcal{E}} = g(\mathcal{E}),\ x_S \geq g(S)\ \forall S\}$ *with the set function* $g = \sum_j (s_j d_j + t_j d_j^*)$*. For a connected family that space is* $\mathbb{R}\mathbf{1}$*, and the condition is* $\tau_S - g(S) > 0$ *for every nonempty proper* S*: the walls at the target are positive. The native gauge is then the unique point, up to scale, at which* $\alpha^{\boldsymbol{\tau}} W(\alpha)$*, constant along each ray, is largest; on the balance wall* $\boldsymbol{\tau} = \mathbf{m}$*.*

A native gauge is a gauge at which the family uses each mark exactly as much as the target asks, and the same equation at a complex point gives the native gauges at complex points that the rays of Chapter 38 use. With real data, nonnegative exponents and positive masses, for a connected family it is unique up to scale and exists exactly when every proper wall at the target is positive (Theorem 8.19(iii)); on a compound it exists exactly when every molecule of the active family is balanced at the target with its proper walls positive there, with one free scale for each such molecule (Proposition 8.20). It is a point at which $\alpha^{\boldsymbol{\tau}} W(\alpha)$ is largest, the saddle of the potential, and it is the measuring stick of every computation on the family.

Proposition 8.20 (The native gauges of a compound)**.** *Let F have real data, $s_j, t_j \geq 0$ not all zero, $\mathbf{m} > 0$, and target $\boldsymbol{\tau}$, and let $\mathcal{E}_1, \ldots, \mathcal{E}_q$ be the molecules of its active family. A native gauge exists exactly when every $\mathcal{E}_i$ is balanced at the target, $\tau_{\mathcal{E}_i} = \sum_j \big(s_j r_j(\mathcal{E}_i) + t_j r_j^*(\mathcal{E}_i)\big)$, and every proper wall of every $\mathcal{E}_i$ is positive there, $\tau_S > \sum_j \big(s_j d_j(S) + t_j d_j^*(S)\big)$ for $\varnothing \neq S \subsetneq \mathcal{E}_i$. The native gauges are then the gauges β with $\beta/\alpha^\star$ constant on every $\mathcal{E}_i$, $\alpha^\star$ any one of them: one free scale for each molecule. When the weights factor across the $\mathcal{E}_i$, the native gauges are the products of native gauges of the molecules. A mark that is a loop or a coloop in every table is a unit, whose letters are monomials.*

Proposition 8.21 (The centre of an arbitrary family)**.** *Take tables on $\mathcal{E}$, $s_j = t_j = \sigma_j \geq 0$ with $\sigma = \sum_j \sigma_j > 0$, and $\mathbf{m} = \sigma\mathbf{1}$. Then $\delta_j = 0$, $\boldsymbol{\mu} = 0$, the centred potential $\Phi^\circ(z) = \sum_j \sigma_j E_j(z)$ is even, and:*

(i) the gauge $\mathbf{1}$ is native, unique modulo one scale for each molecule of the active family (Proposition 8.20);

(ii) the walls are $\kappa_S = \sum_j \sigma_j c_j(S)$, positive on every proper nonempty S exactly when the active family is connected;

(iii) every odd derivative of Φ° vanishes at $z = 0$, so every odd derivative of order at least three of the potential Φ vanishes at $y = 0$.

The family at the centre, every $\delta_j = 0$ (Definition 9.1), with the masses $\sigma\mathbf{1}$ has its offsets zero. It exists for every family, its native gauge is the table's gauge, and its walls are the combinations $\kappa_S = \sum_j \sigma_j c_j(S)$ of the widths; it is where the family is read before any lean is asked of it.

Proposition 8.22 (Prescribing a gauge)**.** *For any positive gauge a and positive exponent pairs, the usage $\tau_e = \sum_j \big(s_j R_{j,e}(a) + t_j R_{j,e}^*(a)\big)$ has total $\sum_j (s_j r_j + t_j r_j^*)$, and every mass vector on the ray $c\boldsymbol{\tau}$, $c > 0$, makes a native. Fixing values $K_j^0 > 0$ and $\Psi_j^0 > 0$ of the letters at a, the constraints*

$$\sum_T \theta_{j,T} a^T = K_j^0, \qquad \sum_T \theta_{j,T} a^{\mathcal{E}\setminus T} = \Psi_j^0, \qquad \sum_{j,T} \theta_{j,T} \Big[\frac{s_j a^T}{K_j^0} \mathbf{1}_T + \frac{t_j a^{\mathcal{E}\setminus T}}{\Psi_j^0} \mathbf{1}_{\mathcal{E}\setminus T} \Big] = \boldsymbol{\tau}$$

are linear in the weights, and every positive deformation in their homogeneous kernel preserves them exactly.

Part III

Classification

Chapter 9

Realizations and the still

9.1 Realizations

Definition 9.1 (Realization, lean, carrier)**.** Let a family carry tables j on its marks $\mathcal{E}$, $n = |\mathcal{E}|$, its potential read as the pair $(\Phi_{\mathbf{E}}, \Phi_{\mathbf{O}})$ of Definition 8.18. A *realization* of the family is $\Upsilon = \big((s_j, t_j)_j;\, \alpha\big)$: exponents $s_j, t_j \geq 0$ with $s_j + t_j > 0$, and a gauge $\alpha \in \mathbb{R}^{\mathcal{E}}_{>0}$. Its pair coordinates are the strengths $\sigma_j = \frac{1}{2}(s_j + t_j) > 0$ and the leans $\delta_j = \frac{1}{2}(s_j - t_j)$ of Definition 8.1, $|\delta_j| \leq \sigma_j$, and in them the realization is written

$$\Upsilon_{\boldsymbol{\sigma},\boldsymbol{\delta};\alpha} = \big((\sigma_j + \delta_j,\ \sigma_j - \delta_j)_j;\ \alpha\big).$$

$\boldsymbol{\delta} = (\delta_j)_j$ is the *lean*, and the *centre* is $\boldsymbol{\delta} = 0$; at the table's gauge the realization at the centre has the masses $\sigma\mathbf{1}$ (Proposition 8.21), and a family at the centre is taken with these masses. Table j has a *basis lean* when $\delta_j > 0$, a *cobasis lean* when $\delta_j < 0$, and *rides the line* when $\delta_j = 0$; its lean is *full* when $|\delta_j| = \sigma_j$ (then the factor of table j in the family word is $K_j^{-s_j}$ alone, or $\Psi_j^{-t_j}$ alone) and *partial* when $0 < |\delta_j| < \sigma_j$. The family has a basis lean when every $\delta_j \geq 0$ and some $\delta_j > 0$, a cobasis lean when every $\delta_j \leq 0$ and some $\delta_j < 0$, and otherwise, off the centre, a mixed lean. The realization is *at one pair* (σ, δ), $\sigma = \sum_j \sigma_j$ and $\delta = \sum_j \delta_j$, when its pairs lie on one ray, $(\sigma_j, \delta_j) = \frac{\sigma_j}{\sigma}(\sigma, \delta)$ for every j; its *lean sign* is the sign of δ. A family with one table is at one pair. The *masses* of Υ are its usage,

$$\tau_e(\Upsilon) = \sum_j \Big(s_j \, \frac{\alpha_e \partial_e K_j}{K_j}(\alpha) + t_j \, \frac{\alpha_e \partial_e \Psi_j}{\Psi_j}(\alpha) \Big),$$

for which α is the native gauge (Proposition 8.22). The *carrier* of Υ is $(\alpha;\, K_j, \Psi_j;\, \boldsymbol{\tau};\, s_j, t_j)$. A gauge is written as a deviation from the table's gauge, $\alpha = e^{y_0}$. Inverting the gauge and swapping the two exponents of every table, $\big((s_j, t_j)_j; \alpha\big) \mapsto \big((t_j, s_j)_j; \alpha^{-1}\big)$, sends the offsets and the lean to $-\boldsymbol{\mu}$ and $-\boldsymbol{\delta}$, the change of data of Theorem 8.14; so *Cremona* swaps basis and cobasis leans, and the table's gauge is its fixed point up to scale (Proposition 7.2).

A realization is read off its exponents: the masses are the usage at its gauge, so the gauge is native by definition, and a realization sits on a wall only along a union of molecules, so that a realization of a molecule never does (Proposition 9.2). A molecule is read at all of its realizations, and a particular integral is one of them, fixed by its exponents and its native gauge.

Proposition 9.2 (A realization sits on a wall only along its molecules)**.** *Let a family carry real exponents $s_j, t_j \geq 0$, $s_j + t_j > 0$, and a gauge α, with masses its usage $\mathbf{m} = \sum_j \big(s_j R_j(\alpha) + t_j R_j^*(\alpha)\big)$, that is, a realization (Definition 9.1). With $N_S = |T \cap S|$,*

$$\kappa_S = \sum_j \Big(s_j \big(\mathbb{E}_{T \sim \mathbb{P}_{j,\alpha}}[N_S] - d_j(S) \big) + t_j \big(r_j(S) - \mathbb{E}_{T \sim \mathbb{P}^*_{j,\alpha}}[N_S] \big) \Big) \;\geq\; 0 \qquad (\varnothing \neq S \subseteq \mathcal{E}),$$

with equality exactly when S is a union of molecules (Definition 7.4). In particular $\kappa_{\mathcal{E}} = 0$, and every proper wall of a connected family is positive.

Proposition 9.3 (Masses at a gauge)**.** *At $\alpha = e^{y_0}$, in this statement write $R^{\pm}_{j,e} = \frac{1}{2}\big(R_{j,e}(e^{y_0}) \pm R_{j,e}(e^{-y_0})\big)$; then*

$$\tau_e = \sum_j \big(s_j R_{j,e}(e^{y_0}) + t_j (1 - R_{j,e}(e^{-y_0})) \big) = \sum_j \big(\sigma_j (1 + 2R^-_{j,e}) + \delta_j (2R^+_{j,e} - 1) \big),$$

and at $\alpha = \mathbf{1}$, where $R^-_{j,e} = 0$ and $R^+_{j,e} = R_{j,e}(\mathbf{1})$, $\tau_e = \sum_j \big(\sigma_j + \delta_j (2R_{j,e}(\mathbf{1}) - 1) \big)$.

9.2 The potential and the still

Definition 9.4 (Still, rungs, tallies, line functions)**.** The *still* of Υ is the sequence of symmetric tensors

$$\kappa_\Upsilon(e_1, \ldots, e_k) = 2^k \, \partial_{y_{e_1}} \cdots \partial_{y_{e_k}} \Phi(\log \alpha), \qquad k \geq 2,$$

the Taylor tensor of Φ in the signed coordinates $z = \frac{1}{2} y$ from order two on; its entries of order k form *rung k*. *Rung one* is the gradient $\partial_{y_e} \Phi(\log \alpha) = \tau_e(\Upsilon)$, the masses (Theorem 8.19), taken without the factor 2. Each part has its own still, $\kappa^{\mathbf{E}}_\Upsilon$ and $\kappa^{\mathbf{O}}_\Upsilon$, with $\kappa_\Upsilon = \kappa^{\mathbf{E}}_\Upsilon + \kappa^{\mathbf{O}}_\Upsilon$. The *tally* of a mark e at rung k is the multiset $\mathrm{tally}^{\mathbf{X}}_k(e) = \{\!\{ \kappa^{\mathbf{X}}_\Upsilon(e, w) : \; w \in \mathcal{E}^{k-1} \}\!\}$. The *self-line* and *partner-line functions* of e are

$$\varphi^{\mathbf{X}}_e(v) = \partial_{y_e} \Phi_{\mathbf{X}}\big(\log \alpha + v \mathbf{1}_e \big), \qquad \varphi^{\mathbf{X}}_{e,g}(v) = \partial_{y_e} \Phi_{\mathbf{X}}\big(\log \alpha + v \mathbf{1}_g \big) \quad (g \neq e).$$

The still is the Taylor tensor of the potential at the realization from rung two on, one object, recording how the marks covary under the two laws; beside it, rung one is the masses. The letters are affine in every variable, so they have finitely many nontrivial derivatives, and every rung is read from those through the logarithm; the readings of Chapter 10 take the potential as one function, of which the still is the expansion.

Proposition 9.5 (The potential of a compound splits by molecules)**.** *Let the weights factor across the molecules. Then $\Phi_{\mathbf{X}}(y) = \sum_M \Phi_{\mathbf{X},M}(y_{\mathcal{E}_M})$ with $\Phi_{\mathbf{X},M}$ the potential of the restriction to M, and every entry of the still on a string that meets two molecules is 0. A mark that is a loop or a coloop in every table is a unit whose letters are monomials (Proposition 8.20): every entry of the still on a string through it is 0, and its rung one is its mass.*

Proposition 9.6 (A deviation reweights the bases)**.** *At the realization $\Upsilon = \big((s_j, t_j)_j; e^{y_0}\big)$, for $k \geq 2$ and every string w of length k,*

$$\kappa_\Upsilon(w) = 2^k \sum_j \Big(s_j \, \kappa_{j, e^{y_0}}(w) + t_j (-1)^k \kappa_{j, e^{-y_0}}(w) \Big).$$

In this statement write $\kappa_j^{\pm}(w) = \frac{1}{2}\big(\kappa_{j,e^{y_0}}(w) \pm \kappa_{j,e^{-y_0}}(w)\big)$*; then*

$$\kappa_\Upsilon(w) = \begin{cases} 2^{k+1} \sum_j \big(\sigma_j \kappa_j^+(w) + \delta_j \kappa_j^-(w)\big), & k \text{ even}, \\ 2^{k+1} \sum_j \big(\sigma_j \kappa_j^-(w) + \delta_j \kappa_j^+(w)\big), & k \text{ odd}, \end{cases}$$

and the cumulants at the deviation are read from those at the table's gauge, $\kappa_{j,e^{y_0}}(w) = \sum_{i\geq 0} \frac{1}{i!} \sum_{u\in\mathcal{E}^i} \kappa_{j,\mathbf{1}}(w,u) \prod_{l=1}^i y_{0,u_l}$*, for* y_0 *in the domain of convergence of the Taylor series of* $y \mapsto \log K_j(e^y)$ *at* 0*.*

Proposition 9.7 (The still at the table's gauge)**.** *At every realization* $\Upsilon = \big((s_j,t_j)_j;\mathbf{1}\big)$*, for* $k \geq 2$ *and every string* w *of length* k*,*

$$\kappa_\Upsilon(w) = 2^k \sum_j \big(s_j + (-1)^k t_j\big)\kappa_{j,\mathbf{1}}(w) = \begin{cases} 2^{k+1} \sum_j \sigma_j\, \kappa_{j,\mathbf{1}}(w), & k \text{ even}, \\ 2^{k+1} \sum_j \delta_j\, \kappa_{j,\mathbf{1}}(w), & k \text{ odd}. \end{cases}$$

This is Proposition 9.6 at $y_0 = 0$*. At the table's gauge* $\Phi_{\mathbf{E}}$ *is even in* y *and* $\Phi_{\mathbf{O}}$ *is odd, each up to a linear term; so the even rungs are those of* $\kappa_\Upsilon^{\mathbf{E}}$*, independent of the lean, and the odd rungs are those of* $\kappa_\Upsilon^{\mathbf{O}}$*, linear in the lean and zero at the centre.*

Proposition 9.8 (Balanced tallies)**.** *At every realization* Υ*, for each part, every rung* $k \geq 2$ *and every mark* e*, the tally of* e *sums to* 0*:* $\sum_{w\in\mathcal{E}^{k-1}} \kappa_\Upsilon^{\mathbf{X}}(e,w) = 0$*.*

Proposition 9.9 (The two occupations of a mark)**.** *For a mark* e *of table* j*, neither a loop nor a coloop, with room* $R = \mathcal{E} - e$*, let* $K_{j,/e}(\alpha_R)$ *and* $K_{j,\setminus e}(\alpha_R)$ *be the basis polynomials of its contraction and deletion at* e *(Definition 7.3), and*

$$\mathrm{D}_{j,e}(y_R) = \log K_{j,/e}(e^{y_R}) - \log K_{j,\setminus e}(e^{y_R}), \qquad \mathrm{D}_{j,e}^{\pm}(y_R) = \tfrac{1}{2}\big(\mathrm{D}_{j,e}(y_R) \pm \mathrm{D}_{j,e}(-y_R)\big).$$

At the gauge e^y *the occupation and the dual occupation of* e *(Theorem 7.16) are*

$$\frac{\alpha_e \partial_e K_j}{K_j} = \frac{1}{1+e^{-\lambda_{j,e}-\eta_{j,e}}}, \qquad \frac{\alpha_e \partial_e \Psi_j}{\Psi_j} = \frac{1}{1+e^{-\lambda_{j,e}+\eta_{j,e}}},$$
$$\lambda_{j,e} = y_e + \mathrm{D}_{j,e}^-(y_R), \qquad \eta_{j,e} = \mathrm{D}_{j,e}^+(y_R),$$

and at the table's gauge $\lambda_{j,e} = 0$*: the two occupations are* $(1+e^{-\eta_{j,e}})^{-1}$ *and* $(1+e^{\eta_{j,e}})^{-1}$*.*

Proposition 9.10 (Occupations at a gauge)**.** *At* $\alpha = e^{y_0}$*, with* $R_{j,e}^{\pm}$ *as in Proposition 9.3,* $\varphi_e^{\mathbf{E}}(0) = \sum_j \sigma_j(1 + 2R_{j,e}^-)$ *and* $\varphi_e^{\mathbf{O}}(0) = \sum_j \delta_j(2R_{j,e}^+ - 1)$*. At* $\alpha = \mathbf{1}$*,* $\varphi_e^{\mathbf{E}}(0) = \sum_j \sigma_j$ *at every mark and* $\varphi_e^{\mathbf{O}}(0) = \sum_j \delta_j(2R_{j,e}(\mathbf{1}) - 1)$*.*

Chapter 10

The reading, classes, atoms

10.1 Views and the reading

Definition 10.1 (Views; the reading; classes; atoms)**.** Let M be a molecule with n marks carrying tables j, and Υ a realization of M (Definition 9.1). The room of a mark e is $\mathcal{E} \setminus \{e\}$ (Chapter 12 calls it the room of the bunch $\{e\}$), and an *order* of a set is a listing of its elements. For a mark e and distinct marks $\mathbf{g} = (g_1, \dots, g_k)$ of its room, $0 \le k \le n-1$, the *view* of e with the partners $\mathbf{g}$ is the pair $(\Phi^{\mathbf{E}}_{e,\mathbf{g}}, \Phi^{\mathbf{O}}_{e,\mathbf{g}})$,

$$\Phi^{\mathbf{X}}_{e,\mathbf{g}}(v_0, v_1, \dots, v_k) = \Phi_{\mathbf{X}}\Big(\log\alpha + v_0 \mathbf{1}_e + \sum_{i=1}^{k} v_i \mathbf{1}_{g_i} \Big),$$

the potential on the scales of e and its partners with every other mark at the gauge; the variable v_i sits at *position* i. The *reading of* e *with* k *partners* is the multiset of its views over all k-tuples of distinct partners,

$$\mathrm{read}^{(k)}_{\Upsilon}(e) = \{\{ (\Phi^{\mathbf{E}}_{e,\mathbf{g}}, \Phi^{\mathbf{O}}_{e,\mathbf{g}}) : \ \mathbf{g} \in (\mathcal{E} \setminus e)^{(k)} \}\} :$$

the functions are kept and the names of the partners are not. With $k = n-1$, $\mathbf{g}$ is an order of the room and the pair $(\Phi^{\mathbf{E}}_{e,\mathbf{g}}, \Phi^{\mathbf{O}}_{e,\mathbf{g}})$ is the potential *written from* e in that order; $\mathrm{read}^{(n-1)}_{\Upsilon}(e)$ is the *reading* of e. The *classes* of Υ are the level sets of $e \mapsto \mathrm{read}^{(n-1)}_{\Upsilon}(e)$; they form the partition $\mathrm{Cl}(\Upsilon)$. The realization is *atomic*, an *atom*, when $\mathrm{Cl}(\Upsilon) = \{\mathcal{E}\}$. For a family whose weights factor across its molecules, the classes of a realization are, by definition, the classes of the realizations of its molecules, each read on its own marks. With the gauge α and $\boldsymbol{\sigma}$ fixed, the partition at the lean $\boldsymbol{\delta}$ is $\mathrm{Cl}(\Upsilon_{\boldsymbol{\sigma},\boldsymbol{\delta};\alpha})$.

The reading of a mark is the whole potential seen from that mark, its partners unnamed, and the reading is a function on the marks whose values are functions. Classes are its level sets, and an atom is a realization at which it is constant, so that the integral cannot tell its marks apart at any order.

Proposition 10.2 (A view through the patterns)**.** *For table j and positions $0, \dots, k$ held by $e, g_1, \dots, g_k$, let the pattern of a basis be the set $p \subseteq \{0, \dots, k\}$ of positions it holds (its trace $T \cap \{e, g_1, \dots, g_k\}$ read in positions, the pattern of the basis on the bunch $\{e, g_1, \dots, g_k\}$ in Chapter 12), $\bar{p}$ its complement, and*

$$K_{j;e,\mathbf{g}}(x) = \sum_{p} \vartheta^{K}_{j,p}\, x^{p}, \qquad \Psi_{j;e,\mathbf{g}}(x) = \sum_{p} \vartheta^{\Psi}_{j,p}\, x^{\bar{p}}, \qquad \vartheta^{K}_{j,p} = \sum_{T:\, p} \theta_{j,T} \alpha^{T}, \quad \vartheta^{\Psi}_{j,p} = \sum_{T:\, p} \theta_{j,T} \alpha^{\mathcal{E}\setminus T},$$

sums over the bases of pattern p. With $x_i = e^{v_i}$,

$$\Phi^{\mathbf{E}}_{e,\mathbf{g}} = \sum_j \sigma_j \log\big(K_{j;e,\mathbf{g}}\Psi_{j;e,\mathbf{g}}\big), \qquad \Phi^{\mathbf{O}}_{e,\mathbf{g}} = \sum_j \delta_j \log\big(K_{j;e,\mathbf{g}}/\Psi_{j;e,\mathbf{g}}\big).$$

At every gauge

$$K_{j;e,\mathbf{g}}(\mathbf{1}+x) = K_j(\alpha) \sum_{A\subseteq\{0,\dots,k\}} \mathbb{P}_{j,\alpha}\big(p(T)\supseteq A\big)\, x^A,$$
$$\Psi_{j;e,\mathbf{g}}(\mathbf{1}+x) = \Psi_j(\alpha) \sum_{A\subseteq\{0,\dots,k\}} \mathbb{P}^*_{j,\alpha}\big(p(T)\cap A=\varnothing\big)\, x^A,$$

with $p(T)$ the pattern of T, so the view with k partners is read from the joint inclusion laws of $e, g_1, \dots, g_k$ under the basis and cobasis laws. At the table's gauge $\vartheta^K_{j,p} = \vartheta^\Psi_{j,p} = \vartheta_{j,p}$, the weight of the bases of pattern p, both laws are the weight law $\mathbb{P}_{j,\mathbf{1}}$, and $\Psi_{j;e,\mathbf{g}}(x) = x^{\{0,\dots,k\}}K_{j;e,\mathbf{g}}(x^{-1})$. For one table, two views of one realization agree at the centre exactly when the polynomials $K_{e,\mathbf{g}}\Psi_{e,\mathbf{g}}$ agree, and at a lean exactly when $K_{e,\mathbf{g}}$ and $\Psi_{e,\mathbf{g}}$ both agree; at the table's gauge $K_{e,\mathbf{g}}$ alone decides at a lean.

Proposition 10.3 (More partners refine; the tallies are inside)**.** *(i) $\mathrm{read}^{(k)}_\Upsilon(e)$ determines $\mathrm{read}^{(k')}_\Upsilon(e)$ for every $k' \le k$; so the level sets of the reading with k partners refine those with k'.*

(ii) For $k \ge 1$, $\mathrm{read}^{(k)}_\Upsilon(e)$ determines the self-line functions $\varphi^{\mathbf{X}}_e$, the multisets $\{\{\varphi^{\mathbf{X}}_{e,g}\}\}_{g\ne e}$ of partner-line functions, and for every rung the multiset of the entries $\kappa^{\mathbf{X}}_\Upsilon(e,w)$ over the strings w of marks with at most k distinct marks other than e; in particular the tallies of e at the rungs $2,\dots,k+1$.

(iii) The reading determines the tallies of e at every rung $k \ge 2$, its self-line and partner-line functions for both parts, and its mass $\tau_e(\Upsilon)$.

Proposition 10.4 (One writing determines the reading)**.** *The reading of e is determined by any one writing of the potential from e. So the reading is constant on a set C of marks exactly when one pair of functions is the potential written from every mark of C: there are orders $\mathbf{g}_e$ of the rooms, $e \in C$, with $\Phi^{\mathbf{X}}_{e,\mathbf{g}_e} = \Phi^{\mathbf{X}}_{f,\mathbf{g}_f}$ for all $e, f \in C$ and both parts. In particular Υ is an atom exactly when one pair of functions is the potential written from every mark.*

10.2 Identifying writings

Theorem 10.5 (One table)**.** *Let M carry one table, $n \ge 2$, at the table's gauge, and let C be a set of marks. The reading is constant on C*

(i) at a lean, exactly when one polynomial is K written from every mark of C;

(ii) at the centre, exactly when one polynomial is, from every mark of C, either K or Ψ written from it.

Here K written from e in the order $\mathbf{g}$ is $K_{e,\mathbf{g}}$ with $k = n-1$, a polynomial in the position variables.

Theorem 10.6 (Several tables: the potential is read factor by factor)**.** *At a realization Υ write every $K_j(\alpha\circ x)$ and $\Psi_j(\alpha\circ x)$ as a positive constant times a product of irreducible polynomials in*

x, each positive on the orthant and equal to 1 at $x = \mathbf{1}$. Give each distinct such polynomial L the exponents

$$w_{\mathbf{E}}(L) = \sum \sigma_j > 0, \qquad w_{\mathbf{O}}(L) = \sum \pm\delta_j,$$

summed over its occurrences with multiplicity, with $+$ in a K_j and $-$ in a Ψ_j. Then $\Phi_{\mathbf{X}}(\log\alpha + \log x) = \Phi_{\mathbf{X}}(\log\alpha) + \sum_L w_{\mathbf{X}}(L)\log L(x)$, and two pairs $(\Phi_{\mathbf{E}}, \Phi_{\mathbf{O}})$ of this form, in the same variables, are equal exactly when they have the same polynomials with the same pairs of exponents $(w_{\mathbf{E}}(L), w_{\mathbf{O}}(L))$. So the reading is constant on C exactly when one set of polynomials with exponents $\{(L, w_{\mathbf{E}}(L), w_{\mathbf{O}}(L))\}$, with the variables placed in positions, is the family written from every mark of C. For tables whose weights factor across their molecules the polynomials L are the normalized Foreman polynomials of their restrictions to those molecules.

Corollary 10.7 (Moving blocks of partners reads alike)**.** *Let $\mathbf{g}, \mathbf{g}'$ be orders of the rooms of e and f with $(\Phi^{\mathbf{E}}_{e,\mathbf{g}}, \Phi^{\mathbf{O}}_{e,\mathbf{g}}) = (\Phi^{\mathbf{E}}_{f,\mathbf{g}'}, \Phi^{\mathbf{O}}_{f,\mathbf{g}'})$, and let β be the bijection of $\mathcal{E}$ with $\beta(e) = f$ and $\beta(g_i) = g'_i$. Then for all disjoint sets $S_1, \dots, S_m$ of the room of e,*

$$\Phi_{\mathbf{X}}\Big(\log\alpha + v_0\mathbf{1}_e + \sum_{i=1}^{m} v_i\mathbf{1}_{S_i}\Big) = \Phi_{\mathbf{X}}\Big(\log\alpha + v_0\mathbf{1}_f + \sum_{i=1}^{m} v_i\mathbf{1}_{\beta(S_i)}\Big).$$

So on a class every move of the gauge that shifts a mark and several sets of partners, each by one amount, reads alike: for every partition $S_1, \dots, S_m$ of the room, the potential moved by v_0 on the mark and by v_i on S_i reads alike from every mark of the class.

Proposition 10.8 (Computing the classes)**.** *Read every mark with $k = 0, 1, 2, \dots$ partners and group the marks by value. The level sets only refine as k grows (Proposition 10.3). A level set is a class as soon as one pair of functions is written from each of its marks (Proposition 10.4); the orders are built one partner at a time, keeping every view equal to the restriction of that one function, which loses nothing since a view with fewer partners is a restriction of a writing. Where no one function serves a whole level set, the marks from which a given function can be written form one class and the rest are read again. The computation ends by $k = n - 1$, and at a gauge α every step is an identity of polynomials with coefficients in the field generated by the weights and the coordinates of α; at the table's gauge that is the field generated by the weights, rational for rational weights and integers for lists (Proposition 10.2, Theorem 10.6).*

10.3 What a class holds

Proposition 10.9 (Masses and occupations on a class)**.** *At every realization Υ the masses $\tau_e(\Upsilon)$ and each of their two parts $\varphi^{\mathbf{E}}_e(0)$ and $\varphi^{\mathbf{O}}_e(0)$ (Proposition 9.10) are constant on every class. At the table's gauge:*

(i) $\sum_j \delta_j(2R_{j,e}(\mathbf{1}) - 1)$ is constant on every class, and $\kappa^{\mathbf{E}}_{\Upsilon}(e,e) = 8\sum_j \sigma_j R_{j,e}(\mathbf{1})(1 - R_{j,e}(\mathbf{1}))$;

(ii) with one table, the occupation $R_e(\mathbf{1})$ is constant on every class at a lean, and at the centre two marks e, f of one class have $R_f(\mathbf{1}) = R_e(\mathbf{1})$ or $R_f(\mathbf{1}) = 1 - R_e(\mathbf{1})$.

Chapter 11

Lean, gauge and label

11.1 The lean

Theorem 11.1 (The lean only splits)**.** *At every gauge and every $\boldsymbol{\sigma}$, the partition at a lean $\boldsymbol{\delta}$ refines the partition at the centre. An atom at a lean is an atom at the centre, and a realization that is not an atom at the centre is an atom at no lean.*

Proposition 11.2 (What of the lean is read)**.** *With the gauge α fixed, $\mathrm{Cl}(\Upsilon_{\boldsymbol{\sigma},\boldsymbol{\delta};\alpha})$ depends on $(\boldsymbol{\sigma},\boldsymbol{\delta})$ only through the rays $\{c\boldsymbol{\sigma}\}$ and $\{c'\boldsymbol{\delta}\}$, $c,c'>0$, and $\mathrm{Cl}(\Upsilon_{\boldsymbol{\sigma},-\boldsymbol{\delta};\alpha})=\mathrm{Cl}(\Upsilon_{\boldsymbol{\sigma},\boldsymbol{\delta};\alpha})$. So at one pair, $\boldsymbol{\delta}=\frac{\delta}{\sigma}\boldsymbol{\sigma}$, there are two partitions: $\mathrm{Cl}(\Upsilon_{\boldsymbol{\sigma},0;\alpha})$ at the centre, and $\mathrm{Cl}(\Upsilon_{\boldsymbol{\sigma},\boldsymbol{\delta};\alpha})$, the same for every $\delta\neq 0$ and every $\boldsymbol{\sigma}$ on its ray, which refines it.*

Proposition 11.3 (A lean reads one side)**.** *Let Υ be at one pair (σ,δ), at the table's gauge, and put*

$$\Phi_K(y)=\frac{1}{\sigma}\sum_j \sigma_j \log K_j(e^y), \qquad \Phi_\Psi(y)=\frac{1}{\sigma}\sum_j \sigma_j \log \Psi_j(e^y)=\Phi_K(-y)+\langle \mathbf{1},y\rangle.$$

Then $\Phi_{\mathbf{E}}=\sigma(\Phi_K+\Phi_\Psi)$ and $\Phi_{\mathbf{O}}=\delta(\Phi_K-\Phi_\Psi)$, and:

(i) at every lean the reading of a mark determines, and is determined by, the multiset of writings of Φ_K from it; so for $\delta\neq 0$, $\mathrm{Cl}(\Upsilon)$ is the partition of the marks into the level sets of the multiset of writings of Φ_K, and equally of Φ_Ψ;

(ii) with the tensors $\mathcal{K}_k(w)=\frac{1}{\sigma}\sum_j \sigma_j \kappa_{j,\mathbf{1}}(w)$ on the strings of length k, rung k is $2^{k+1}\sigma\mathcal{K}_k$ for even k and $2^{k+1}\delta\mathcal{K}_k$ for odd k: at a basis lean every rung is a positive multiple of the cumulant sequence $(\mathcal{K}_k)_k$ of the bases, at a cobasis lean of the cumulant sequence $((-1)^k\mathcal{K}_k)_k$ of the cobases, and at the centre only the even rungs, common to the two sequences, are read.

A lean reads the molecule with a preference: at a basis lean it reads the cumulant sequence of the bases, at a cobasis lean that of the cobases, and at the centre only what the two sequences share. The lean can only split the classes of the centre, never join them.

11.2 The gauge

Theorem 11.4 (The gauge step)**.** *Let $\Upsilon=((s_j,t_j)_j;\alpha)$ be a realization of a molecule. If the self-line functions $\varphi_e^{\mathbf{E}}$ of all marks agree up to additive constants, in particular if Υ is an atom, then $\alpha\propto\mathbf{1}$.*

Corollary 11.5 (Scale changes nothing)**.** *At $\alpha = c\mathbf{1}$ every writing is the writing at $\mathbf{1}$ plus a constant that depends on neither the mark nor the order. So $\mathrm{Cl}(\Upsilon_{\boldsymbol{\sigma},\boldsymbol{\delta};c\mathbf{1}}) = \mathrm{Cl}(\Upsilon_{\boldsymbol{\sigma},\boldsymbol{\delta};\mathbf{1}})$, and every atom is an atom at the table's gauge.*

11.3 Answers and the label

Proposition 11.6 (Assembly from arbitrary seed tables)**.** *Let H be a set of bijections of $\mathcal{E}$ closed under composition and inverses that takes every mark to every other. Start from seed tables on $\mathcal{E}$, and for each seed include its image under every $h \in H$, weights transported with the bases and repetitions kept. Give every image of seed a the exponents (s_a, t_a); let q_a be the number of its images with multiplicity, r_a its rank, $D = \sum_a q_a(s_a r_a + t_a(n - r_a))$, $\mathbf{m} = \frac{D}{n}\mathbf{1}$, and suppose the active assembled family is connected. Then for every positive exponent pairs the gauge $\mathbf{1}$ is native, every proper wall is positive, and the realization $((s_a, t_a)_a; \mathbf{1})$ of the assembled family is an atom.*

(i) At $\mathbf{1}$ the occupations summed over the images of seed a are the same at every mark, $q_a r_a/n$, and the dual occupations summed likewise are $q_a(n - r_a)/n$; their sum with the coefficients s_a and t_a is D/n.

(ii) The images under all permutations of a seed with at least two bases form a connected family.

(iii) The seed weights may vary over any positive values before assembly, giving atoms at the one gauge $\mathbf{1}$.

Definition 11.7 (Answers and the label)**.** A molecule *answers yes* when some realization of it is atomic, and *no* otherwise. Let k be the number of molecules of a family with at least two marks and i the number of them that answer yes; units are atomic at every realization and are not counted. The family is *Foreman k-symmetric* when $i = k$ and *Foreman asymmetric* when $i < k$; an asymmetric family with $i > 0$ is *sub-symmetric (i of k)*. The *label* of the family is the pair (i, k).

Theorem 11.8 (The answer is read at the centre)**.** *A molecule answers yes if and only if some centre $\Upsilon_{\boldsymbol{\sigma},0;\mathbf{1}}$ is atomic. With one table this holds if and only if one polynomial is, from every mark, either K or Ψ written from it; the condition does not involve σ.*

Corollary 11.9 (The label is read at the centres)**.** *By Theorem 11.8 the label of a family is read at the centres $\Upsilon_{\boldsymbol{\sigma},0;\mathbf{1}}$ of the table's gauge of its molecules, and a molecule carrying one table is decided by reading it once, at any one such centre.*

Corollary 11.10 (The leaning realizations at one pair)**.** *Let a molecule be read at one pair at the table's gauge, with the strengths $\boldsymbol{\sigma}$. Its leaning realizations $\Upsilon_{\boldsymbol{\sigma},\boldsymbol{\delta};\mathbf{1}}$, $\boldsymbol{\delta} = \frac{\delta}{\sigma}\boldsymbol{\sigma}$, $\delta \neq 0$, are atomic all together or not at all; if they are, so is the centre, and an atomic centre need not make them atomic.*

Whether a molecule can be atomic and whether a particular realization of it is atomic are read differently. The first is read at the centres of the table's gauge, at any one centre when the molecule carries one table; the second at the realization itself, and a lean may split what the centre held together.

Lemma 11.11 (No degenerate pair)**.** *At every realization Υ of a family and for marks $e \neq f$, $\kappa^{\mathbf{E}}_{\Upsilon}(e, f)^2 \leq \kappa^{\mathbf{E}}_{\Upsilon}(e, e)\,\kappa^{\mathbf{E}}_{\Upsilon}(f, f)$, with equality exactly when e or f is a unit or $\{e, f\}$ is a molecule. In particular the inequality is strict for any two marks of a molecule with at least three marks.*

Lemma 11.12 (Equal diagonals on a class)**.** *At every realization Υ, for each part and every $k \geq 2$, the diagonal entry $\kappa^{\mathbf{X}}_{\Upsilon}(e,\dots,e) = 2^k(\varphi^{\mathbf{X}}_e)^{(k-1)}(0)$ of rung k is the same at every mark of a class, the reading determining the self-line functions (Proposition 10.3(iii)); in particular $\kappa^{\mathbf{E}}_{\Upsilon}(e,e) = 4\,(\varphi^{\mathbf{E}}_e)'(0)$ is constant on every class, and at an atom it is the same at every mark.*

11.4 Maps as certificates

Definition 11.13 (Carrying and exchanging)**.** Let F and F' be families on $\mathcal{E}$ and $\mathcal{E}'$ with tables indexed by $\{1,\dots,N\}$ and $\{1,\dots,N'\}$. A bijection $g : \mathcal{E} \to \mathcal{E}'$ *carries* F to F' when some bijection $h : \{1,\dots,N\} \to \{1,\dots,N'\}$ has $g(\mathcal{B}_j) = \mathcal{B}'_{h(j)}$, $\theta'_{h(j),g(T)} = \theta_{j,T}$ and $(\sigma'_{h(j)}, \delta'_{h(j)}) = (\sigma_j, \delta_j)$; it *exchanges* F with F' when instead $T \mapsto \mathcal{E}' \setminus g(T)$ maps $\mathcal{B}_j$ onto $\mathcal{B}'_{h(j)}$ with $\theta'_{h(j),\mathcal{E}'\setminus g(T)} = \theta_{j,T}$ and the same condition on the pairs. With $F' = F$, g carries or exchanges the family. Write $(g^*y)_e = y_{g(e)}$ for $y \in \mathbb{R}^{\mathcal{E}'}$.

Proposition 11.14 (What a map certifies)**.** *At gauges α of F and α' of F' with $g^* \log \alpha' = \log \alpha$, the tables' gauges in particular, and in this statement writing $\Phi^{\boldsymbol{\delta}}_{\mathbf{O}}$ for the odd potential at the lean $\boldsymbol{\delta}$: if g carries F to F' then $\Phi_{\mathbf{X}} \circ g^* = \Phi'_{\mathbf{X}}$, and the reading of $g(e)$ in F' equals that of e in F; if g exchanges F with F' then $\Phi_{\mathbf{E}} \circ g^* = \Phi'_{\mathbf{E}}$ and $\Phi^{-\boldsymbol{\delta}}_{\mathbf{O}} \circ g^* = \Phi'^{\boldsymbol{\delta}}_{\mathbf{O}}$, and the reading of $g(e)$ in F' at $-\boldsymbol{\delta}$ equals that of e in F at $\boldsymbol{\delta}$. So a map carrying the family takes classes onto classes, and an exchange of the family takes the classes at $\boldsymbol{\delta}$ onto those at $-\boldsymbol{\delta}$ and the classes of the centre onto the classes of the centre.*

A map is a certificate, not a definition: classes are the level sets of the reading, and a map carrying or exchanging the family is one way to exhibit that two marks read alike. With one table the writings and the maps say the same thing (Corollary 11.16); with several tables the reading is the definition.

Corollary 11.15 (An exchange negates odd cumulants)**.** *If g exchanges a family, with h the bijection of its tables (Definition 11.13), then under the weight laws $\kappa_{h(j),\mathbf{1}}(g(w)) = (-1)^k \kappa_{j,\mathbf{1}}(w)$ for every table j and every string w of length $k \geq 2$; so the stills at the table's gauge satisfy $\kappa_{\Upsilon_{\boldsymbol{\sigma},\boldsymbol{\delta};\mathbf{1}}}(g(w)) = \kappa_{\Upsilon_{\boldsymbol{\sigma},-\boldsymbol{\delta};\mathbf{1}}}(w)$, and g maps every class of the centre onto itself.*

Corollary 11.16 (With one table the writings are certificates)**.** *In a one-table molecule at the table's gauge, e and f lie in one class at a lean exactly when some bijection taking e to f carries the table, and in one class at the centre exactly when some bijection taking e to f carries or exchanges it.*

Theorem 11.17 (A class across the centre)**.** *In a one-table molecule at the table's gauge, a class C of the centre is, at every lean, one class or two classes with equally many marks. In the second case the two are C_K and C_Ψ, the marks of C from which K, respectively Ψ, is written as one and the same polynomial, and an exchange β built from two such writings has $\beta(C) = C$ and $\beta(C_K) = C_\Psi$.*

Leaning away from the centre, a class of a one-table molecule either stays whole or splits into the half from which the basis polynomial is written and the half from which the cobasis polynomial is: the lean sign decides which half the Foreman meets first (Corollary 13.11).

Chapter 12

Restriction to a bunch

12.1 Patterns and the Taylor cube

Definition 12.1 (Patterns and children)**.** Let $(\mathcal{B},\theta)$ be a table of rank r on $\mathcal{E}$. A bunch (Definition 3.1) is here any nonempty set $B\subseteq\mathcal{E}$, and $R=\mathcal{E}\setminus B$ is its *room*; for a family the objects of a bunch in table j carry the index j. The *patterns* of B are the traces of the bases on it, $\mathrm{pat}(B)=\{T\cap B:\ T\in\mathcal{B}\}$, and $\mathrm{pat}_j(B)$ for table j of a family. For $p\in\mathrm{pat}(B)$ the *signed pattern* is $\chi_p=\mathbf{1}_p-\mathbf{1}_{B\setminus p}\in\mathbb{R}^B$ and the *signed level* is $\ell_p=|p|-\frac{|B|}{2}$. The *child* at p is the table on R with the bases $\mathcal{B}_{(p)}=\{T\setminus p:\ T\cap B=p\}$ and the weights $\theta_{(p),X}=\theta_{X\cup p}$; its Foreman polynomials and its centred polynomial are $K_{(p)}$, $\Psi_{(p)}$ and $\Lambda_{(p)}$.

Lemma 12.2 (Children are tables)**.** *$\mathcal{B}_{(p)}$ is the set of bases of the minor contracting p and deleting $B\setminus p$ (Definition 7.5); it has the exchange property and rank $r-|p|$.*

Lemma 12.3 (Children do not widen)**.** *Let B be a bunch of a table with the room R, p a pattern of B, $A\subseteq R$ and $W\subseteq B$. The width of A in the child at p is at most the width of $A\cup W$ in the table: $c_{(p)}(A)\le c(A\cup W)$.*

Definition 12.4 (Communicatroid; interchange)**.** The *communicatroid* of B is the indexed family of its children $(\mathcal{B}_{(p)},\theta_{(p)})_{p\in\mathrm{pat}(B)}$, tables on the room indexed by their patterns; its *gluing* is $\{U\sqcup p:\ p\in\mathrm{pat}(B),\ U\in\mathcal{B}_{(p)}\}$ with the weights $\theta_{(p),U}$. An indexed family $(\mathcal{A}_p)_p$ of tables on R, indexed by sets $p\subseteq B$ with $\mathcal{A}_p$ of rank $r-|p|$, has *interchange* when, for $U\sqcup p$ and $U'\sqcup p'$ in its gluing and $x\in(U\sqcup p)\setminus(U'\sqcup p')$, there is $y\in(U'\sqcup p')\setminus(U\sqcup p)$ with

$$U-x+y\in\mathcal{A}_p\ \ (x,y\in R),\qquad U+y\in\mathcal{A}_{p-x}\ \ (x\in B,\ y\in R),$$
$$U-x\in\mathcal{A}_{p+y}\ \ (x\in R,\ y\in B),\qquad U\in\mathcal{A}_{p-x+y}\ \ (x,y\in B):$$

a step of the exchange property inside a child, one level down, one level up, or along a level.

Proposition 12.5 (Interchange is the parent's exchange property)**.** *The gluing of the communicatroid of B is the table, weights included, and the communicatroid has interchange. Conversely, an indexed family of tables on R with interchange is the communicatroid of B in its gluing, which is a table: the children remember the parent because the parent is the glued children.*

Proposition 12.6 (Adjacent siblings)**.** *If p and $p+b$ are patterns of B, the children at p and at $p+b$ are the deletion and the contraction of b in one table on $R+b$, the minor contracting p and deleting $B\setminus(p+b)$. So the child at $p+b$ is a quotient of the child at p of rank one less: every*

set of room marks that is maximal for its rank in the child at $p+b$ is maximal for its rank in the child at p, every basis of the child at $p+b$ extends by one room mark to a basis of the child at p, and every basis of the child at p less one suitable mark is a basis of the child at $p+b$.

Theorem 12.7 (The Taylor cube)**.** *For $\alpha=(\alpha_B,\alpha_R)$ and $z=(z_B,z_R)$,*

$$K(\alpha)=\sum_{p\in\mathrm{pat}(B)}\alpha_B^{p}K_{(p)}(\alpha_R),\qquad \Psi(\alpha)=\sum_{p\in\mathrm{pat}(B)}\alpha_B^{B\setminus p}\Psi_{(p)}(\alpha_R),$$
$$\Lambda(z)=\sum_{p\in\mathrm{pat}(B)}e^{\langle z_B,\chi_p\rangle}\Lambda_{(p)}(z_R),$$

with $K_{(p)}=(\partial^p K)|_{\alpha_B=0}$. Along the scale of B, $\alpha_B=e^{2z_B}=\rho u$ with $u\in\Delta_B$, the factor of p in Λ is $e^{\langle z_B,\chi_p\rangle}=\rho^{\ell_p}u^{\chi_p/2}$; the values $|p|$ fill $\{d(B),\dots,r(B)\}$, and the signed levels fill a window of width $c(B)$ centred at $\varepsilon(B)/2$. For $B=\{g\}$ this is the expansion $K=K_{\setminus g}+\alpha_g K_{/g}$, $\Psi=\alpha_g\Psi_{\setminus g}+\Psi_{/g}$ of Definition 7.3.

The Taylor cube is the bunch read on its own coordinates: each pattern contributes a monomial on the bunch, at the level $|p|$, times the polynomial of its child on the room. The levels that occur fill the window of the bunch (Theorem 7.13), and nothing about the room is lost, since the children glued back are the table.

Theorem 12.8 (The pattern tensor)**.** *Under the basis law at α, $\mathbb{P}_\alpha(T\cap B=p)=\alpha_B^{p}K_{(p)}(\alpha_R)/K(\alpha)$, and under the cobasis law $\mathbb{P}^*_\alpha(T\cap B=p)=\alpha_B^{B\setminus p}\Psi_{(p)}(\alpha_R)/\Psi(\alpha)$. The moments of the bunch are the upper sums $\mathbb{P}_\alpha(T\cap B\supseteq S)=\sum_{p\supseteq S}\mathbb{P}_\alpha(T\cap B=p)$, and the joint cumulants $\kappa_\alpha(w)$ on the strings w of marks of B are their image under the moment–cumulant relation. Scaling α_B multiplies the entry of p by its own monomial, and inverting the gauge swaps the two laws pattern by pattern (Proposition 12.28(ii) below).*

Proposition 12.9 (Tinkers along a bunch; selecting patterns)**.** *For a* tinker *$v=(v_p)_{p\in\mathrm{pat}(B)}$ of positive numbers, the weights $v_{T\cap B}\theta_T$ define the* tinkered table*, with the same bases and the Foreman polynomials*

$$K_v(\alpha)=\sum_p v_p\,\alpha_B^{p}K_{(p)}(\alpha_R),\qquad \Psi_v(\alpha)=\sum_p v_p\,\alpha_B^{B\setminus p}\Psi_{(p)}(\alpha_R).$$

Selecting the pattern p on B, that is keeping the bases with $T\cap B=p$, and then p' on B' selects $p\cup p'$ on $B\cup B'$ when $p\cap B'=p'\cap B$, and nothing otherwise; so the selections on a table with n marks are at most the 3^n conditions that require each mark present, absent, or nothing. At the centre every tinkered table keeps $\mathbf{1}$ native (Proposition 8.21).

12.2 The Skeleton polynomials of a bunch

Definition 12.10 (Skeleton polynomials, values and coins)**.** At a gauge α, with the level $N_B=|T\cap B|$ and the *colevel* $N_B^*=|B\setminus T|$, the *Skeleton polynomials* of B are

$$\mathsf{Q}_B^{K}(x;\alpha)=\mathbb{E}_{T\sim\mathbb{P}_\alpha}\big[x^{N_B-d(B)}\big]=x^{-d(B)}\frac{K(x\alpha_B,\alpha_R)}{K(\alpha)},$$
$$\mathsf{Q}_B^{\Psi}(x;\alpha)=\mathbb{E}_{T\sim\mathbb{P}^*_\alpha}\big[x^{N_B^*-d^*(B)}\big]=x^{-d^*(B)}\frac{\Psi(x\alpha_B,\alpha_R)}{\Psi(\alpha)},$$

and $\mathsf{Q}^K_{j,B}$, $\mathsf{Q}^\Psi_{j,B}$ for table j of a family. Each has degree $c(B)$, positive coefficients and value 1 at $x=1$, so its roots avoid $[0,\infty)$; writing them $-\xi_1,\dots,-\xi_{c(B)}$,

$$\mathsf{Q}^K_B(x;\alpha)=\prod_{i=1}^{c(B)}\frac{x+\xi_i}{1+\xi_i}=\prod_{i=1}^{c(B)}(1-p_i+p_ix),\qquad p_i=\frac{1}{1+\xi_i}.$$

The ξ_i are the *Skeleton values*, their multiset $\operatorname{spec}^K_B(\alpha)\subset\mathbb{C}\setminus(-\infty,0]$ is the *Skeleton spectrum*, and the p_i are the *coins*; likewise $\operatorname{spec}^\Psi_B(\alpha)$ and the coins of Q^Ψ_B. The *cumulants of a coin* are $\varkappa_1(p)=p$ and $\varkappa_{k+1}(p)=p(1-p)\,\varkappa_k'(p)$.

The Skeleton polynomial is the law of the level of the bunch, shifted to start at its floor: its degree is the width of the bunch, and its roots are the negatives of the Skeleton values. When the spectrum is positive the level less its floor $d(B)$ is a sum of $c(B)$ independent $\{0,1\}$-valued variables whose means are the coins.

Proposition 12.11 (Relations of the Skeleton polynomials)**.** *(i)* Scaling. *Scaling α_B by $\lambda>0$ divides the spectrum by λ:*

$$\mathsf{Q}^K_B\big(x;(\lambda\alpha_B,\alpha_R)\big)=\mathsf{Q}^K_B(\lambda x;\alpha)/\mathsf{Q}^K_B(\lambda;\alpha);$$

likewise for Ψ; scaling all of α changes nothing.

(ii) Complement. $\mathsf{Q}^K_R(x;\alpha)=x^{c(B)}\mathsf{Q}^K_B(x^{-1};\alpha)$*: the spectrum of the room is the reciprocal of that of the bunch, and each coin p_i becomes $1-p_i$; likewise for Ψ.*

(iii) Cremona. $\mathsf{Q}^\Psi_B(x;\alpha)=x^{c(B)}\mathsf{Q}^K_B(x^{-1};\alpha^{-1})$*; at the table's gauge,* $\mathsf{Q}^\Psi_B(x;\mathbf{1})=x^{c(B)}\mathsf{Q}^K_B(x^{-1};\mathbf{1})$.

(iv) Coins. $\log\mathsf{Q}^K_B(e^v;\alpha)=\sum_i\log(1-p_i+p_ie^v)$*; under $\mathbb{P}_\alpha$ the level N_B has mean $d(B)+\sum_i p_i=\sum_{e\in B}R_e(\alpha)$ and k-th cumulant $\sum_i\varkappa_k(p_i)$ for $k\ge2$. When the spectrum is positive the coins lie in $(0,1)$ and $N_B-d(B)$ is distributed as a sum of independent $\{0,1\}$-valued variables whose means are the coins.*

Proposition 12.12 (The still read along a bunch)**.** *Let a family be at a gauge α, let $p_{j,i}$ be the coins of $\mathsf{Q}^K_{j,B}(\cdot;\alpha)$ and $p^*_{j,i}$ those of $\mathsf{Q}^\Psi_{j,B}(\cdot;\alpha)$, and put $\partial_B=\sum_{e\in B}\partial_{y_e}$. Then*

$$\sum_j\Big(s_j\sum_i p_{j,i}+t_j\sum_i p^*_{j,i}\Big)=\partial_B\Phi(\log\alpha)-\sum_j\big(s_jd_j(B)+t_jd^*_j(B)\big),$$
$$\partial_B^k\Phi(\log\alpha)=\sum_j\Big(s_j\sum_i\varkappa_k(p_{j,i})+t_j\sum_i\varkappa_k(p^*_{j,i})\Big)\qquad(k\ge2).$$

At a native gauge the first total is the wall κ_B at the masses $\boldsymbol{\tau}$, and on the balance wall it is κ_B; the entries of rung k of the still of $\big((s_j,t_j)_j;\alpha\big)$, summed over B^k, are 2^k times the second total.

Proposition 12.13 (Coins of a tensorminental table)**.** *In the setting of Theorem 7.23, let $p_i^{(kl)}$, $1\le i\le|B|$, be the eigenvalues of $\Pi^{(kl)}_{BB}$. Then*

$$x^{d(B)}\mathsf{Q}^K_B(x;\alpha)=\sum_{k,l}w_{kl}\prod_{i=1}^{|B|}\big(1-p_i^{(kl)}+p_i^{(kl)}x\big)\,:$$

the Skeleton polynomial is the w-mixture of the coin products of the components. At tensor rank one over $\mathbb{F}\in\{\mathbb{R},\mathbb{C}\}$ there is one component, and $\Pi^{(11)}_{BB}$ is similar to the compression to $\mathbb{F}^B$ of the

orthogonal projection onto the row space of $AD_\alpha^{1/2}$, A the slice; its eigenvalues are $\cos^2\vartheta_i$ for the principal angles ϑ_i between $\mathbb{F}^B$ and that row space. Of these, $d(B)$ are 1 and $d^*(B)$ are 0, and the $c(B)$ coins are the values $\cos^2\vartheta_i \in (0,1)$, with the positive Skeleton values $\tan^2\vartheta_i$.

Definition 12.14 (The pair of Skeleton functions)**.** The *even* and *odd Skeleton functions* of B are $\mathsf{Q}^{\mathbf{E}}_B(x;\alpha) = \mathsf{Q}^K_B(x;\alpha)\,\mathsf{Q}^\Psi_B(x;\alpha)$ and $\mathsf{Q}^{\mathbf{O}}_B(x;\alpha) = \mathsf{Q}^K_B(x;\alpha)/\mathsf{Q}^\Psi_B(x;\alpha)$. So

$$\mathsf{Q}^{\mathbf{E}}_B(x;\alpha) = \mathbb{E}_{(T,T')\sim\mathbb{P}_\alpha\otimes\mathbb{P}^*_\alpha}\Big[x^{|T\cap B|-d(B)+|B\setminus T'|-d^*(B)}\Big],$$

and its roots are the negatives of the *joint spectrum* $\operatorname{spec}^K_B(\alpha)\cup\operatorname{spec}^\Psi_B(\alpha)$.

Proposition 12.15 (A set on its own scale is read by its Skeleton functions)**.** *For a family at a gauge α, a set C of marks and $x = e^v$,*

$$\Phi_{\mathbf{E}}(\log\alpha + v\mathbf{1}_C) - \Phi_{\mathbf{E}}(\log\alpha) = \sum_j \sigma_j\Big(\log\mathsf{Q}^{\mathbf{E}}_{j,C}(x;\alpha) + \big(d_j(C)+d_j^*(C)\big)v\Big),$$
$$\Phi_{\mathbf{O}}(\log\alpha + v\mathbf{1}_C) - \Phi_{\mathbf{O}}(\log\alpha) = \sum_j \delta_j\Big(\log\mathsf{Q}^{\mathbf{O}}_{j,C}(x;\alpha) + \big(d_j(C)-d_j^*(C)\big)v\Big).$$

Along the scale of a set the K-half of each table's joint spectrum carries the exponent $s_j = \sigma_j + \delta_j$ and the Ψ-half carries $t_j = \sigma_j - \delta_j$.

12.3 Levels

Definition 12.16 (Levels)**.** For $d(B) \le k \le r(B)$ the *level-k patterns* are $\operatorname{pat}^{(k)}(B) = \{p \in \operatorname{pat}(B) :\ |p| = k\}$, the *level-$k$ bases* are $\mathcal{B}^{(k)}_B = \{T \in \mathcal{B} :\ |T\cap B| = k\}$, and the *level letter* is

$$K^{(k)}_B(\alpha) = \sum_{T\in\mathcal{B}^{(k)}_B}\theta_T\alpha^T = \sum_{p\in\operatorname{pat}^{(k)}(B)}\alpha^p_B K_{(p)}(\alpha_R).$$

For $d^*(B) \le k \le |B| - d(B)$ the *colevel letter* is $\Psi^{(k)}_B(\alpha) = \sum_{T:\,|B\setminus T|=k}\theta_T\alpha^{\mathcal{E}\setminus T}$. The *excess* of the level k, of its patterns and of its bases is $k - d(B)$, and that of the colevel k is $k - d^*(B)$. Then $K = \sum_k K^{(k)}_B$, $\Psi = \sum_k \Psi^{(k)}_B$,

$$x^{d(B)}\mathsf{Q}^K_B(x;\alpha) = \sum_k x^k\,\frac{K^{(k)}_B(\alpha)}{K(\alpha)}, \qquad x^{d^*(B)}\mathsf{Q}^\Psi_B(x;\alpha) = \sum_k x^k\,\frac{\Psi^{(k)}_B(\alpha)}{\Psi(\alpha)}.$$

Proposition 12.17 (Pattern levels are lifts)**.** *Let $\mathcal{B}|B$ be the restriction to B and $\mathcal{B}/R$ the contraction of the room, a table on B with rank function $r_{\mathcal{B}/R}(X) = r(X\cup R) - r(R)$ and rank $d(B)$.*

(i) $p \subseteq B$ is a pattern if and only if p is independent and $r_{\mathcal{B}/R}(p) = d(B)$.

(ii) For $i = k - d(B)$, the independent sets $X \subseteq B$ with $|X| - r_{\mathcal{B}/R}(X) \le i$ are the independent sets of a table on B of rank k, the i-th lift of $\mathcal{B}/R$ toward $\mathcal{B}|B$, whose bases are the level-k patterns. So every pattern level $\operatorname{pat}^{(k)}(B)$ is a table on B.

(iii) The room sides $T\cap R$ of the level-k bases are the bases of the $(r(B)-k)$-th lift of $\mathcal{B}/B$ toward $\mathcal{B}|R$.

Definition 12.18 (Interaction)**.** Let a table have a bunch B with room R and $\mathrm{pat}(B) = 2^B$: every $p \subseteq B$ is a pattern, equivalently $c(B) = |B|$, that is B is independent and some basis avoids it (Proposition 12.17(i)). The *interaction* and the *dual interaction* of B are

$$\iota_B(\alpha_R) = \sum_{p\subseteq B} (-1)^{|B\setminus p|} \log K_{(p)}(\alpha_R), \qquad \iota^*_B(\alpha_R) = \sum_{p\subseteq B} (-1)^{|p|} \log \Psi_{(p)}(\alpha_R),$$

the second the interaction of the dual table, and for a split of B into blocks $B_1, \dots, B_k$,

$$\iota_{(B_1,\dots,B_k)}(\alpha_R) = \sum_{A\subseteq\{1,\dots,k\}} (-1)^{k-|A|} \log K_{(\cup_{a\in A} B_a)}(\alpha_R).$$

For two marks, $\iota_{\{e,f\}} = \log \frac{K_{(\{e,f\})} K_{(\varnothing)}}{K_{(\{e\})} K_{(\{f\})}}$, the logarithm of the odds ratio of the presence of the two marks. For a family with $\mathrm{pat}_j(B) = 2^B$ in every active table j, the *interaction* of B is the pair

$$\iota^{\mathbf{E}}_B = \sum_j \sigma_j\big(\iota_{j,B} + \iota^*_{j,B}\big), \qquad \iota^{\mathbf{O}}_B = \sum_j \delta_j\big(\iota_{j,B} - \iota^*_{j,B}\big), \qquad \iota^{\mathbf{E}}_B + \iota^{\mathbf{O}}_B = \sum_j \big(s_j \iota_{j,B} + t_j \iota^*_{j,B}\big),$$

the interactions of the even and the odd part of the potential (Definition 8.18).

Theorem 12.19 (Levels are sums of children)**.** $\mathcal{B}^{(k)}_B = \bigsqcup_{p\in\mathrm{pat}^{(k)}(B)} \mathcal{B}_{[p]}$, *where* $\mathcal{B}_{[p]} = \{T \in \mathcal{B} : T \cap B = p\}$ *is the set of bases of the table on* $\mathcal{E}$ *that has* p *as coloops,* $B \setminus p$ *as loops and the child at* p *on* R*, with the parent's weights; its basis polynomial is* $\alpha^p_B K_{(p)}(\alpha_R)$*. A bijection* g *of* $\mathcal{E}$ *that carries the table and keeps* B *takes* $\mathcal{B}_{[p]}$ *to* $\mathcal{B}_{[g(p)]}$*. The extreme levels have constant children:*

$$\mathcal{B}^{(d(B))}_B = \{p \sqcup X :\ p \in \mathcal{B}/R,\ X \in \mathcal{B}|R\}, \qquad \mathcal{B}^{(r(B))}_B = \{p \sqcup X :\ p \in \mathcal{B}|B,\ X \in \mathcal{B}/B\};$$

for a table determinantal over $\mathbb{R}$ *or* $\mathbb{C}$ *the weights of the extreme levels factor along these products, and with them the extreme letters,* $K^{(d(B))}_B(\alpha) = K_{\mathcal{B}/R}(\alpha_B)\, K_{\mathcal{B}|R}(\alpha_R)$ *and* $K^{(r(B))}_B(\alpha) = K_{\mathcal{B}|B}(\alpha_B)\, K_{\mathcal{B}/B}(\alpha_R)$*.*

The bases of one level need not form a table: a step of the exchange property may leave the level, and it then moves to an adjacent one (Proposition 12.5). What a level keeps is its patterns, which form a table (Proposition 12.17); its bases are the glued children of those patterns, and children on adjacent levels are linked by Proposition 12.6. The level is the coordinate the bunch keeps for itself, and the children hand the rest down to the room.

Proposition 12.20 (The bottom of a chain factors over its steps)**.** *Let* $(\mathcal{B}, \theta)$ *be a table on* $\mathcal{E}$ *and* $\varnothing = S_0 \subsetneq S_1 \subsetneq \cdots \subsetneq S_\ell \subsetneq S_{\ell+1} = \mathcal{E}$*,* $\ell \geq 1$*, a chain with the steps* $Z_i = S_i \setminus S_{i-1}$*,* $1 \leq i \leq \ell+1$*. Some bases are at the bottom of every* S_i*,* $|T \cap S_i| = d(S_i)$ *for* $1 \leq i \leq \ell$*. For any one of them,* T_0*, and every* i*, the traces on* Z_i *of these bases are the bases of the child* $\mathcal{B}_{(T_0\setminus Z_i)}$ *at the pattern* $T_0 \setminus Z_i$ *of* $\mathcal{E} \setminus Z_i$ *(Definition 12.1), the* step table at the bottom *at* Z_i*, which depends on* S_{i-1} *and* S_i *alone; and the bases at the bottom of every* S_i *are exactly the unions* $\bigsqcup_i X_i$ *of one basis* X_i *of each step table. Likewise the bases at the top of every* S_i*,* $|T \cap S_i| = r(S_i)$*, with one of them* T_1*, give the* step tables at the top $\mathcal{B}_{(T_1\setminus Z_i)}$*.*

For a list, the terms of K *of the least degree in* α_{S_i} *for every* i *at once are the product* $\prod_i K_{\mathcal{B}_{(T_0\setminus Z_i)}}(\alpha_{Z_i})$*, and those of* Ψ *the product* $\prod_i \Psi_{\mathcal{B}_{(T_1\setminus Z_i)}}(\alpha_{Z_i})$*; the factors are the* step letters *of* K *and of* Ψ*, the same products holding for a table whose weights on these bases are products of one factor for each step. For the linear letter* α_J*, the basis polynomial of* $\binom{J}{1}$ *read on* $\mathcal{E}$ *with the marks outside* J *as loops, the step letter is* $\alpha_{J\cap Z_i}$ *at the first step* Z_i *with* $J \subseteq S_i$ *and* 1 *at the other*

steps. Along a maximal chain, every step one mark, exactly one basis is at the bottom of every S_i, and for a list the terms of K of the least degree in every α_{S_i} at once are one monomial with the coefficient 1.

Theorem 12.21 (Shared walls)**.** *Let $L_i = \sum_h K_{i,h}$, $i = 1, \dots, q$, each a sum of the basis polynomials $K_{i,h}$ of tables $\mathcal{B}_{i,h}$ on $\mathcal{E}$, with exponents $w_i > 0$, and put $d_{i,h}(S) = \min_{T \in \mathcal{B}_{i,h}} |T \cap S|$. Then*

$$\int_{\mathbb{R}^{\mathcal{E}}_{>0}} \alpha^{\mathbf{m}-\mathbf{1}} e^{-|\alpha|} \prod_i L_i(\alpha)^{-w_i}\, d\alpha$$

converges if and only if there are $w_{i,h} > 0$ with $\sum_h w_{i,h} = w_i$ and $m_S > \sum_{i,h} w_{i,h}\, d_{i,h}(S)$ for every nonempty $S \subseteq \mathcal{E}$; equivalently $\mathbf{m} \in \operatorname{int}\big(\sum_i w_i \operatorname{conv} \bigcup_h P_{i,h} + \mathbb{R}^{\mathcal{E}}_{\geq 0}\big)$, with $P_{i,h}$ the base polytope of $\mathcal{B}_{i,h}$.

Proposition 12.22 (The walls of one level are exact)**.** *With P the base polytope, $P_B^{(k)} = \operatorname{conv}\{\mathbf{1}_T : T \in \mathcal{B}_B^{(k)}\}$ and $d_B^{(k)}(S) = \min_{T \in \mathcal{B}_B^{(k)}} |T \cap S|$:*

$$P_B^{(k)} = P \cap \{x_B = k\}, \qquad P_B^{(k)} + \mathbb{R}^{\mathcal{E}}_{\geq 0} = \{x :\ x_S \geq d_B^{(k)}(S) \text{ for all } S\}.$$

So for $w > 0$ the integral $\int_{\mathbb{R}^{\mathcal{E}}_{>0}} \alpha^{\mathbf{m}-\mathbf{1}} e^{-|\alpha|} K_B^{(k)}(\alpha)^{-w} d\alpha$ converges exactly when $m_S > w\, d_B^{(k)}(S)$ for every nonempty S. The one-dimensional faces of $P_B^{(k)}$ that do not join two bases differing by a single step of the exchange property are diagonals of square two-dimensional faces of P, one step into B and one out of it.

For several levels together the 0/1 walls need not be exact: the facets of $\sum_k w_k P_B^{(k)} + \mathbb{R}^{\mathcal{E}}_{\geq 0}$ are normal to rays of the common refinement of the normal fans of the $P_B^{(k)}$, which can lie outside $\{0,1\}^{\mathcal{E}}$, and the exact domain of several levels together is then the one of Theorem 12.21.

Corollary 12.23 (The native level split is interior)**.** *Let a family with real data, $s_j, t_j \geq 0$ not all zero and $\mathbf{m} > 0$, have a native gauge $\alpha^\star$, and give the level letters $K_{j,B}^{(k)}$ of table j the exponents $s_j\, \mathbb{P}_{j,\alpha^\star}(N_B = k)$ and its colevel letters $\Psi_{j,B}^{(k)}$ the exponents $t_j\, \mathbb{P}^*_{j,\alpha^\star}(N_B^* = k)$. Then $\boldsymbol{\tau}$ lies in the relative interior of the Minkowski sum of the level and colevel polytopes, each multiplied by the exponent of its letter, and every wall of these letters at the masses $\boldsymbol{\tau}$,*

$$\tau_S - \sum_{j,k} \Big(s_j\, \mathbb{P}_{j,\alpha^\star}(N_B = k)\, d_{j,B}^{(k)}(S) + t_j\, \mathbb{P}^*_{j,\alpha^\star}(N_B^* = k)\, d_{j,B}^{*(k)}(S) \Big),$$

$d_{j,B}^{(k)}$ the level counts of Proposition 12.22 and $d_{j,B}^{*(k)}(S)$ the least of $|S \setminus T|$ over the colevel-k bases, is positive except on the sets S on which x_S is constant over every level and colevel polytope, among them B and R. If the marks of B are joined to one another, and the marks of R to one another, by chains in which consecutive marks lie in a common circuit of a table with a positive exponent, as they are when such a table is connected, then the directions v with $\langle v, x\rangle$ constant on that Minkowski sum are spanned by $\mathbf{1}_B$ and $\mathbf{1}_R$, there are no exceptions besides these and $\varnothing, \mathcal{E}$, and

$$\int_{\Delta_B \times \Delta_R} u^{\boldsymbol{\tau}|_B - \mathbf{1}} v^{\boldsymbol{\tau}|_R - \mathbf{1}} \prod_{j,k} K_{j,B}^{(k)}(u,v)^{-s_j \mathbb{P}_{j,\alpha^\star}(N_B = k)} \Psi_{j,B}^{(k)}(u,v)^{-t_j \mathbb{P}^*_{j,\alpha^\star}(N_B^* = k)}\, d\omega_B(u)\, d\omega_R(v)$$

converges.

12.4 Shares and the native split

Definition 12.24 (Shares, loads, children of a family)**.** For a family and a bunch B, *shares* are $\mathbf{a}_j = (a_{j,p})_{p\in \mathrm{pat}_j(B)}$ with $|\mathbf{a}_j| = s_j$ and $\mathbf{b}_j = (b_{j,p})_{p\in \mathrm{pat}_j(B)}$ with $|\mathbf{b}_j| = t_j$; the *pair shares* are $\sigma_{j,p} = \frac{a_{j,p}+b_{j,p}}{2}$ and $\delta_{j,p} = \frac{a_{j,p}-b_{j,p}}{2}$. A K-share of pattern p loads the marks of p, and a Ψ-share loads those of $B \setminus p$: the *load* and the *odd load* on $e \in B$ are

$$\mathrm{load}_e = \sum_j \Big(\sum_{p\ni e} a_{j,p} + \sum_{p\not\ni e} b_{j,p} \Big) = \sigma + \langle \boldsymbol{\delta} \rangle_e, \qquad \langle \boldsymbol{\delta} \rangle_e = \sum_{j,p} \delta_{j,p} \chi_p(e).$$

The *children* are the family

$$F_B(\mathbf{a}, \mathbf{b}) = \big((\mathcal{B}_{j,(p)}, \theta_{j,(p)});\, a_{j,p}, b_{j,p} \big)_{j,p} \quad \text{on } R.$$

Definition 12.25 (Pattern probabilities; the native split)**.** At a gauge β the *pattern probabilities* of table j are $\pi_{j,p}(\beta) = \mathbb{P}_{j,\beta}(T \cap B = p)$ and $\pi^*_{j,p}(\beta) = \mathbb{P}^*_{j,\beta}(T \cap B = p)$. At a native gauge $\alpha^\star$ the *native split* is the choice of shares $\mathbf{a}^\star$, $\mathbf{b}^\star$ with $a^\star_{j,p} = s_j \pi_{j,p}(\alpha^\star)$ and $b^\star_{j,p} = t_j \pi^*_{j,p}(\alpha^\star)$, and $F_B(\mathbf{a}^\star, \mathbf{b}^\star)$ are the children at the native split.

Theorem 12.26 (Nativity is hereditary)**.** *$\alpha^\star|_R$ is a native gauge for the children $F_B(\mathbf{a}^\star, \mathbf{b}^\star)$ with target $\boldsymbol{\tau}|_R$, and they lie on their own balance wall at the masses $\boldsymbol{\tau}|_R$; every set $S \subseteq R$ with $c_{j,(p)}(S) = 0$ for every child table is balanced, $\tau_S = \sum_{j,p} \big(a^\star_{j,p} r_{j,(p)}(S) + b^\star_{j,p} r^*_{j,(p)}(S) \big)$.*

Proposition 12.27 (The centre is hereditary)**.** *Let $\Upsilon = ((s_j, t_j)_j; \mathbf{1})$ be at the table's gauge, with its masses. The native split gives the child (j,p) the pair*

$$\sigma_{j,p} = \pi_{j,p}(\mathbf{1})\, \sigma_j, \qquad \delta_{j,p} = \pi_{j,p}(\mathbf{1})\, \delta_j, \qquad \pi_{j,p}(\mathbf{1}) = \mathbb{P}_{j,\mathbf{1}}(T \cap B = p) > 0,$$

and the gauge $\mathbf{1}$ on R, the children's own table's gauge, native for them. At a centre every child sits at a centre; at one pair the children are at the same pair; a full lean is handed down full.

Proposition 12.28 (The split is forced)**.** *(i) For every gauge β and every probability vector w on $\mathrm{pat}_j(B)$ with every $w_p > 0$,*

$$K_j(\beta) \;\geq\; \prod_p \Big(\frac{\beta_B^p K_{j,(p)}(\beta_R)}{w_p} \Big)^{w_p},$$

with equality if and only if $\pi_{j,p}(\beta) = w_p$ for every p; likewise for Ψ_j with the pattern terms $\beta_B^{B\setminus p} \Psi_{j,(p)}(\beta_R)$ and $\pi^*_{j,p}(\beta)$. So the shares $a_{j,p} = s_j w_p$ replace $K_j^{-s_j}$ by the product of its pattern terms exactly at the gauges where the basis law puts the proportions w on the patterns; at the gauge of a realization the only such shares are its native split.

(ii) $\beta_B^{-p} K_{j,(p)}(\beta_R^{-1}) = \beta^{-\mathcal{E}} \beta_B^{B\setminus p} \Psi_{j,(p)}(\beta_R)$ and $\pi_{j,p}(\beta^{-1}) = \pi^*_{j,p}(\beta)$: Cremona turns the K-term of each pattern into its Ψ-term, acting on each child as the child's own Cremona. At the table's gauge $\pi^*_{j,p}(\mathbf{1}) = \pi_{j,p}(\mathbf{1})$: the forced shares split s_j and t_j in the same proportions.

A bunch hands its room a family of children, one for each pattern of each table, and the native split is the one choice of shares under which the room inherits everything: the gauge stays native, the masses restrict, and a centre hands down centres. The inequality of (i) is why: at a gauge, the pattern terms of a letter can stand in for the letter with no loss only in the proportions in which the law at that gauge already uses them.

Chapter 13

The order of classes and the Foreman bunch

13.1 The rises of a class

Definition 13.1 (The rises of a class)**.** Let a molecule M with n marks be read at realizations $\Upsilon_{\boldsymbol{\sigma},\boldsymbol{\delta};\mathbf{1}}$ at the table's gauge with $\boldsymbol{\sigma}$ fixed, and let C be a class of the realization at hand, with m marks, and R its room. For a function f of $v = (v_0, \dots, v_k)$ analytic at 0, $\mathring{f}(v) = f(v) - f(0) - \sum_i v_i\, \partial_{v_i} f(0)$ is f less its value and its tangent.

(i) For $0 \le k \le n-m$ and distinct partners $\mathbf{g} = (g_1, \dots, g_k)$ in R, the *rise of C with the partners* $\mathbf{g}$ is the increase of the potential along the class, each partner on its own scale:

$$V^{\mathbf{X}}_{C,\mathbf{g}}(v_0, \dots, v_k) = \Phi_{\mathbf{X}}\Big(v_0 \mathbf{1}_C + \sum_{i=1}^{k} v_i \mathbf{1}_{g_i}\Big) - \Phi_{\mathbf{X}}\Big(\sum_{i=1}^{k} v_i \mathbf{1}_{g_i}\Big).$$

Stage k is the multiset $\mathcal{V}_k(C)$ of the pairs $(\mathring{V}^{\mathbf{E}}_{C,\mathbf{g}}, \mathring{V}^{\mathbf{O}}_{C,\mathbf{g}})$ over the k-tuples of distinct marks of R; stage 0 is the class on its own scale.

(ii) For an order $w = (c_1, \dots, c_m; r_1, \dots, r_{n-m})$ of the marks that lists those of C first and then those of R, the *rise from the class* is

$$\overline{V}^{\mathbf{X}}_{C,w}(u_1, \dots, u_m, v_1, \dots, v_{n-m}) = \Phi_{\mathbf{X}}\Big(\sum_i u_i \mathbf{1}_{c_i} + \sum_j v_j \mathbf{1}_{r_j}\Big) - \Phi_{\mathbf{X}}(0),$$

with positions $0, \dots, n-1$ in the order of w, and the *last stage* is the multiset $\mathcal{V}_*(C)$ of the pairs $(\overline{V}^{\mathbf{E}}_{C,w}, \overline{V}^{\mathbf{O}}_{C,w})$ over the $m!\,(n-m)!$ such orders.

$\mathcal{V}_k(C)$ has $(n-m)!/(n-m-k)!$ elements; $v_k = 0$ turns the rise with $(g_1, \dots, g_k)$ into the rise with $(g_1, \dots, g_{k-1})$; for a single mark an element of $\mathcal{V}_*(\{e\})$ is a writing of the potential from e, less $\Phi_{\mathbf{X}}(0)$.

A class is first read on its own scale, then with one partner of the room at a time, then with more, and last from the class with every mark on its own scale. Every stage before the last is taken less its value and tangent; the last stage holds the whole potential.

Proposition 13.2 (Every rise is read by the Skeleton functions of the class)**.** *With $x = e^{v_0}$ and $\alpha = e^{\sum_i v_i \mathbf{1}_{g_i}}$, the gauge the partners move to,*

$$V^{\mathbf{E}}_{C,\mathbf{g}}(v_0, \dots, v_k) = \sum_j \sigma_j \Big(\log \mathsf{Q}^{\mathbf{E}}_{j,C}(x;\alpha) + \big(d_j(C) + d^*_j(C)\big) v_0 \Big),$$

$$V^{\mathbf{O}}_{C,\mathbf{g}}(v_0,\dots,v_k)=\sum_j \delta_j\Big(\log \mathsf{Q}^{\mathbf{O}}_{j,C}(x;\alpha)+\big(d_j(C)-d^*_j(C)\big)v_0\Big).$$

Stage 0 reads the Skeleton functions of C at the table's gauge, and stage k reads them at every gauge that k partners move to.

Proposition 13.3 (The rises hold the cumulants of the class with its partners)**.** *For $\mathbf{a}=(a_0,\dots,a_k)\in\mathbb{N}^{k+1}$ write, in this statement, $\kappa_j(\mathbf{a})=\kappa_{j,\mathbf{1}}\big(N_C^{\times a_0},X_{g_1}^{\times a_1},\dots,X_{g_k}^{\times a_k}\big)$, the joint cumulant, under the weight law $\mathbb{P}_{j,\mathbf{1}}$, of the sequence of variables in which the level N_C appears a_0 times and the indicator X_{g_i} appears a_i times. For $a_0\geq 1$ and $|\mathbf{a}|\geq 2$,*

$$[v^{\mathbf{a}}]\,V^{\mathbf{E}}_{C,\mathbf{g}}=\frac{1+(-1)^{|\mathbf{a}|}}{\mathbf{a}!}\sum_j\sigma_j\kappa_j(\mathbf{a}),\qquad [v^{\mathbf{a}}]\,V^{\mathbf{O}}_{C,\mathbf{g}}=\frac{1-(-1)^{|\mathbf{a}|}}{\mathbf{a}!}\sum_j\delta_j\kappa_j(\mathbf{a}),$$

and the coefficients with $a_0=0$ vanish. By multilinearity $\kappa_j(\mathbf{a})$ is the sum, over the strings $u\in C^{a_0}$, of the cumulants $\kappa_{j,\mathbf{1}}$ along the strings that continue u with each g_i taken a_i times: the entries of the still on those strings, summed over the class and read table by table.

Corollary 13.4 (The first two stages in coins)**.** *(i) For $a\geq 2$, $[v_0^a]\,\mathring{V}^{\mathbf{E}}_{C,()}=\frac{2}{a!}\sum_j\sigma_j\kappa_{j,\mathbf{1}}(N_C^{\times a})$ for even a and $[v_0^a]\,\mathring{V}^{\mathbf{O}}_{C,()}=\frac{2}{a!}\sum_j\delta_j\kappa_{j,\mathbf{1}}(N_C^{\times a})$ for odd a, the other coefficients being zero; and $\kappa_{j,\mathbf{1}}(N_C^{\times a})=\sum_i\varkappa_a(p_{j,i})$ over the coins $p_{j,i}$ of $\mathsf{Q}^K_{j,C}(\cdot;\mathbf{1})$.*

(ii) For a partner g and $q\geq 1$, with $R_{j,g}(e^{\pm v_0\mathbf{1}_C})$ the occupation of g in table j at the gauge $e^{\pm v_0\mathbf{1}_C}$,

$$[v_1^q]\,V^{\mathbf{E}}_{C,(g)}=\frac{1}{q!}\sum_j\sigma_j\Big(\varkappa_q\big(R_{j,g}(e^{v_0\mathbf{1}_C})\big)+(-1)^q\varkappa_q\big(R_{j,g}(e^{-v_0\mathbf{1}_C})\big)-\big(1+(-1)^q\big)\varkappa_q\big(R_{j,g}(\mathbf{1})\big)\Big),$$

$$[v_1^q]\,V^{\mathbf{O}}_{C,(g)}=\frac{1}{q!}\sum_j\delta_j\Big(\varkappa_q\big(R_{j,g}(e^{v_0\mathbf{1}_C})\big)-(-1)^q\varkappa_q\big(R_{j,g}(e^{-v_0\mathbf{1}_C})\big)-\big(1-(-1)^q\big)\varkappa_q\big(R_{j,g}(\mathbf{1})\big)\Big).$$

13.2 The order

Definition 13.5 (Comparing)**.** (i) *Exponents.* For $\mathbf{a},\mathbf{a}'\in\mathbb{N}^{k+1}$, $\mathbf{a}\sqsubset\mathbf{a}'$ when $a_i<a'_i$ at the largest position i with $a_i\neq a'_i$.

(ii) *Functions.* For functions $f\neq f'$ of the positions $0,\dots,k$, analytic at 0: $f\lhd f'$ when $[v^{\mathbf{a}}]f<[v^{\mathbf{a}}]f'$ at the $\sqsubset$-least exponent at which their coefficients differ.

(iii) *Pairs.* $(f^{\mathbf{E}},f^{\mathbf{O}})\lhd(f'^{\mathbf{E}},f'^{\mathbf{O}})$ when $f^{\mathbf{E}}\lhd f'^{\mathbf{E}}$, or $f^{\mathbf{E}}=f'^{\mathbf{E}}$ and $f^{\mathbf{O}}\lhd f'^{\mathbf{O}}$.

(iv) *Multisets.* Two different multisets of pairs with equally many elements are read from the least element upward in $\lhd$, and the one that first holds the smaller element comes first.

(v) *Classes.* For classes $C\neq D$ of one realization with m marks each, $C\prec D$ when $\mathcal{V}_s(C)\lhd\mathcal{V}_s(D)$ at the first s in $0,1,\dots,n-m,*$ with $\mathcal{V}_s(C)\neq\mathcal{V}_s(D)$.

Definition 13.6 (The Foreman bunch)**.** At the centre, the *Foreman bunch* $B(M;\boldsymbol{\sigma},0)$ is the class of $\Upsilon_{\boldsymbol{\sigma},0;\mathbf{1}}$ with the fewest marks and, among those, the $\prec$-least. At a lean $\boldsymbol{\delta}$ each class C of $\Upsilon_{\boldsymbol{\sigma},\boldsymbol{\delta};\mathbf{1}}$ lies in one class C° of the centre (Theorem 11.1), and $B(M;\boldsymbol{\sigma},\boldsymbol{\delta})$ is the class with the least

$$\mathrm{key}_{\boldsymbol{\sigma},\boldsymbol{\delta}}(C)=\big(|C|,\ |C^\circ|,\ C^\circ,\ C\big),$$

compared entry by entry: sizes as integers, C° by $\prec$ at the centre, C by $\prec$ at the lean. At every realization the Foreman bunch is a class with the fewest marks among the classes of that realization; the classes of the centre and the order only choose among those.

Theorem 13.7 (What the order is)**.** *(i)* Total. *For every m, $\prec$ is a strict total order on the classes with m marks; $B(M;\boldsymbol{\sigma},0)$ and $B(M;\boldsymbol{\sigma},\boldsymbol{\delta})$ are each one class.*

(ii) Directions. *With the classes given, $\prec$ depends on the realization only through the rays of $\boldsymbol{\sigma}$ and $\boldsymbol{\delta}$; at one pair only through the lean sign.*

(iii) Mirror. *If g exchanges the family (Definition 11.13), every stage of $g(C)$ at $-\boldsymbol{\delta}$ equals that stage of C at $\boldsymbol{\delta}$; so $C \prec D$ at $\boldsymbol{\delta}$ exactly when $g(C) \prec g(D)$ at $-\boldsymbol{\delta}$, and $B(M;\boldsymbol{\sigma},-\boldsymbol{\delta}) = g\big(B(M;\boldsymbol{\sigma},\boldsymbol{\delta})\big)$. If g carries the family, the same holds at one lean.*

(iv) Nesting. *When some class at $\boldsymbol{\delta}$ inside $B(M;\boldsymbol{\sigma},0)$ has the fewest marks among the classes at $\boldsymbol{\delta}$, $B(M;\boldsymbol{\sigma},\boldsymbol{\delta}) \subseteq B(M;\boldsymbol{\sigma},0)$, and it is the class at $\boldsymbol{\delta}$ inside $B(M;\boldsymbol{\sigma},0)$ with the fewest marks and, among those, the $\prec$-least. In a one-table molecule this is so whenever $B(M;\boldsymbol{\sigma},0)$ splits at $\boldsymbol{\delta}$. Otherwise $B(M;\boldsymbol{\sigma},\boldsymbol{\delta})$ need not lie in $B(M;\boldsymbol{\sigma},0)$.*

Every rise is a linear combination of logarithms of polynomials in $e^{v_0},\dots,e^{v_k}$, less the same combination at $v_0 = 0$ (Proposition 13.2), so equality of two rises is an identity of polynomials with exponents (Theorem 10.6). When two rises differ, the first differing exponent is found column by column: $v_k = 0$ is the rise with one partner fewer, the coefficient of v_k^b is a rational function of the scales at the other positions (Corollary 13.4(ii) for $k = 1$), each column is certified equal by a polynomial identity, and the deciding coefficient is a joint cumulant of Proposition 13.3, multiplied by the σ_j or the δ_j, and rational when the weights of the tables are.

Proposition 13.8 (Rung one enters only at the last stage)**.** *Every stage before the last reads the still from rung two on; the masses, rung one, enter only at the last stage, and at a centre they are the same at every mark.*

13.3 What the first stages read

Proposition 13.9 (At the centre the first number is how far the class is from a scale of its own)**.** $\operatorname{Var}_{T\sim\mathbb{P}_{j,\mathbf{1}}} |T\cap U| = 0$ *in every table exactly when U is a union of molecules. So for a class C of a molecule other than the whole,*

$$[v_0^2]\,\mathring{V}^{\mathbf{E}}_{C,()} = \sum_j \sigma_j \operatorname{Var}_{T\sim\mathbb{P}_{j,\mathbf{1}}} |T\cap C| > 0.$$

Proposition 13.10 (Mirror classes)**.** *Let C, D be classes with equally many marks whose levels are mirrored across the tables: there are a bijection h of the tables with $(\sigma_{h(j)},\delta_{h(j)}) = (\sigma_j,\delta_j)$ and integers k_j with $\mathbb{P}_{h(j),\mathbf{1}}(|T\cap D| = a) = \mathbb{P}_{j,\mathbf{1}}(|T\cap C| = k_j - a)$ for every j and every a. This holds with h the identity for two classes that together make up the molecule ($k_j = r_j$), and for C and $g(C)$ under an exchange g of the family, h the bijection of its tables ($k_j = |C|$). Then:*

(i) $\kappa_{h(j),\mathbf{1}}(N_D^{\times a}) = (-1)^a \kappa_{j,\mathbf{1}}(N_C^{\times a})$ *for $a \geq 2$, so $\sum_j \sigma_j \kappa_{j,\mathbf{1}}(N_D^{\times a}) = (-1)^a \sum_j \sigma_j \kappa_{j,\mathbf{1}}(N_C^{\times a})$, and likewise with the δ_j: the $\mathbf{E}$ parts of $\mathcal{V}_0(C)$ and $\mathcal{V}_0(D)$ are equal and their $\mathbf{O}$ parts are negatives;*

(ii) at a lean, if some odd $a \geq 3$ has $\sum_j \delta_j \kappa_{j,\mathbf{1}}(N_C^{\times a}) \neq 0$ and a is the least such, then $C \prec D$ exactly when $\sum_j \delta_j \kappa_{j,\mathbf{1}}(N_C^{\times a}) < 0$, and at the opposite lean the order is the other one;

(iii) at the centre stage 0 *does not separate* C *and* D*, and a later stage does.*

Corollary 13.11 (A bunch across the centre)**.** *In a one-table molecule, if* $B(M;\sigma,0)$ *splits at a lean* δ *into* C_K *and* C_Ψ *(Theorem 11.17), then* $B(M;\sigma,\delta) \in \{C_K, C_\Psi\}$ *and* $B(M;\sigma,-\delta) = \beta\big(B(M;\sigma,\delta)\big)$ *is the other one,* β *the exchange of Theorem 11.17; the two are mirror classes, ordered at a lean by Proposition 13.10(ii).*

The Foreman bunch is the least of the smallest classes, and the order that chooses it reads the class first on its own scale. At the centre the first number read is the spread of the level of the class under the weight laws, which vanishes only for a union of molecules; a lean adds the odd cumulants of that level, and two mirror classes are told apart by the first of them that does not vanish, the opposite lean reversing the choice.

Chapter 14

Peel, children and the Foreman tree

14.1 The peel and the tree

Definition 14.1 (Peel; childcules)**.** Families are read at realizations at the table's gauge, and for a molecule M of a family F, $F|M$ is the family of the restrictions of its tables to M. The *peel* of a family F at a bunch B is the family of its children at the native split of the table's gauge (Proposition 12.27),

$$F_B(\mathbf{a}^\star, \mathbf{b}^\star), \qquad a^\star_{j,p} = \pi_{j,p}(\mathbf{1})\, s_j, \quad b^\star_{j,p} = \pi_{j,p}(\mathbf{1})\, t_j,$$

on the room R; children with the same bases and weights are one table, with their exponents added. A *childcule* is a molecule of the peel.

Definition 14.2 (The record of a peel)**.** The *record* of the peel of F at B is the bunch B with, for every table j, the communicatroid of B (Definition 12.4) and the pattern probabilities $\pi_{j,p}(\mathbf{1})$: the indexed children $\big(j,p;\ \mathcal{B}_{j,(p)}, \theta_{j,(p)};\ \pi_{j,p}(\mathbf{1})s_j,\ \pi_{j,p}(\mathbf{1})t_j\big)$. The peel is the record with the indices (j,p) forgotten and equal children merged.

Proposition 14.3 (The record keeps the parent)**.** *The record determines F: table j is the gluing of its communicatroid (Proposition 12.5), and its exponents are the sums of its children's,* $\sum_p \pi_{j,p}(\mathbf{1})(s_j, t_j) = (s_j, t_j)$.

Merging equal children forgets which pattern each share came from, and the Gammas $\Gamma\big(\mu_e - \langle\boldsymbol{\delta}\rangle_e\big)$ of the port (Theorem 15.15) depend on it. The record keeps it. A bunch of width one whose communicatroid is that of one mark, two children on two levels, may instead be pooled into one mark of the room, its shape integrated and its scale kept (Theorem 19.8).

Definition 14.4 (The Foreman tree)**.** For a family F read at $\Upsilon_{\boldsymbol{\sigma},\boldsymbol{\delta};\mathbf{1}}$, the *Foreman tree* $\mathrm{Tree}(F;\boldsymbol{\sigma},\boldsymbol{\delta})$ splits F into molecules. A molecule with one mark is a unit (Definition 7.4), and a molecule M whose realization is atomic is an atom (Definition 10.1); otherwise the tree records the Foreman bunch $B(M;\boldsymbol{\sigma}_M,\boldsymbol{\delta}_M)$, $(\boldsymbol{\sigma}_M,\boldsymbol{\delta}_M)$ the pair coordinates of the tables of M, and continues with the peel of $F|M$ at that bunch, on its room.

The tree asks each molecule whether it is an atom; where it is not, the tree takes the least of its smallest classes as the bunch, hands the room the children of the bunch at the native split, and asks again. Nothing is lost on the way down: the record keeps the parent, and the native split keeps the gauge native and the centre a centre.

Proposition 14.5 (Peeling in two steps is peeling at once)**.** *For $B = B_1 \sqcup B_2$, the peel at B_2 of the peel of F at B_1 is the peel of F at B: the child of F at (j,p) and the child at $\big((j, p\cap B_1), p\cap B_2\big)$ of the peel at B_1 are one table on $\mathcal{E}\setminus B$ with the same exponents. So if a molecule is peeled at B_1, its room is one childcule and the bunch there is B_2, the family reached is the peel at $B_1 \sqcup B_2$.*

Theorem 14.6 (Three trees)**.** $\mathrm{Tree}(F;\boldsymbol{\sigma},\boldsymbol{\delta})$ *depends on $(\boldsymbol{\sigma},\boldsymbol{\delta})$ only through their rays; at one pair only through the lean sign. So a molecule at one pair has three Foreman trees,* $\mathrm{Tree}(F;\boldsymbol{\sigma},0)$ *and* $\mathrm{Tree}(F;\boldsymbol{\sigma},\pm\boldsymbol{\delta})$ *for a basis lean $\boldsymbol{\delta}$, fixed by its tables.*

Lemma 14.7 (Maps descend)**.** *Let $g:\mathcal{E}\to\mathcal{E}'$ be a bijection, $B\subseteq\mathcal{E}$ with room R, and $B'=g(B)$.*

(i) If g carries F to F', then $g|_R$ carries the peel of F at B to the peel of F' at B', the child (j,p) going to $(h(j),g(p))$, h the bijection of the tables of Definition 11.13.

(ii) If g exchanges F with F', then $g|_R$ exchanges the peel of F at B with the peel of F' at B', the child (j,p) going to $(h(j),B'\setminus g(p))$.

(iii) In both cases g maps the molecules of F onto those of F', and on a molecule M its restriction carries, respectively exchanges, $F|M$ with $F'|g(M)$.

Theorem 14.8 (The mirror)**.** *If g exchanges F with F', then $g\big(\mathrm{Tree}(F;\boldsymbol{\sigma},\boldsymbol{\delta})\big)=\mathrm{Tree}(F';\boldsymbol{\sigma},-\boldsymbol{\delta})$: molecules go onto molecules, units onto units, atoms onto atoms, each recorded bunch onto the bunch recorded at the same place, rooms onto rooms. If g carries F to F' the same holds at the same lean.*

Corollary 14.9 (A molecule with an exchange)**.** *If g exchanges a molecule M (Definition 11.13), then g maps* $\mathrm{Tree}(M;\boldsymbol{\sigma},0)$ *onto itself, every class of the centre onto itself (Corollary 11.15), and* $\mathrm{Tree}(M;\boldsymbol{\sigma},\boldsymbol{\delta})$ *onto* $\mathrm{Tree}(M;\boldsymbol{\sigma},-\boldsymbol{\delta})$*: $B(M;\boldsymbol{\sigma},-\boldsymbol{\delta})=g\big(B(M;\boldsymbol{\sigma},\boldsymbol{\delta})\big)$ and $g\big(B(M;\boldsymbol{\sigma},0)\big)=B(M;\boldsymbol{\sigma},0)$. If g carries M, it maps every class of $\Upsilon_{\boldsymbol{\sigma},\boldsymbol{\delta};\mathbf{1}}$ onto itself and each of the trees at 0, $\boldsymbol{\delta}$ and $-\boldsymbol{\delta}$ onto itself.*

Lemma 14.10 (An exchange turns a window over)**.** *If g exchanges a family F with F', with the bijection h of the tables (Definition 11.13), and $S'=g(S)$, then for every table j the window of S' in table $h(j)$ of F' is $\{|S|-r_j(S),\dots,|S|-d_j(S)\}$: S in table j and S' in table $h(j)$ have the same width, and the bases of table j at level k on S correspond to those of table $h(j)$ at level $|S|-k$ on S'.*

Corollary 14.11 (Below a no)**.** *A molecule that answers no is peeled at its Foreman bunch read at a centre of the table's gauge; each childcule is a molecule at a centre of the table's gauge, and whether it answers yes is read there in turn.*

14.2 Patterns of one kind

Proposition 14.12 (Level form)**.** *A function of the patterns of a bunch B has* level form *when it depends on $|p|$ alone, and B is in level form in a table when its children are, and in a family when it is in level form in every table. B is in level form in table j, $K_{j,(p)}=K_{j,(p')}$ whenever $|p|=|p'|$, if and only if every transposition of two marks of B, fixing every other mark, maps the bases of table j onto themselves with their weights; so B is in level form in a family exactly when every such transposition carries the family with the identity on its tables.*

Definition 14.13 (Kinds of pattern)**.** Let a one-table molecule be read at the table's gauge and B a set of marks. A *writing from a pattern p* is K written in an order whose first $|p|$ positions hold

p, the next $|B \setminus p|$ hold $B \setminus p$, and the rest the room; a writing of Ψ from $B \setminus p$ likewise. Patterns p, p' are of one *kind at a lean* when one polynomial is written from p and from p', and of one *kind at the centre* when moreover a writing from p may equal a writing of Ψ from $B \setminus p'$.

Theorem 14.14 (One child per kind)**.** *(i) p, p' are of one kind at a lean exactly when a bijection keeping B and carrying the table maps p to p', and of one kind at the centre exactly when, in addition, an exchanging bijection keeping B may map p to $B \setminus p'$. Being of one kind is reflexive, symmetric and transitive.*

(ii) Patterns of one kind have one child between them: the child at p' is the image of the child at p under the bijection restricted to the room, or the dual of that image when the bijection exchanges; their pattern probabilities are equal.

(iii) So the level letters $K_B^{(k)}(\alpha) = \sum_{p \in \mathrm{pat}^{(k)}(B)} \alpha_B^p K_{(p)}(\alpha_R)$ are determined by one child per kind, the patterns of each kind, and the bijections.

Corollary 14.15 (A family with maps in hand)**.** *Let $\mathcal{G}$ be any set of bijections keeping B that carry or exchange a family. Patterns reached from one another by the moves $p \mapsto g(p)$, $g \in \mathcal{G}$ carrying, and $p \mapsto B \setminus g(p)$, $g \in \mathcal{G}$ exchanging, have children that are one table up to the bijections on the room and duality, with equal pattern probabilities.*

Kinds are read on the writings of the two polynomials of one table; with several tables there is no single pair of polynomials to write, and the corollary takes the bijections as given.

Theorem 14.16 (The pattern tensor of a class)**.** *Let B be a class of a one-table molecule at a realization at the table's gauge, $e, f \in B$, and β the bijection taking an order in which the class's one function is written from e to one in which it is written from f (Theorem 10.5). Then:*

(i) β carries the table, or at the centre possibly exchanges it, and maps every class onto itself; in particular $\beta(B) = B$ and $\beta(R) = R$;

(ii) the child at $\beta(p)$ is the child at p with the room mapped by β, or, when β exchanges, the child at $B \setminus \beta(p)$ is the dual of that image; so p and $\beta(p)$, respectively p and $B \setminus \beta(p)$, are of one kind;

(iii) when β carries, the patterns through e correspond to those through f; when it exchanges, the patterns through e correspond to those avoiding f; in both cases with equal pattern probabilities and with children equal up to the bijection on the room and duality.

So the pattern tensor of a class is the same from each of its marks, at the centre up to complements.

14.3 What the room keeps

Definition 14.17 (Keeping the potential; twins; descents; copies)**.** Let a family be read at a realization $\Upsilon = ((s_j, t_j)_j; \alpha)$, with the potential $(\Phi_{\mathbf{E}}, \Phi_{\mathbf{O}})$ of Definition 8.18 and $(g^* y)_e = y_{g(e)}$ as in Definition 11.13. A bijection g of the marks of a molecule M *keeps the potential* when $\Phi_{\mathbf{X}}(\log \alpha + g^* y) = \Phi_{\mathbf{X}}(\log \alpha + y)$ for every y and both parts; at the table's gauge this is $\Phi_{\mathbf{X}} \circ g^* = \Phi_{\mathbf{X}}$. A bijection $g : M \to M'$ onto the marks of a molecule M', read at a realization with the gauge α', *takes the potential* of M to that of M' when $\Phi_{\mathbf{X}}(\log \alpha + g^* y) = \Phi'_{\mathbf{X}}(\log \alpha' + y) + c_{\mathbf{X}}$ for every y and both parts, with constants $c_{\mathbf{X}}$. Twins, descents and copies are read at the table's gauge, $\alpha = \mathbf{1}$: two childcules of the peel of M are *twins* when a bijection keeping the potential of M maps one onto the other. A *descent* of a Foreman tree is a sequence $M_0 \supset M_1 \supset \cdots \supset M_d$ of its nodes from the molecule M_0 to a leaf M_d, each M_{k+1} a childcule of the peel of M_k at its bunch.

On a descent, with B_i the bunch of M_i, the *copies inside* M_k of $Y = M_i$ or $Y = B_i$, $k \le i$, are the sets $g_k(g_{k+1}(\cdots g_{i-1}(Y)\cdots))$, each g_l a bijection keeping the potential of M_l; for $k = i$ they are Y alone.

Lemma 14.18 (The writings certify the potential)**.** *Let a molecule be read at a realization* $\Upsilon = ((s_j, t_j)_j; \alpha)$.

(i) If e and f read alike, the bijection β that takes, position by position, an order with e first to an order with f first in which one pair of functions is written from both (Proposition 10.4) keeps the potential, and $\beta(e) = f$.

(ii) A bijection keeping the potential maps every class onto itself, and a bijection taking the potential of M to that of M' maps the classes of M onto those of M', at the centre and at the realization's lean.

So two marks read alike exactly when a bijection keeping the potential takes one to the other.

Lemma 14.19 (The peel reads the factors of the letters)**.** *Write the potential of a family by its irreducible factors with their exponents $(L, w_{\mathbf{E}}(L), w_{\mathbf{O}}(L))$, each normalized by $L(\mathbf{1}) = 1$ (Theorem 10.6), and for a bunch B let $L_{[q]}$ be the coefficient of α_B^q in L, a polynomial on the room R. In this statement write $\Phi_{\mathbf{X}}^{\mathrm{peel}}$ for the potential of the peel $F_B(\mathbf{a}^\star, \mathbf{b}^\star)$. Up to a constant,*

$$\Phi_{\mathbf{X}}^{\mathrm{peel}}(y_R) = \sum_L w_{\mathbf{X}}(L) \sum_q L_{[q]}(\mathbf{1}) \log L_{[q]}\big(e^{y_R}\big),$$

the inner sum over the q with $L_{[q]} \neq 0$, whose values $L_{[q]}(\mathbf{1})$ add to 1.

Theorem 14.20 (The room keeps its classes)**.** *Let a molecule M be read at a realization at the table's gauge, let B be a union of its classes, and let the children's weights factor across the childcules of the peel. Every bijection g keeping the potential of M keeps B; its restriction to the room keeps the potential of the peel, maps each childcule Y onto a childcule $g(Y)$, and takes the potential of Y to that of $g(Y)$, the constant being 0 when $g(Y) = Y$. Consequently, for a class C of M inside the room:*

(i) the childcules that C meets are twins of one another, and C meets each of them in equally many marks;

(ii) inside each childcule, C lies in one class.

Proposition 14.21 (The tree is read off the potential)**.** *Let a molecule M of F and a molecule M' of F' be read at realizations at the table's gauge, with pair coordinates $(\boldsymbol{\sigma}, \boldsymbol{\delta})$ and $(\boldsymbol{\sigma}', \boldsymbol{\delta}')$, the children's weights factoring across the childcules at every node of their trees, and let $g : M \to M'$ take the potential of M to that of M'. Then g maps* $\mathrm{Tree}(F|M; \boldsymbol{\sigma}, \boldsymbol{\delta})$ *onto* $\mathrm{Tree}(F'|M'; \boldsymbol{\sigma}', \boldsymbol{\delta}')$*: classes onto classes, units onto units, atoms onto atoms, each bunch onto the bunch recorded at the same place, and each childcule onto a childcule, its potential to that of its image.*

Theorem 14.22 (The leaf bounds the bunches)**.** *Let a molecule F be read at a realization at the table's gauge, the centre or a lean, the children's weights factoring across the childcules at every node, and let $M_0 \supset M_1 \supset \cdots \supset M_d$ be a descent of its Foreman tree at that realization, B_k the bunch of M_k and $R_k = M_k \setminus B_k$. Let h_k be the number of twins of M_{k+1} among the childcules of M_k, M_{k+1} itself included, and $h_{<k} = h_0 h_1 \cdots h_{k-1}$.*

(i) A class of M_k inside R_k that meets M_{k+1} meets the twins of M_{k+1} and no other childcule, each in equally many marks, and lies in one class of each. The copies inside M_k of M_i,

$k \le i \le d$, respectively of B_i, $k \le i < d$, are $h_{<i}/h_{<k}$ disjoint nodes, respectively bunches, of the subtree at M_k, leaves when $i = d$; and M_d together with its copies inside M_k is a union of whole classes of M_k.

(ii) A class C of M_k that meets M_{k+1} has at least $|B_k|$ marks and meets M_{k+1} in $|C|/h_k \ge |B_k|/h_k$ of them, all in one class of M_{k+1}; the bunch B_{k+1}, and the leaf when $k+1 = d$, contains such a part. So

$$|B_0| \le h_{<1}|B_1| \le h_{<2}|B_2| \le \cdots \le h_{<d-1}|B_{d-1}| \le h_{<d}|M_d|,$$

the k-th term being the number of marks of the copies of B_k inside M_0, and the last that of the copies of M_d: down the descent the bunches with their copies never shrink, and the leaf with its copies has at least as many marks as every bunch with its copies.

Theorem 14.22 rests on two things: the peel splits a class only across twin childcules, each part inside one class (Theorem 14.20), and the bunch is a class with the fewest marks of the realization at which its node is read. Peeled at another bunch, a molecule can end at a leaf smaller than the bunch above it; at a lean the count is read on the classes of the lean, which can split a class of the centre into parts smaller than the least class of the centre; and the copies are needed when a room falls into twins.

Part IV

Evaluation

Chapter 15

The integral at a bunch

15.1 The scale of a bunch

Proposition 15.1 (A scale integral is a Breta of one bunch)**.** *Let $J = \{0, \dots, L\}$ carry coefficients $\boldsymbol{\xi} = (\xi_\ell)_{\ell \in J}$ and letter exponents $\mathbf{w} = (w_\ell)_{\ell \in J}$ with total $|\mathbf{w}| = \sum_\ell w_\ell$, and let I_J be the unit configuration on J. For $\boldsymbol{\xi} > 0$, $\operatorname{Re} w_\ell > 0$ and $0 < \operatorname{Re}\kappa < \operatorname{Re}|\mathbf{w}|$,*

$$\int_0^\infty x^{\kappa-1} \prod_{\ell \in J} (x + \xi_\ell)^{-w_\ell}\, dx = \Gamma_{\,|J|}^{\,2}\begin{bmatrix} \kappa, & |\mathbf{w}| - \kappa \\ & \mathbf{w} \end{bmatrix} \mathsf{B}^{\{J\}}_{\mathbf{w},\, |\mathbf{w}|-\kappa;\, I_J}(\boldsymbol{\xi}) :$$

the Breta of Definition 3.1 with the one bunch J, the shape index $\mathbf{w}$, the scale index $|\mathbf{w}| - \kappa$, the unit configuration as its terms and $\boldsymbol{\xi}$ as its coefficients. For $\xi_\ell \in \mathbb{C} \setminus (-\infty, 0]$ the left side, with principal branches, converges exactly when $0 < \operatorname{Re}\kappa < \operatorname{Re}|\mathbf{w}|$ and is holomorphic in its data there, and it continues the right side from positive coefficients and from letter exponents with positive real part; wherever the left side converges, the product on the right denotes its value. Coincident coefficients merge into one with the summed letter exponent.

The scale of a bunch is integrated against a product of linear letters, one for each point of the joint spectrum, and that integral is a Breta: the points of the spectrum are the coefficients, the letter exponents the shape index, and the index of the scale integral sits in the scale index as $|\mathbf{w}| - \kappa$. Nothing beyond the general Breta is needed to write it. With one coefficient the Breta is the power $\xi_0^{\kappa - w_0}$, and the identity is the integral of a linear letter: for $c_0, c_1 > 0$ and $0 < \operatorname{Re}\nu < \operatorname{Re} s$, $\int_0^\infty \rho^{\nu-1}(c_0 + c_1\rho)^{-s}\, d\rho = \Gamma_{\,1}^{\,2}\begin{bmatrix} \nu, & s - \nu \\ & s \end{bmatrix} c_0^{\nu - s} c_1^{-\nu}$. A stacked Gamma $\Gamma_{\,1}^{\,2}\begin{bmatrix} a, & b \\ & a+b \end{bmatrix}$ is a *Beta corner*.

Proposition 15.2 (Where the Breta of one bunch converges)**.** *In Proposition 15.1 let $\operatorname{Re} w_\ell > 0$ for every ℓ and $0 < \operatorname{Re}\kappa < \operatorname{Re}|\mathbf{w}|$, and let Ξ_J be the set of the $\boldsymbol{\xi} \in (\mathbb{C} \setminus (-\infty, 0])^J$ whose convex hull avoids $(-\infty, 0]$. It is open, star-shaped about $\mathbf{1}$, and contains every $\boldsymbol{\xi}$ whose coordinates have positive real parts. On Ξ_J the integral that defines the Breta at positive coefficients (Definition 3.1),*

$$\int_{\Delta_J} u^{\mathbf{w}-\mathbf{1}} \Big(\sum_{\ell \in J} \xi_\ell u_\ell \Big)^{-(|\mathbf{w}|-\kappa)} d\omega_J(u),$$

with the principal branch, converges, is holomorphic in $\boldsymbol{\xi}$, and continues the Breta $\mathsf{B}^{\{J\}}_{\mathbf{w},\, |\mathbf{w}|-\kappa;\, I_J}(\boldsymbol{\xi})$ from positive coefficients; so the identity of Proposition 15.1 holds on Ξ_J with both sides convergent integrals.

Theorem 15.3 (The scale of a bunch is one Breta)**.** *Let a family F on $\mathcal{E}$ be at a gauge α with masses $\mathbf{m}$, let B be a proper bunch with room R, its Skeleton polynomials, values and coins those of Definition 12.10, and let $\xi_0, \dots, \xi_L$ be the distinct points of the joint spectrum of the letters with nonzero exponent, the union of the spectra $\operatorname{spec}^K_{j,B}(\alpha)$ with $s_j \neq 0$ and $\operatorname{spec}^\Psi_{j,B}(\alpha)$ with $t_j \neq 0$, with the letter exponents*

$$w_\ell = \sum_j \big(s_j \operatorname{mult}^K_{j,\ell} + t_j \operatorname{mult}^\Psi_{j,\ell}\big) = \sum_j \big(\sigma_j(\operatorname{mult}^K_{j,\ell} + \operatorname{mult}^\Psi_{j,\ell}) + \delta_j(\operatorname{mult}^K_{j,\ell} - \operatorname{mult}^\Psi_{j,\ell})\big),$$

$\operatorname{mult}^K_{j,\ell}$ and $\operatorname{mult}^\Psi_{j,\ell}$ the multiplicities of ξ_ℓ in $\operatorname{spec}^K_{j,B}(\alpha)$ and $\operatorname{spec}^\Psi_{j,B}(\alpha)$, and $J = \{0, \dots, L\}$. The scale integral

$$\operatorname{Sc}_B(\alpha; \mathbf{m}; \mathbf{s}, \mathbf{t}) = \int_0^\infty x^{m_B - 1} \prod_j K_j(x\alpha_B, \alpha_R)^{-s_j} \Psi_j(x\alpha_B, \alpha_R)^{-t_j}\, dx$$

converges exactly when $\operatorname{Re}\kappa_B > 0$ and $\operatorname{Re}\kappa_B^{\text{top}} > 0$, and then

$$\operatorname{Sc}_B(\alpha; \mathbf{m}; \mathbf{s}, \mathbf{t}) = \prod_j K_j(\alpha)^{-s_j} \Psi_j(\alpha)^{-t_j} \prod_\ell (1 + \xi_\ell)^{w_\ell}\ \Gamma_{\,2\,|J|}\begin{bmatrix} \kappa_B, & \kappa_B^{\text{top}} \\ & \mathbf{w} \end{bmatrix} \mathsf{B}^{\{J\}}_{\mathbf{w},\, \kappa_B^{\text{top}};\, I_J}(\boldsymbol{\xi}),$$

with $|\mathbf{w}| = \sum_j (s_j + t_j) c_j(B) = \kappa_B + \kappa_B^{\text{top}}$, so that the scale index $|\mathbf{w}| - \kappa_B$ of Proposition 15.1 is the top wall; the Breta is read by that proposition at complex spectra.

Corollary 15.4 (The scale of a bunch of width one)**.** *Let B be a bunch with room R. Along B each letter of a table j with $c_j(B) = 1$ has one Skeleton value, the level letter at the floor over the level letter at the largest level, colevel letters for Ψ_j (Definition 12.16), and its coin is the probability of the largest level, respectively colevel; the letters of a table with $c_j(B) = 0$ have none:*

$$\operatorname{spec}^K_{j,B}(\alpha) = \Big\{ \frac{K^{(d_j(B))}_{j,B}(\alpha)}{K^{(d_j(B)+1)}_{j,B}(\alpha)} \Big\},\ \text{coin } \mathbb{P}_{j,\alpha}\big(N_B = d_j(B) + 1\big);$$

$$\operatorname{spec}^\Psi_{j,B}(\alpha) = \Big\{ \frac{\Psi^{(d^*_j(B))}_{j,B}(\alpha)}{\Psi^{(d^*_j(B)+1)}_{j,B}(\alpha)} \Big\},\ \text{coin } \mathbb{P}^*_{j,\alpha}\big(N^*_B = d^*_j(B) + 1\big).$$

At $B = \{e\}$, e neither a loop nor a coloop of table j, the two levels are $K_{j,\setminus e}(\alpha_R)$ and $\alpha_e K_{j,/e}(\alpha_R)$ and the two colevels $\Psi_{j,/e}(\alpha_R)$ and $\alpha_e \Psi_{j,\setminus e}(\alpha_R)$: each Skeleton value is a deletion–contraction ratio, and the coins are the occupation $R_{j,e}(\alpha)$ and the dual occupation $R^*_{j,e}(\alpha)$.

Corollary 15.5 (One share per coefficient beyond the first)**.** *Let $\operatorname{Re} w_\ell > 0$ for all ℓ, $0 < \operatorname{Re}\kappa < \operatorname{Re}|\mathbf{w}|$, and choose $c_\ell \in (0, \operatorname{Re} w_\ell)$, $\ell = 1, \dots, L$, with $\operatorname{Re}\kappa - \operatorname{Re} w_0 < \sum_\ell c_\ell < \operatorname{Re}\kappa$, possible exactly under these conditions. With the share integrals on $\operatorname{Re} a_\ell = c_\ell$ and $|\mathbf{a}| = a_1 + \cdots + a_L$,*

$$\Gamma_{\,2\,|J|}\begin{bmatrix} \kappa, & |\mathbf{w}| - \kappa \\ & \mathbf{w} \end{bmatrix} \mathsf{B}^{\{J\}}_{\mathbf{w},\, |\mathbf{w}| - \kappa;\, I_J}(\boldsymbol{\xi})$$
$$= \int_{a_1 + b_1 = w_1} \cdots \int_{a_L + b_L = w_L} \prod_{\ell=1}^{L} \Gamma_{\,2\,1}\begin{bmatrix} a_\ell, & b_\ell \\ & w_\ell \end{bmatrix} \xi_\ell^{-b_\ell} \cdot \xi_0^{\kappa - |\mathbf{a}| - w_0}\, \Gamma_{\,2\,1}\begin{bmatrix} \kappa - |\mathbf{a}|, & w_0 - \kappa + |\mathbf{a}| \\ & w_0 \end{bmatrix}.$$

Any coefficient may serve as ξ_0; $L + 1$ distinct values need L shares.

Theorem 15.6 (The scale in its spectral gaps)**.** *Let $\xi_\ell \in \mathbb{C}\setminus(-\infty,0]$ and $w_\ell \in \mathbb{C}$, $\ell \in J$, with $0 < \operatorname{Re}\kappa < \operatorname{Re}|\mathbf{w}|$, and let $r>0$ have $|\xi_\ell - r| < r$ for every ℓ; such an r exists exactly when every ξ_ℓ has positive real part, since $|\xi_\ell - r| < r$ reads $\operatorname{Re}\xi_\ell > |\xi_\ell|^2/(2r)$. Put $g_\ell = 1-\xi_\ell/r$, the* spectral gaps *at r, so that $|g_\ell|<1$. Then*

$$\Gamma_{\,2\,|J|}\!\begin{bmatrix}\kappa,\ |\mathbf{w}|-\kappa\\ \mathbf{w}\end{bmatrix}\,\mathsf{B}^{\{J\}}_{\mathbf{w},\,|\mathbf{w}|-\kappa;\,I_J}(\boldsymbol{\xi}) = r^{\kappa-|\mathbf{w}|}\sum_{\mathbf{n}\in\mathbb{N}^J}\prod_{\ell\in J}\frac{(w_\ell)_{n_\ell}}{n_\ell!}g_\ell^{\,n_\ell}\;\Gamma_{\,2\,1}\!\begin{bmatrix}\kappa,\ |\mathbf{w}|+|\mathbf{n}|-\kappa\\ |\mathbf{w}|+|\mathbf{n}|\end{bmatrix},$$

a convergent series whose terms, grouped by the total order $|\mathbf{n}|$, have root rate at most $\max_\ell|g_\ell|$. A coefficient equal to r has spectral gap zero and drops out. For $0<\xi_\ell\le r$, $w_\ell>0$ and $0<\kappa<|\mathbf{w}|$ the gaps lie in $[0,1)$ and every term is positive. For positive coefficients the bound $\max_\ell|g_\ell|$ is least at $r=\frac12(\max_\ell\xi_\ell+\min_\ell\xi_\ell)$, where it is $\frac{\max_\ell\xi_\ell-\min_\ell\xi_\ell}{\max_\ell\xi_\ell+\min_\ell\xi_\ell}$, against $1-\frac{\min_\ell\xi_\ell}{\max_\ell\xi_\ell}$ at $r=\max_\ell\xi_\ell$.

Corollary 15.7 (Inversion is Cremona on the scale)**.** *In Theorem 15.3:*

$$\mathsf{B}^{\{J\}}_{\mathbf{w},\,|\mathbf{w}|-\kappa;\,I_J}(\boldsymbol{\xi}) = \prod_\ell \xi_\ell^{-w_\ell}\,\mathsf{B}^{\{J\}}_{\mathbf{w},\,\kappa;\,I_J}(\boldsymbol{\xi}^{-1}),$$

$$\mathrm{Sc}_B(\alpha;\mathbf{m};\mathbf{s},\mathbf{t}) = (\alpha^{\mathcal{E}})^{-2\sigma}\;\mathrm{Sc}_B(\alpha^{-1};2\sigma\mathbf{1}-\mathbf{m};\mathbf{t},\mathbf{s})\,:$$

the joint spectrum at $(\alpha^{-1};\mathbf{t},\mathbf{s})$ is the reciprocal of that at $(\alpha;\mathbf{s},\mathbf{t})$ with the same letter exponents, and the index of the scale integral moves from κ_B to $\kappa_B^{\mathrm{top}}=|\mathbf{w}|-\kappa_B$.

15.2 Closing

Definition 15.8 (Exceedance polynomials)**.** For a bunch B of a table the *exceedance polynomials* are $\mathsf{Q}^K_{B,>}(x;\alpha)=\sum_{k\ge0}\mathbb{P}_\alpha(N_B-d(B)>k)\,x^k$ and $\mathsf{Q}^\Psi_{B,>}(x;\alpha)=\sum_{k\ge0}\mathbb{P}^*_\alpha(N^*_B-d^*(B)>k)\,x^k$. They have nonnegative coefficients and degree $c(B)-1$, and $1-\mathsf{Q}^K_B=(1-x)\mathsf{Q}^K_{B,>}$, $1-\mathsf{Q}^\Psi_B=(1-x)\mathsf{Q}^\Psi_{B,>}$.

Theorem 15.9 (The scale closes on its two sectors)**.** *Let B be a proper bunch of a family with room R, and let the data be real with $s_j,t_j\ge0$, $\kappa_B>0$ and $\kappa_B^{\mathrm{top}}>0$. For $S\in\{B,R\}$ write the polynomials $\mathsf{Q}^K_{j,S}(\cdot;\alpha)$, with the exponents s_j, and $\mathsf{Q}^\Psi_{j,S}(\cdot;\alpha)$, with the exponents t_j, as $\mathsf{Q}_{S,i}(\cdot;\alpha)$ with exponents w_i, $1\le i\le 2N$ for a family of N tables, $\mathbf{w}=(w_i)_i$, and their exceedance polynomials as $\mathsf{Q}_{S,i,>}$.*

(i) The scale integral is the sum of the Trailmoments of its two sectors, with the coefficient functions $x\mapsto(\mathsf{Q}_{S,i}(x;\alpha))_i$ and the inputs $x^{\kappa-1}\mathbb{I}_{(0,1)}$:

$$\mathrm{Sc}_B(\alpha;\mathbf{m};\mathbf{s},\mathbf{t}) = \prod_j K_j(\alpha)^{-s_j}\Psi_j(\alpha)^{-t_j}\Big(\big(\mathsf{T}_{\mathbf{w};I_{2N}}[(\mathsf{Q}_{B,i}(x;\alpha))_i]\,x^{\kappa_B-1}\mathbb{I}_{(0,1)}\big)\big((0,1)\big) + \big(\mathsf{T}_{\mathbf{w};I_{2N}}[(\mathsf{Q}_{R,i}(x;\alpha))_i]\,x^{\kappa_B^{\mathrm{top}}-1}\mathbb{I}_{(0,1)}\big)\big((0,1)\big)\Big).$$

(ii) With $\lambda_S=\max_i\big(1-\mathsf{Q}_{S,i}(0;\alpha)\big)<1$ and $\kappa>0$,

$$\big(\mathsf{T}_{\mathbf{w};I_{2N}}[(\mathsf{Q}_{S,i}(x;\alpha))_i]\,x^{\kappa-1}\mathbb{I}_{(0,1)}\big)\big((0,1)\big) = \int_0^1 x^{\kappa-1}\prod_i\mathsf{Q}_{S,i}(x;\alpha)^{-w_i}\,dx = \sum_{\mathbf{n}\in\mathbb{N}^{2N}}\prod_i\frac{(w_i)_{n_i}}{n_i!}\sum_{k\ge0}\Big([x^k]\prod_i\mathsf{Q}_{S,i,>}(x;\alpha)^{n_i}\Big)\Gamma_{\,2\,1}\!\begin{bmatrix}\kappa+k,\ |\mathbf{n}|+1\\ \kappa+k+|\mathbf{n}|+1\end{bmatrix},$$

a series of nonnegative terms, those with $|\mathbf{n}|=M$ summing to at most $\frac{(|\mathbf{w}|)_M}{M!}\lambda_S^M\kappa^{-1}$.

For complex exponents with $\operatorname{Re}\kappa > 0$ *the series converges absolutely to the same value. No Skeleton value is used, and a complex spectrum closes as a real one does.*

Proposition 15.10 (Closing around a point of the axis)**.** *The expansion* $x+\xi = (x+r)\big(1-\frac{r-\xi}{x+r}\big)$, $r>0$, *converges uniformly on* $x \ge 0$ *exactly when* $|\xi - r| < r$*; one* r *serves every value of a finite spectrum exactly when every value has positive real part, that is, when every irreducible real factor of every Skeleton polynomial has positive coefficients.*

Corollary 15.11 (The period closes on the ordering sectors)**.** *Let the data be complex with* $\kappa_{\mathcal{E}} = 0$ *and* $\operatorname{Re}\kappa_S > 0$ *for every nonempty proper* S*. For an order* π *with tails* U_k *and sector letters* $k_{j,\pi}, \psi_{j,\pi}$ *(Theorem 8.5), with* $N_S = |T \cap S|$*, on* $[0,1]^{n-1}$

$$1 - \frac{k_{j,\pi}(q)}{K_j(\mathbf{1})} = \sum_{k=2}^{n} (1-q_k)\, \mathbb{E}_{T\sim\mathbb{P}_{j,\mathbf{1}}}\Big[\prod_{k'<k} q_{k'}^{\,N_{U_{k'}} - d_j(U_{k'})} \sum_{0 \le i < N_{U_k} - d_j(U_k)} q_k^{\,i} \Big],$$

the same for $\psi_{j,\pi}$ *with the colevels and* d_j^**; both sides lie in* $[0,\lambda]$*,* $\lambda < 1$ *the largest of the numbers* $1 - \theta_{j,T^{\pm}_{j,\pi}}/K_j(\mathbf{1})$*. Consequently*

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \prod_j K_j(\mathbf{1})^{-s_j-t_j} \sum_{\pi} \sum_{\mathbf{n},\mathbf{n}'} \prod_j \frac{(s_j)_{n_j}(t_j)_{n_j'}}{n_j!\, n_j'!} \times \int_{[0,1]^{n-1}} \prod_k q_k^{\,\kappa_{U_k}-1} \prod_j \Big(1 - \frac{k_{j,\pi}(q)}{K_j(\mathbf{1})}\Big)^{n_j} \Big(1 - \frac{\psi_{j,\pi}(q)}{K_j(\mathbf{1})}\Big)^{n_j'} dq,$$

a convergent series, each integral a finite positive combination of products

$$\prod_k \Gamma \begin{bmatrix} \kappa_{U_k} + \beta_k,\ \gamma_k + 1 \\ \kappa_{U_k} + \beta_k + \gamma_k + 1 \end{bmatrix}, \qquad \beta_k, \gamma_k \in \mathbb{N};$$

for real data with $s_j, t_j \ge 0$ *every term is nonnegative. With* $w = \sum_j (|s_j| + |t_j|)$*, the sum of the moduli of the exponents, the terms with* $|\mathbf{n}| + |\mathbf{n}'| = M$ *have moduli summing to at most* $\frac{(w)_M}{M!} \lambda^M \prod_j K_j(\mathbf{1})^{-\operatorname{Re}(s_j+t_j)} \sum_\pi \prod_k (\operatorname{Re}\kappa_{U_k})^{-1}$*.*

Proposition 15.12 (An enclosure of the period in the field of its data)**.** *In Corollary 15.11 let the data be real, and let the weights, masses and exponents lie in a subfield* k *of* $\mathbb{R}$*. For an order* π *put* $a_{j,\pi} = 1 - k_{j,\pi}/K_j(\mathbf{1})$ *and* $b_{j,\pi} = 1 - \psi_{j,\pi}/K_j(\mathbf{1})$*, let* $\lambda_\pi < 1$ *be the largest of the numbers* $1 - \theta_{j,T^{\pm}_{j,\pi}}/K_j(\mathbf{1})$*, and let* $f_{\pi,M}(q)$ *be the coefficient of* ζ^M *in the power series* $\prod_j (1-\zeta a_{j,\pi})^{-s_j}(1-\zeta b_{j,\pi})^{-t_j}$*.*

(i) $\prod_j K_j(\mathbf{1})^{s_j+t_j}\, P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \sum_\pi \sum_{M\ge 0} I_{\pi,M}$ *with* $I_{\pi,M} = \int_{[0,1]^{n-1}} \prod_k q_k^{\,\kappa_{U_k}-1} f_{\pi,M}(q)\, dq$*, an element of* k*, nonnegative when* $s_j, t_j \ge 0$*, by* $\int \prod_k q_k^{\,\kappa_{U_k}-1+\beta_k} dq = \prod_k (\kappa_{U_k}+\beta_k)^{-1}$*.*

(ii) With $w = \sum_j (|s_j| + |t_j|)$*, if* $r_{\pi,Q} = \lambda_\pi \max\big(1, \frac{w+Q+1}{Q+2}\big) < 1$*, then* $\big|\sum_{M>Q} I_{\pi,M}\big| \le \operatorname{err}_{\pi,Q} = \prod_k \kappa_{U_k}^{-1} \frac{(w)_{Q+1}}{(Q+1)!} \frac{\lambda_\pi^{Q+1}}{1-r_{\pi,Q}}$*, the sum being nonnegative when* $s_j, t_j \ge 0$*, and* $\operatorname{err}_{\pi,Q} \to 0$ *as* $Q \to \infty$*: the partial sums minus and plus* $\sum_\pi \operatorname{err}_{\pi,Q}$*, and for* $s_j, t_j \ge 0$ *the partial sums and the partial sums plus* $\sum_\pi \operatorname{err}_{\pi,Q}$*, are elements of* k *enclosing the left side of (i) within any prescribed width.*

(iii) The coefficients $f_{\pi,M}$ satisfy a linear recurrence in M with coefficients polynomial in M and in the $a_{j,\pi}, b_{j,\pi}$: the power series $f(\zeta)=\prod_i(1-\zeta A_i)^{-w_i}$, with (A_i,w_i) running over the pairs $(a_{j,\pi},s_j)$ and $(b_{j,\pi},t_j)$, satisfies $\prod_i(1-\zeta A_i)\,f'(\zeta)=\big(\sum_i w_iA_i\prod_{i'\neq i}(1-\zeta A_{i'})\big)f(\zeta)$.

Theorem 15.13 (The peak closing of a period)**.** *Let the data be real with $s_j,t_j\geq 0$, $\kappa_{\mathcal{E}}=0$ and every proper wall positive. Write the letters K_j (exponent s_j, degree r_j, counts d_j) and Ψ_j (exponent t_j, degree $n-r_j$, counts d_j^*) as L_i with exponents w_i, degrees g_i and counts $d_i(S)$, choose references $M_i\geq\max_{\Delta_{\mathcal{E}}}L_i$, and put $b_{\mathbf{n}}=\int_{\Delta_{\mathcal{E}}}u^{\mathbf{m-1}}\prod_i(M_i-L_i(u))^{n_i}d\omega_{\mathcal{E}}(u)\geq 0$.*

(i) $P_F(\mathbf{m};\mathbf{s},\mathbf{t})=\sum_{\mathbf{n}}\prod_i\frac{(w_i)_{n_i}}{n_i!}M_i^{-w_i-n_i}b_{\mathbf{n}}$, a series of nonnegative terms. With the references $M_i=\max_T\theta_{j,T}/g_i!$, j the table of the letter L_i, every $b_{\mathbf{n}}$ is a finite positive combination of the stacked Gammas $\Gamma^{\,n}_{\,1}\!\left[\begin{matrix}\mathbf{m}+\boldsymbol{\gamma}\\ m_{\mathcal{E}}+|\boldsymbol{\gamma}|\end{matrix}\right]$, $\boldsymbol{\gamma}\in\mathbb{N}^{\mathcal{E}}$; the same series, with every $b_{\mathbf{n}}$ such a finite positive combination, holds for $\int_{\Delta_{\mathcal{E}}}u^{\mathbf{m-1}}\prod_i L_i^{-w_i}\,d\omega_{\mathcal{E}}$ with any letters L_i homogeneous of degree g_i with nonnegative coefficients and squarefree monomials, M_i being the largest coefficient of L_i over $g_i!$.

(ii) For each letter let ϖ_i be the least of $\kappa_S/d_i(S)$ over nonempty proper S with $d_i(S)>0$, and k_i the largest length of a chain $S_1\subsetneq\cdots\subsetneq S_{k_i}$ with $\kappa_{S_l}=\varpi_i d_i(S_l)$; put $\varpi=\min_i\varpi_i$ and $k=\max\{k_i:\varpi_i=\varpi\}$. The partial sums $P^{\leq Q}$ of (i) over $\max_i n_i\leq Q$ satisfy $P_F(\mathbf{m};\mathbf{s},\mathbf{t})-P^{\leq Q}=\Theta\big(Q^{-\varpi}(\log Q)^{k-1}\big)$, and if a single letter attains ϖ,

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t})-P^{\leq Q}\sim\frac{c_i\,\Gamma(w_i+\varpi)}{\varpi\,\Gamma(k)\,\Gamma(w_i)}\,Q^{-\varpi}(\log Q)^{k-1},$$

with $c_i>0$ the coefficient of $(z+\varpi_i)^{-k_i}$ in $M_i^{-z}\int_{\Delta_{\mathcal{E}}}u^{\mathbf{m-1}}L_i^z\prod_{i'}L_{i'}^{-w_{i'}}d\omega_{\mathcal{E}}$, whose pole at $-\varpi_i$ has order exactly k_i. A letter that vanishes on no proper face closes geometrically.

(iii) The fastest start is the sharp reference $M_i=\max_{\Delta_{\mathcal{E}}}L_i$; where it is attained inside the simplex, $u_e^\star\partial_e\log L_i(u^\star)=g_iu_e^\star$ for every mark. It can be attained on a proper face of the simplex.

(iv) At the target of a molecule with a native gauge every proper wall is positive (Theorem 8.19(iii)), so the series applies there and its rate ϖ is positive.

Theorem 15.14 (Continued Beta corners)**.** *In Theorem 15.9 and Corollary 15.11 let the data be complex and let no index κ, respectively no κ_{U_k}, be a nonpositive integer; for an index with $\operatorname{Re}\kappa\leq 0$ let $h\in\mathbb{N}$ have $-h-1<\operatorname{Re}\kappa\leq -h$. Then the series converge, with each Beta corner $\Gamma^{\,2}_{\,1}\!\left[\begin{matrix}\kappa+k,\ |\mathbf{n}|+1\\ \kappa+k+|\mathbf{n}|+1\end{matrix}\right]$ in Theorem 15.9 and $\Gamma^{\,2}_{\,1}\!\left[\begin{matrix}\kappa_{U_k}+\beta_k,\ \gamma_k+1\\ \kappa_{U_k}+\beta_k+\gamma_k+1\end{matrix}\right]$ in Corollary 15.11 read as the meromorphic stacked Gamma, to the* Reg *of the integral, its continuation in the indices; the terms of total order M are at most $\frac{(w)_M}{M!}\lambda^M$ times a polynomial in M whose degree is the sum of the integers $h+1$ over the indices with real part at most 0 (over the proper walls with $\operatorname{Re}\kappa_S\leq 0$ in Corollary 15.11), with $w=\sum_j(|s_j|+|t_j|)$ the sum of the moduli of the exponents. The sector series needs no positivity of the walls and computes the continued value at every point off the pole hyperplanes.*

The closings expand each letter around a reference and integrate term by term: on the two sectors of a bunch's scale the reference is the letter's value at the end of the sector, on the ordering sectors of the simplex it is the total weight, and at the peak it is a bound on the simplex. For real data with nonnegative exponents every term is a positive combination of stacked Gammas, nonnegative where the walls are positive, and the rate at which they fall is read from the walls.

15.3 The port

Theorem 15.15 (The port)**.** *Let B be a bunch of a family F on $\mathcal{E}$, with room R, and suppose there are reals $c_{j,p}, c'_{j,p} > 0$, one for each pattern p of B in table j, with $\sum_p c_{j,p} = \operatorname{Re} s_j$ and $\sum_p c'_{j,p} = \operatorname{Re} t_j$, such that (a) $\operatorname{Re}\mu_e - \sum_{j,p} \frac{c_{j,p}-c'_{j,p}}{2}\chi_p(e) > 0$ for $e \in B$, and (b) the children $F_B(\mathbf{c},\mathbf{c}')$ converge at the masses $\operatorname{Re}\mathbf{m}|_R$. Then $J_F(\mathbf{m};\mathbf{s},\mathbf{t})$ converges and, with the share integrals on $\operatorname{Re} a_{j,p} = c_{j,p}$, $\operatorname{Re} b_{j,p} = c'_{j,p}$,*

$$J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \int_{|\mathbf{a}_j|=s_j} \int_{|\mathbf{b}_j|=t_j} \prod_j \Gamma_{|\operatorname{pat}_1^j(B)|}\begin{bmatrix}\mathbf{a}_j\\ s_j\end{bmatrix} \Gamma_{|\operatorname{pat}_1^j(B)|}\begin{bmatrix}\mathbf{b}_j\\ t_j\end{bmatrix} \times \prod_{e\in B} \Gamma\big(\mu_e - \langle\boldsymbol{\delta}\rangle_e\big)\, J_{F_B(\mathbf{a},\mathbf{b})}(\mathbf{m}|_R;\mathbf{a},\mathbf{b}),$$

with the odd loads $\langle\boldsymbol{\delta}\rangle_e$ of the shares (Definition 12.24). For $B = \mathcal{E}$ this is the atom formula*: every child is $\{\varnothing\}$ with the weight $\theta_{j,T}$, and $J_{F_{\mathcal{E}}(\mathbf{a},\mathbf{b})}(\varnothing;\mathbf{a},\mathbf{b}) = \prod_{j,T} \theta_{j,T}^{-a_{j,T}-b_{j,T}}$.*

The port opens every letter over the patterns of the bunch, one share for each pattern and letter. On the bunch the shares leave a product of Gammas, one per mark, whose arguments are the offsets less the odd loads; on the room they leave the interest of the children at the shares as their exponents.

Corollary 15.16 (A loop or coloop in every table)**.** *Let every mark of a set A be in every table a loop or a coloop, with $\eta_{j,e} = -1$ for a loop and $\eta_{j,e} = +1$ for a coloop. Then $J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \prod_{e\in A}\Gamma\big(\mu_e - \sum_j \eta_{j,e}\delta_j\big)\, J_{F'}(\mathbf{m}|_{\mathcal{E}\setminus A};\mathbf{s},\mathbf{t})$, with F' the family on $\mathcal{E}\setminus A$ of the deletions of its tables at the loops and the contractions at the coloops (Definition 7.3).*

Corollary 15.17 (The damped bunch integral is a Breta)**.** *In Theorem 15.15 fix α_R, let $\operatorname{Re} s_j, \operatorname{Re} t_j > 0$ (a letter with exponent zero is 1 and gets no scale), put $z = \frac{1}{2}\log\alpha$, introduce one singleton scale per letter, $V = \{v_{j,+}, v_{j,-}\}_j$, put $\mathbf{q} = (\mathbf{s},\mathbf{t})$ on V, and take the partition $\mathcal{P}_{\text{port}} = \{B\} \cup \{\{v\} : v \in V\}$. The term arrays $(\pi^{\text{port}}, \ell^{\text{port}})$ of the letter presentation (Proposition 3.6) have the columns:*

- *for each $e \in B$, the kernel column with shape exponent $(\mathbf{e}_e, 0_V)$, level $(1, 0_V)$ and coefficient 1;*
- *for every (j,p), a column with shape exponent $(\chi_p/2, \mathbf{e}_{j,+})$, level $(\ell_p, \mathbf{e}_{j,+})$ and coefficient $\Lambda_{j,(p)}(z_R)$;*
- *for every (j,p), a column with shape exponent $(-\chi_p/2, \mathbf{e}_{j,-})$, level $(-\ell_p, \mathbf{e}_{j,-})$ and coefficient $\Lambda_{j,(p)}(-z_R)$;*

and $\boldsymbol{\xi}_{\text{port}}(\alpha_R)$ lists the coefficients in this order. Then, either side converging with the other,

$$\int_{\mathbb{R}^B_{>0}} \alpha_B^{\boldsymbol{\mu}|_B - \mathbf{1}} e^{-|\alpha_B|} \prod_j \Lambda_j(z)^{-s_j}\Lambda_j(-z)^{-t_j}\, d\alpha_B = \Gamma(\mu_B)\, \mathsf{B}^{\mathcal{P}_{\text{port}}}_{(\boldsymbol{\mu}|_B,\mathbf{q}),\,(\mu_B,\mathbf{q});\,(\pi^{\text{port}},\ell^{\text{port}})}\big(\boldsymbol{\xi}_{\text{port}}(\alpha_R)\big).$$

The scale of Theorem 15.3 keeps the letters closed and integrates the scale alone, one share per distinct Skeleton value beyond the first (Corollary 15.5).

Theorem 15.18 (The native split is an admissible contour)**.** *For real data with $s_j, t_j \geq 0$, not all zero, $\mathbf{m} > 0$ and $\kappa_{\mathcal{E}} > 0$, a native gauge $\alpha^\star$ and a bunch B, the real parts $c_{j,p} = s_j\pi_{j,p}(\alpha^\star)$, $c'_{j,p} = t_j\pi^*_{j,p}(\alpha^\star)$ of the native split satisfy the hypotheses of Theorem 15.15; a letter with exponent zero is 1 and is not opened.*

Corollary 15.19 (The port decides convergence)**.** *For real data with $s_j, t_j \geq 0$ and any bunch B, $J_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$ converges if and only if some real parts satisfy the hypotheses of Theorem 15.15 at B.*

15.4 Signed letters

Definition 15.20 (Signed letters)**.** A *signed letter* is $L = L_+ - L_-$ with $L_\pm$ positive combinations of monomials of one degree g; adjoining $\zeta|u|^g$ gives $L+\zeta$ on the simplex, positive for $\zeta > -\min_{\Delta_\mathcal{E}} L$.

Proposition 15.21 (A signed letter is a boundary value)**.** *Let a signed letter L enter a form with exponent s beside positive letters L_i with exponents w_i, and for $\zeta > -\min_{\Delta_\mathcal{E}} L$ put $G(\zeta) = \int_{\Delta_\mathcal{E}} u^{\mathbf{m-1}} (L+\zeta)^{-s} \prod_i L_i^{-w_i}\, d\omega_\mathcal{E}$.*

(i) With ν the image of $u^{\mathbf{m-1}} \prod_i L_i^{-w_i} d\omega_\mathcal{E}$ under $u \mapsto L(u)$, $G(\zeta) = \int (y+\zeta)^{-s}\, \nu(dy)$ is holomorphic off $(-\infty, -\min_{\Delta_\mathcal{E}} L]$, continues across that half-line except at the negatives of the critical values of L on the simplex and its faces, and satisfies a linear differential equation in ζ with polynomial coefficients.

(ii) $G(0 \pm i0) = \int_{L>0} u^{\mathbf{m-1}} L^{-s} \prod_i L_i^{-w_i} d\omega_\mathcal{E} + e^{\mp i\pi s} \int_{L<0} u^{\mathbf{m-1}} |L|^{-s} \prod_i L_i^{-w_i} d\omega_\mathcal{E}$, the region integrals convergent for $\operatorname{Re} s < 1$ near regular zeros and taken by Lemma 8.4 in the coordinate $y = L(u)$ otherwise.

(iii) $G(0+i0) - G(0-i0) = -2i \sin(\pi s) \int_{L<0} u^{\mathbf{m-1}} |L|^{-s} \prod_i L_i^{-w_i} d\omega_\mathcal{E}$.

On the scale of a bunch a zero of a signed letter is a split point: on each of the intervals it bounds, rescaled to $[0,1]$, the zero is at an endpoint, where it is a wall of the integral over that interval and Theorem 15.14 applies, and the phase $e^{\mp i\pi s}$ attaches to the interval on which the letter is negative.

Chapter 16

Integrals, expectations and the Foreman procedure

16.1 Forms, sections, completions

Definition 16.1 (Differential forms, charts, schedules)**.** The *differential form* of a family at masses $\mathbf{m}$ is

$$\omega = W\, d\alpha_{\mathbf{m}} = \alpha^{\mathbf{m-1}} \prod_j K_j(\alpha)^{-s_j} \Psi_j(\alpha)^{-t_j} d\alpha,$$

the family word against the measure $d\alpha_{\mathbf{m}}$ (Definition 8.1). It is *projective* when $\kappa_{\mathcal{E}} = 0$, and then it is integrated over the rays of the orthant, over any section (Lemma 16.2, next). The *chart* at a mark g is the section $\alpha_g = 1$ with the coordinates α_e, $e \neq g$, and the chart integral is $\int_{\alpha_g=1} \omega = \int_{\mathbb{R}^{\mathcal{E}-g}_{>0}} (\cdots)|_{\alpha_g=1} \prod_{e\neq g} d\alpha_e$. Passing to the chart at g is the *snip* at g. A *schedule* $\mathfrak{s} = (g; \varsigma)$ is the chart at a mark g and an order $\varsigma(1), \dots, \varsigma(n-1)$ of the other marks.

Lemma 16.2 (Every section gives the period)**.** *If ω is projective with convergent period, f its integrand, $h > 0$ homogeneous of degree one and φ a function on $(0,\infty)$ with $\int_0^\infty |\varphi(\rho)|\, d\rho/\rho < \infty$, then $\int_{\mathbb{R}^{\mathcal{E}}_{>0}} f\, \varphi(h)\, d\alpha = \big(\int_0^\infty \varphi(\rho) \frac{d\rho}{\rho}\big) P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$. In particular every chart integral converges and equals $P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$.*

Proposition 16.3 (A section is a table)**.** *Let $W = \prod_j K_j^{-s_j} \Psi_j^{-t_j}$ be a family word, in this statement of the degree $-d_W$, $d_W = \sum_j (s_j r_j + t_j r_j^*)$, and $\mathbf{m}$ masses with every proper wall positive. Then $\int_{\Delta_{\mathcal{E}}} u^{\mathbf{m-1}} W\, d\omega_{\mathcal{E}}$ is the value on its balance wall of the family with the list $\binom{\mathcal{E}}{1}$, whose bases are the singletons and whose letter is $K_0 = |\alpha|$, added at the exponents $(m_{\mathcal{E}} - d_W, 0)$; its proper walls are those of the family. In particular, for the family F_0 of the one table $\binom{\mathcal{E}}{1}$, $\mathrm{Dir}_{\mathbf{m}} = \mathrm{Breta}^\circ(F_0; \mathbf{m}; m_{\mathcal{E}}, 0)$, the Breta shape law of $\binom{\mathcal{E}}{1}$ at a full basis lean; and for two families F_1, F_2 on $\mathcal{E}$ with words W_1, W_2, the logarithms of the letters of F_2 under the law on $\Delta_{\mathcal{E}}$ with density proportional to $u^{\mathbf{m-1}} W_1$ have the Laplace transform*

$$\int_{\Delta_{\mathcal{E}}} u^{\mathbf{m-1}} W_1 W_2\, d\omega_{\mathcal{E}} \Big/ \int_{\Delta_{\mathcal{E}}} u^{\mathbf{m-1}} W_1\, d\omega_{\mathcal{E}}$$

in the exponents of W_2, a ratio of two values of the family $F_1 \cup F_2 \cup F_0$.

Definition 16.4 (Completions)**.** For $w \in \mathbb{R}^{\mathcal{E}}$ with $w_{\mathcal{E}} = 1$ the *completion* of $\omega = W\, d\alpha_{\mathbf{m}}$ along w is $\omega_{\mathbf{m}'} = \alpha^{-\kappa_{\mathcal{E}} w} \omega = W\, d\alpha_{\mathbf{m}'}$, $\mathbf{m}' = \mathbf{m} - \kappa_{\mathcal{E}} w$, which is projective: a completion acts on the measure

and leaves the word. The *chart completion* at g has $w = \mathbf{e}_g$ and the masses $\mathbf{m}^{(g)} = \mathbf{m} - \kappa_{\mathcal{E}}\mathbf{e}_g$. For real data the *native completion* has $w = \mathbf{m}/m_{\mathcal{E}}$; its measure is the differential

$$d\alpha_{\boldsymbol{\tau}} = \alpha^{-(\kappa_{\mathcal{E}}/m_{\mathcal{E}})\mathbf{m}}\, d\alpha_{\mathbf{m}}, \qquad \boldsymbol{\tau} = \frac{n\sigma + \sum_j \delta_j(2r_j - n)}{n\sigma + \mu_{\mathcal{E}}}\,\mathbf{m},$$

at the target, with $\kappa_{\mathcal{E}} = \mu_{\mathcal{E}} - \sum_j \delta_j(2r_j - n)$ and $m_{\mathcal{E}} = n\sigma + \mu_{\mathcal{E}}$ in pair coordinates (Theorem 8.2(iii)), and the completed form is $\omega_{\boldsymbol{\tau}} = W\, d\alpha_{\boldsymbol{\tau}}$.

Proposition 16.5 (Snips are completions)**.** *(i)* $\int_{\alpha_g=1}\omega = \int_{\alpha_g=1}\omega_{\mathbf{m}^{(g)}}$*, the period* $P_F(\mathbf{m}^{(g)};\mathbf{s},\mathbf{t})$ *wherever it converges.*

(ii) $K_j|_{\alpha_g=1} = K_{j,\backslash g} + K_{j,/g}$ *and* $\Psi_j|_{\alpha_g=1} = \Psi_{j,\backslash g} + \Psi_{j,/g}$*, and for* $\operatorname{Re} s_j, \operatorname{Re} t_j > 0$*, on the contours of Corollary 4.4,*

$$\prod_j K_j^{-s_j}\Psi_j^{-t_j}\Big|_{\alpha_g=1} = \int\cdots\int \prod_j \Gamma_1^2\begin{bmatrix} a_j,\ a_j' \\ s_j \end{bmatrix}\Gamma_1^2\begin{bmatrix} b_j,\ b_j' \\ t_j \end{bmatrix} K_{j,\backslash g}^{-a_j}K_{j,/g}^{-a_j'}\Psi_{j,\backslash g}^{-b_j}\Psi_{j,/g}^{-b_j'}$$

over $a_j + a_j' = s_j$*,* $b_j + b_j' = t_j$*: a snip opens every letter into its deletion and its contraction, with stacked-Gamma shares.*

(iii) For a bunch B*, the integral of* ω *over the bunch section* $|\alpha_B| = 1$ *is the integral over the rays of the projective form* $|\alpha_B|^{-\kappa_{\mathcal{E}}}\omega$*. In this statement write* F' *for* F *with one table appended at the exponents* $(\kappa_{\mathcal{E}}, 0)$*: the list* $\binom{B}{1}$ *read on* $\mathcal{E}$*, whose bases are the singletons of* B*, with the marks outside* B *as loops, and whose letter is* $|\alpha_B|$*. Then* $|\alpha_B|^{-\kappa_{\mathcal{E}}}\omega$ *is the form of* F' *at the masses* $\mathbf{m}$*,* F' *is balanced there, its proper walls are* $\kappa_S - \kappa_{\mathcal{E}}\,\mathbf{1}[B \subseteq S]$*, and*

$$\int_{|\alpha_B|=1}\omega = P_{F'}\big(\mathbf{m};(\mathbf{s},\kappa_{\mathcal{E}}),(\mathbf{t},0)\big)$$

wherever $\operatorname{Re}\kappa_S - \operatorname{Re}\kappa_{\mathcal{E}}\,\mathbf{1}[B \subseteq S] > 0$ *for every nonempty proper* S*. At* $B = \{g\}$ *the appended letter is the monomial* α_g*, and this is (i); at* $B = \mathcal{E}$ *the appended table is the list* $\binom{\mathcal{E}}{1}$ *(Proposition 16.3). For* $k = -\kappa_{\mathcal{E}} \in \mathbb{N}$*,* $k \geq 1$*,* $|\alpha_B|^k = \sum_{|\mathbf{n}|=k}\binom{k}{\mathbf{n}}\alpha_B^{\mathbf{n}}$*, so* $\int_{|\alpha_B|=1}\omega = \sum_{\mathbf{n}\in\mathbb{N}^B,\,|\mathbf{n}|=k}\binom{k}{\mathbf{n}}\int_{|\alpha_B|=1}\omega_{\mathbf{m}+\mathbf{n}}$*, each term the period* $P_F(\mathbf{m}+\mathbf{n};\mathbf{s},\mathbf{t})$ *wherever it converges.*

Corollary 16.6 (The period fibres over the scale of a bunch)**.** *Let* B *be a proper bunch of a family* F *on* $\mathcal{E}$*, with room* R*, and let* $h > 0$ *be a function of* α_R *homogeneous of degree one. Wherever the integral of* $W\, d\alpha_{\mathbf{m}}$ *over the section* $\{h(\alpha_R) = 1\}$ *of the orthant converges, both sections taken with the measures of Lemma 16.2,*

$$\int_{h(\alpha_R)=1} W\, d\alpha_{\mathbf{m}} = \int_{\{\alpha_R\in\mathbb{R}^R_{>0}:\ h(\alpha_R)=1\}}\int_{\Delta_B} u^{\mathbf{m}|_B - \mathbf{1}}\alpha_R^{\mathbf{m}|_R - \mathbf{1}}\ \mathrm{Sc}_B(u,\alpha_R;\mathbf{m};\mathbf{s},\mathbf{t})\, d\omega_B(u),$$

and at every point Sc_B *is the product of Theorem 15.3, a stacked Gamma times a Breta of one bunch. On the balance wall the left side is* $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$*. At the chart* $h = \alpha_g$*,* $g \in R$*, the left side is* $P_F(\mathbf{m}^{(g)};\mathbf{s},\mathbf{t})$ *(Proposition 16.5(i)) and the outer integral is over* α_{R-g} *at* $\alpha_g = 1$*; at* $h = |\alpha_R|$ *it is over* Δ_R *against* $d\omega_R$*.*

Proposition 16.7 (The scaling mode)**.** *Along $z \mapsto z + c\mathbf{1}$, $E_j(z + c\mathbf{1}) = E_j(z)$, $O_j(z + c\mathbf{1}) = O_j(z) + 2c(2r_j - n)$, and the exponent $2\langle \boldsymbol{\mu}, z\rangle - \sum_j (\sigma_j E_j + \delta_j O_j)$ of the pair form moves by $2c\kappa_{\mathcal{E}}$. Off the balance wall the form is not integrable along this direction; it is* damped *by $e^{-|\alpha|}$ (the interest, $J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \Gamma(\kappa_{\mathcal{E}})P_F(\mathbf{m};\mathbf{s},\mathbf{t})$),* conditioned *by a section (at a chart a completion, Proposition 16.5; in general another projective form, Proposition 16.32 below), or* slid *by moving the masses along their ray to the balance wall (the native completion).*

Theorem 16.8 (The slide)**.** *Let ω have real data on a connected family, with $s_j, t_j \geq 0$, not all zero, and $\mathbf{m} > 0$, native gauge $\alpha^\star$ and target $\boldsymbol{\tau}$.*

(i) If $\kappa_{\mathcal{E}} \neq 0$, exactly one completion of ω has $\alpha^\star$ as a native gauge: $\omega_{\boldsymbol{\tau}}$. If $\kappa_{\mathcal{E}} = 0$, every completion is ω and $\boldsymbol{\tau} = \mathbf{m}$.

(ii) As the masses slide along their ray, $\mathbf{m} \mapsto \lambda\mathbf{m}$, the data $(\lambda\mathbf{m};\mathbf{s},\mathbf{t})$ lie on the balance wall exactly when $\lambda\mathbf{m} = \boldsymbol{\tau}$.

(iii) Every proper wall of $\omega_{\boldsymbol{\tau}}$ is positive, so its period converges.

(iv) $\boldsymbol{\tau}$, $\omega_{\boldsymbol{\tau}}$ and $\alpha^\star$ are the same at every point of the ray of $\mathbf{m}$.

Each of the three treatments of the free scaling mode (Proposition 16.7) is an evaluation, and sliding keeps the native gauge.

16.2 Three integrals and their expectations

Lemma 16.9 (The period is meromorphic in the data)**.** *For every family, P_F is meromorphic in the masses and the exponents, with poles only where a proper wall is a nonpositive integer, and so is its restriction to the balance wall.*

Definition 16.10 (Three integrals and their expectations)**.** Let $\omega = W\, d\alpha_{\mathbf{m}}$ have real data, $s_j, t_j \geq 0$ not all zero and $\mathbf{m} > 0$, so that W is homogeneous of degree $-\tau_{\mathcal{E}}$, $\tau_{\mathcal{E}} = n\sigma + \sum_j \delta_j(2r_j - n)$ with $\sigma = \sum_j \sigma_j$. On a connected family the centre of ω is the form of the family at the centre (Definition 9.1), at the exponents $(\boldsymbol{\sigma}, \boldsymbol{\sigma})$ and the masses $\sigma\mathbf{1}$,

$$\omega_{\mathrm{c}} = \prod_j \big(K_j \Psi_j\big)^{-\sigma_j} d\alpha_{\sigma\mathbf{1}}.$$

It is projective, its proper walls $\sum_j \sigma_j c_j(S)$ are positive and the table's gauge is native for it (Proposition 8.21), so its period $P_{\mathrm{c}} = P_F(\sigma\mathbf{1};\boldsymbol{\sigma},\boldsymbol{\sigma})$ is a positive convergent integral, and $\mathbb{P}_{\mathrm{c}} = \mathrm{Breta}^\circ(F;\sigma\mathbf{1};\boldsymbol{\sigma},\boldsymbol{\sigma})$, the measure $\omega_{\mathrm{c}}/P_{\mathrm{c}}$ read on the rays, is the *law of the centre*. For masses $\mathbf{m}'$ of total $\tau_{\mathcal{E}}$ the *departure* of $W\, d\alpha_{\mathbf{m}'}$ from the centre is the ratio of the two forms,

$$\frac{W\, d\alpha_{\mathbf{m}'}}{\omega_{\mathrm{c}}}(\alpha) = \alpha^{\mathbf{m}' - \sigma\mathbf{1}} \prod_j \Big(\frac{K_j(\alpha)}{\Psi_j(\alpha)}\Big)^{-\delta_j},$$

homogeneous of degree 0: an *offset factor* $\alpha^{\mathbf{m}'-\sigma\mathbf{1}}$ and a *lean factor* $\prod_j (K_j/\Psi_j)^{-\delta_j}$. Each integral below is unnormalized. On a connected family its expectation divides it by P_{c}: it is the expectation, under the law of the centre, of the departure that its evaluation sets.

(i) The *integral* $\int W\, d\alpha_{\mathbf{m}}$ is defined when ω is projective with convergent period: it is the integral of ω over any section, $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$, and $\int W\, d\alpha_{\mathbf{m}} = P_{\mathrm{c}}\, \mathbb{E}_{U\sim\mathbb{P}_{\mathrm{c}}}\big[(\omega/\omega_{\mathrm{c}})(U)\big]$.

(ii) For a schedule $\mathfrak{s} = (g; \varsigma)$ the *quasi-integral* is the iterated finite part

$$\operatorname{Reg}^{\mathfrak{s}}\!\int W\, d\alpha_{\mathbf{m}} = \operatorname{Reg}\!\int_0^\infty dx_{n-1} \cdots \operatorname{Reg}\!\int_0^\infty dx_1 \Big(\alpha^{\mathbf{m}-\mathbf{1}} \prod_j K_j^{-s_j} \Psi_j^{-t_j}\Big)\Big|_{\alpha_g = 1}, \qquad x_k = \alpha_{\varsigma(k)},$$

defined whenever the integrand of every one of these iterated integrals has log-power expansions at 0 and at ∞. It sets the departure of the chart completion, and the *quasi-expectation* is $\mathfrak{E}^{\mathfrak{s}}_{U\sim\mathbb{P}_{\mathrm{c}}}\big[(\omega_{\mathbf{m}^{(g)}}/\omega_{\mathrm{c}})(U)\big] = \operatorname{Reg}^{\mathfrak{s}}\!\int W\, d\alpha_{\mathbf{m}} \big/ P_{\mathrm{c}}$.

(iii) For a connected family of at least two marks, the *pseudointegral* is

$$\Big\backslash\!\!\!\int W\, d\alpha_{\mathbf{m}} = \operatorname*{CT}_{\eta=0} P_F(\boldsymbol{\tau} + \eta\mathbf{m}; \mathbf{s}, \mathbf{t}),$$

the constant term at the target along the ray of the masses, P_F being meromorphic in the masses with poles only where a proper wall is a nonpositive integer, on the *pole hyperplanes* $\kappa_S = -q$, S proper, $q \in \mathbb{N}$ (Lemma 16.9). Off those hyperplanes it is $P_F(\boldsymbol{\tau}; \mathbf{s}, \mathbf{t})$, the value at the target of the meromorphic function P_F on the balance wall. With a native gauge every proper wall is positive at $\boldsymbol{\tau}$ and $\backslash\!\!\int W\, d\alpha_{\mathbf{m}} = \int W\, d\alpha_{\boldsymbol{\tau}}$: the Foreman sets the measure to the native completion. It sets the departure of the native completion, and the *pseudoexpectation* is

$$\mathsf{E}_{U\sim\mathbb{P}_{\mathrm{c}}}\Big[\frac{\omega_{\boldsymbol{\tau}}}{\omega_{\mathrm{c}}}(U)\Big] = \Big\backslash\!\!\!\int W\, d\alpha_{\mathbf{m}} \Big/ P_{\mathrm{c}};$$

with a native gauge it is the expectation $\mathbb{E}_{U\sim\mathbb{P}_{\mathrm{c}}}[(\omega_{\boldsymbol{\tau}}/\omega_{\mathrm{c}})(U)]$: the Foreman sets the departure and the centre sets the law. On a family whose weights factor across its molecules, the pseudointegral and the pseudoexpectation are products over the molecules, each at its own target and with its own centre; a one-mark factor contributes the value of its integrand at $\alpha = \mathbf{1}$ to the pseudointegral and 1 to the pseudoexpectation, its integrand and its centre's agreeing there.

A point $(\boldsymbol{\mu}; \boldsymbol{\sigma}, \boldsymbol{\delta})$ splits into an even part, the strengths σ_j, and an odd part, the offsets and the leans; the fold (Theorem 16.18) negates the odd part and keeps the even part. The centre is the point with the same even part and no odd part. It lies on the balance wall, it is inside its walls at every strength on a connected family, and its native gauge is the table's gauge, so its period is a convergent integral of the family itself, the same for every evaluation. Dividing by it prices the odd part of a point against its even part: with a native gauge the pseudoexpectation is the exponential of a divergence from the law of the centre, at least 1, equal to 1 exactly when the native completion is the centre's form, and unchanged by the fold (Proposition 16.34).

Theorem 16.11 (Quasi-integrals extend the integral)**.** *Each* $\operatorname{Reg}^{\mathfrak{s}}\!\int$ *is linear in the integrand, and* $\operatorname{Reg}^{\mathfrak{s}}\!\int W\, d\alpha_{\mathbf{m}} = \int W\, d\alpha_{\mathbf{m}}$ *for every schedule wherever* $\int W\, d\alpha_{\mathbf{m}}$ *is defined; there every chart completion is* ω*,* $\mathbf{m}^{(g)} = \mathbf{m}$*, and on a connected family* $\mathfrak{E}^{\mathfrak{s}}_{U\sim\mathbb{P}_{\mathrm{c}}}[(\omega_{\mathbf{m}^{(g)}}/\omega_{\mathrm{c}})(U)] = \mathbb{E}_{U\sim\mathbb{P}_{\mathrm{c}}}[(\omega/\omega_{\mathrm{c}})(U)]$*. Elsewhere the value can depend on the chart, on the order and on the coordinates (Lemma 1.9).*

Proposition 16.12 (The form of a compound at one point)**.** *Let* F *be the direct sum of families* $F_1, \dots, F_q$ *on* $\mathcal{E}_1, \dots, \mathcal{E}_q$*,* $q \geq 2$*,* $\mathcal{E} = \mathcal{E}_1 \sqcup \cdots \sqcup \mathcal{E}_q$*, every table a direct sum across the split with factoring weights, so that* $K_j = \prod_i K_{j,i}$ *and* $\Psi_j = \prod_i \Psi_{j,i}$*; let the data be real, the masses* $\mathbf{m} = (\mathbf{m}_1, \dots, \mathbf{m}_q)$ *on the balance wall of* F*, and* κ_i *the imbalance of* F_i *at* $\mathbf{m}_i$*, so* $\sum_i \kappa_i = 0$*. On the section* $|\alpha_q| = 1$ *with* $\alpha_i = \rho_i u_i$*,* $u_i \in \Delta_{\mathcal{E}_i}$*, for* $i < q$ *and* $u_q = \alpha_q$*, the form of* F *is*

$$\prod_{i<q} \rho_i^{\kappa_i - 1} d\rho_i \;\cdot\; \prod_{i=1}^{q} u_i^{\mathbf{m}_i - \mathbf{1}} \prod_j K_{j,i}^{-s_j} \Psi_{j,i}^{-t_j}\, d\omega_{\mathcal{E}_i}.$$

(i) Its integral diverges for all $\kappa_1, \dots, \kappa_q$.

(ii) The finite part of each ρ_i-integral is 0 for every κ_i.

(iii) On the masses $\mathbf{m}(\boldsymbol{\eta}) = (\mathbf{m}_i^0 + i\eta_i w_i)_{i=1}^q$, $\boldsymbol{\eta} \in \mathbb{R}^q$ with $\sum_i \eta_i = 0$, with $\mathbf{m}_i^0$ balanced for F_i inside its walls and $w_i \in \mathbb{R}^{\mathcal{E}_i}$ of total 1, so that $\kappa_i = i\eta_i$, the integral of the form is, as a distribution in $(\eta_1, \dots, \eta_{q-1})$, $(2\pi)^{q-1} \prod_{i=1}^q P_{F_i}(\mathbf{m}_i^0; \mathbf{s}, \mathbf{t})$ times the Dirac measure at 0.

So the compound carries nothing beyond the points of its parts, and only where each molecule is balanced on its own.

Theorem 16.13 (Presentations)**.** *Let $\omega = W\, d\alpha_{\mathbf{m}}$ have real data on a connected family, $s_j, t_j \geq 0$ not all zero and $\mathbf{m} > 0$. A* presentation *of ω is a bijection φ of the marks together with coordinates $x = \lambda^{-1}\alpha$, $\lambda \in \mathbb{R}^{\mathcal{E}}_{>0}$, in which the letters are $K_j(\lambda x)$, $\Psi_j(\lambda x)$ and the form carries the constant $\lambda^{\mathbf{m}}$. The split, the targets, the native gauges as points of the torus, the stills, the classes, the native splits and the children computed from a presentation are the images under φ of those computed from ω, and, when the target lies on no pole hyperplane, the pseudointegral and the pseudoexpectation of the presentation, its centre presented with it, are $(\lambda^{\mathbf{m}})^{\kappa\varepsilon/m_{\mathcal{E}}}$ times those of ω, the factor being 1 on the balance wall; on a pole hyperplane the constant term moves with the coordinates as well (Proposition 16.31 below). In the coordinates x the table's gauge is $x = \lambda^{-1}$, and the Foreman tree is the same. On a family whose weights factor across its molecules the factor is the product of the molecules' factors.*

Definition 16.14 (The Foreman procedure)**.** *Classification*, from the tables alone:

(1) *Split* the marks into molecules and units (Proposition 9.5).

(2) *Read* each molecule M at a centre $\Upsilon_{\boldsymbol{\sigma},0;\mathbf{1}}$ of the table's gauge (Chapter 10).

(3) *Answer*: a constant reading is an atom; otherwise take the Foreman bunch $B(M; \boldsymbol{\sigma}, 0)$ (Definition 13.6).

(4) *Peel* at $B(M; \boldsymbol{\sigma}, 0)$; the childcules sit at the centres they inherit (Proposition 12.27).

(5) *Recurse* to atoms and units: the output is the Foreman tree and, at the root, the label.

Evaluation at a real point $(\mathbf{m}; \mathbf{s}, \mathbf{t})$ with $s_j, t_j \geq 0$, not all zero, and $\mathbf{m} > 0$:

(6) *Native gauge* of each molecule, and its target $\boldsymbol{\tau}$ (Theorem 8.19).

(7) *Slide* the masses to the target (Theorem 16.8).

(8) *Ports* along the tree, every share contour through the native split (Theorems 15.15, 15.18 and 12.26); on the balance wall the port of Chapter 18.

(9) *Atoms*: the atom formula (Theorem 15.15 with $B = \mathcal{E}$; on the balance wall, Chapter 18).

On the orthant side the ports integrate the Foreman bunch of each node inside the integral over its room, all its marks at once in scale and shape (Corollary 15.17): the root's bunch first and the atoms last. This is the *Foreman's order*.

Theorem 16.15 (The Foreman computes the pseudointegral)**.** *Let $\omega = W\, d\alpha_{\mathbf{m}}$ have real data on a connected family, with $s_j, t_j \geq 0$, not all zero, and $\mathbf{m} > 0$, and a native gauge. For every $\eta > 0$ the procedure at the masses $\boldsymbol{\tau} + \eta\mathbf{m}$ runs on admissible contours and computes $J_F(\boldsymbol{\tau} + \eta\mathbf{m}; \mathbf{s}, \mathbf{t})$, and*

$$\int W\, d\alpha_{\mathbf{m}} = \lim_{\eta \to 0^+} \frac{J_F(\boldsymbol{\tau} + \eta\mathbf{m}; \mathbf{s}, \mathbf{t})}{\Gamma(\eta m_{\mathcal{E}})}.$$

No finite part, chart, order or closing rule enters: the regulator η leaves by a limit.

Corollary 16.16 (One member among the generalized integrals)**.** *Wherever $\int W\, d\alpha_{\mathbf{m}}$ is defined for real data on a connected family, $⨍ W\, d\alpha_{\mathbf{m}} = \int W\, d\alpha_{\mathbf{m}}$, and with Theorem 16.11 every evaluation sets the one departure $\omega/\omega_{\mathrm{c}}$ on the balance wall. Off the balance wall, with $s_j, t_j \geq 0$, not all zero, and $\mathbf{m} > 0$, the period at the target converges exactly when the family has a native gauge (Theorem 8.19(iii)), and otherwise $⨍ W\, d\alpha_{\mathbf{m}}$ is its continuation in the masses, on a pole hyperplane the constant term of the continuation along the ray.*

Theorem 16.17 (The pseudointegral off the domain)**.** *For every family, if some nonempty proper S has $c_j(S) = 0$ in every active table, then, first where every proper wall has positive real part and then as meromorphic functions (Lemma 16.9),*

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \Gamma{\scriptstyle\begin{bmatrix}\kappa_S,\ \kappa_{\mathcal{E}\setminus S}\\ \kappa_{\mathcal{E}}\end{bmatrix}}_{\!2}^{\!1} \int_{\Delta_S\times\Delta_{\mathcal{E}\setminus S}} \alpha^{\mathbf{m}-\mathbf{1}} \prod_j K_j(\alpha)^{-s_j}\Psi_j(\alpha)^{-t_j}\, d\omega_S\, d\omega_{\mathcal{E}\setminus S},$$

and the restriction of P_F to the balance wall is 0. Let now F be connected with real data, $s_j, t_j \geq 0$ not all zero; on the balance wall the value of P_F at a target depends on no path.

(i) The continuation in the masses of $f \mapsto \int_{\Delta_{\mathcal{E}}} f\, u^{\mathbf{m}-\mathbf{1}} \prod_j K_j^{-s_j}\Psi_j^{-t_j} d\omega_{\mathcal{E}}$, taken by Lemma 8.4 on each ordering sector, is a distribution on $\Delta_{\mathcal{E}}$ with normaliser $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ and monomial moments $P_F(\mathbf{m}+\boldsymbol{\gamma};\mathbf{s},\mathbf{t})/P_F(\mathbf{m};\mathbf{s},\mathbf{t})$; where every proper wall is positive it is $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ times the Breta shape law. Just past the first wall crossed it is not a positive measure: P_F passes from $+\infty$ to $-\infty$ there, while $P_F(\mathbf{m}+\boldsymbol{\gamma};\mathbf{s},\mathbf{t})$ is a positive convergent integral for γ_S large.

(ii) Theorem 8.14 and the recurrences of Theorem 8.9 hold for these values as identities of meromorphic functions.

Theorem 16.18 (The fold: Cremona off the balance wall)**.** *Let $\omega = W\, d\alpha_{\mathbf{m}}$, with the exponents $(\mathbf{s},\mathbf{t})$, have real data on a connected family, with $s_j, t_j \geq 0$, not all zero, and $\mathbf{m} > 0$, native gauge $\alpha^\star$ and target $\boldsymbol{\tau}$. Then $2\sigma\mathbf{1} - \boldsymbol{\tau}$ is positive and balanced for the exponents $(\mathbf{t},\mathbf{s})$, with native gauge $(\alpha^\star)^{-1}$, and for every $\lambda > 0$*

$$⨍ \prod_j K_j^{-s_j}\Psi_j^{-t_j}\, d\alpha_{\mathbf{m}} = ⨍ \prod_j K_j^{-t_j}\Psi_j^{-s_j}\, d\alpha_{\lambda(2\sigma\mathbf{1}-\boldsymbol{\tau})}.$$

The map from the ray of $\mathbf{m}$ to the ray of $2\sigma\mathbf{1} - \boldsymbol{\tau}$ is an involution on rays.

The fold swaps the two letters of every table and reflects the target through $\sigma\mathbf{1}$, negating the offsets and the leans; it keeps the strengths, so the two forms have one centre, and it carries uniform masses to uniform masses.

Proposition 16.19 (Points and realizations)**.** *A real point $(\mathbf{m};\mathbf{s},\mathbf{t})$ of a connected family, with $s_j, t_j \geq 0$, not all zero, and $\mathbf{m} > 0$ and native gauge $\alpha^\star$, determines the realization $((s_j,t_j)_j;\alpha^\star)$, whose masses are the target; every realization arises so (Proposition 8.22). The reading of a point is the reading of its realization and may differ from point to point; the label is read at centres of the table's gauge, the Foreman tree at the realizations of the table's gauge at the centre and at the leans (Theorem 14.6), and both are functions of the tables. An atomic point is at the table's gauge up to scale (Theorem 11.4), and its centre is atomic (Theorem 11.1).*

Theorem 16.20 (Parity)**.** *Let g be an exchange of a connected family, with the bijection h of its tables (Definition 11.13); then $r_{h(j)} = n - r_j$ for every j. With $(g^*z)_e = z_{g(e)}$ (Definition 11.13), let Φ° be the centred potential (Theorem 8.19).*

(i) $\Lambda_j(g^*z) = \Lambda_{h(j)}(-z)$*; so* $E_j(g^*z) = E_{h(j)}(z)$*,* $O_j(g^*z) = -O_{h(j)}(z)$ *and* $\Phi^\circ(-g^*z) = \Phi^\circ(z)$*.*

(ii) If the data are real with $s_j, t_j \geq 0$*, not all zero, and* $\mathbf{m} > 0$*, have a native gauge, and* $\tau_{g(e)} = 2\sigma - \tau_e$ *for every* e*, the native gauge* $e^{2z^\star}$ *with* $\langle \mathbf{1}, z^\star \rangle = 0$ *has* $-g^*z^\star = z^\star$*, and the still of the realization* $\Upsilon = ((s_j, t_j)_j; e^{2z^\star})$ *has* $\kappa_\Upsilon(g(e_1), \dots, g(e_k)) = (-1)^k \kappa_\Upsilon(e_1, \dots, e_k)$ *for every* k*.*

(iii) Under (ii) even rungs never separate e *from* $g(e)$*, and at odd rungs their tallies (Definition 9.4) are negatives of each other.*

(iv) If moreover $\boldsymbol{\delta} = 0$ *and* $\boldsymbol{\tau} = \sigma\mathbf{1}$*, then* $z^\star = 0$*, every odd rung vanishes, and no rung separates* e *from* $g(e)$*.*

(v) At $(\mathbf{t}, \mathbf{s})$ *and the target* $2\sigma\mathbf{1} - \boldsymbol{\tau}$ *the native gauge is* $e^{-2z^\star}$ *and rung* k *is* $(-1)^k$ *times rung* k *at* $(\mathbf{s}, \mathbf{t})$*; under (ii) this is the still at* $(\mathbf{s}, \mathbf{t})$ *carried by* g*, and the Foreman bunch at* $(\mathbf{t}, \mathbf{s})$ *is the image under* g^{-1} *of the Foreman bunch at* $(\mathbf{s}, \mathbf{t})$*.*

16.3 Quasi-integrals as Laurent data

Definition 16.21 (Regular schedules)**.** For a schedule $\mathfrak{s} = (g; \varsigma)$ put $x_k = \alpha_{\varsigma(k)}$ and $v_k = \mathbf{e}_{\varsigma(k)} - \mathbf{e}_g$. Let $\mathcal{J}_0$ be the chart integrand and $\mathcal{J}_k(\varepsilon_1, \dots, \varepsilon_k; x_{>k}) = \int_0^\infty x_k^{\varepsilon_k} \mathcal{J}_{k-1}\, dx_k$, with $\int_0^1$ and $\int_1^\infty$ each continued meromorphically in the *regulator* ε_k. The schedule is *regular* when for every k, as $x_k \to 0$ and as $x_k \to \infty$, $\mathcal{J}_{k-1}$ is a finite sum of terms $c(\varepsilon, x_{>k})\, x_k^{a(\varepsilon)}$ plus $O(x_k^{\pm M})$ for every M, the exponents affine in $\varepsilon_{<k}$ and independent of $x_{>k}$, uniformly for the regulators in a small polydisc away from their poles.

Theorem 16.22 (Bridge)**.** *For real data on a connected family and a regular schedule,* $\mathrm{Reg}^{\mathfrak{s}} \int W\, d\alpha_{\mathbf{m}}$ *is defined and*

$$\mathrm{Reg}^{\mathfrak{s}} \int W\, d\alpha_{\mathbf{m}} = \operatorname*{CT}_{\varepsilon_{n-1}} \cdots \operatorname*{CT}_{\varepsilon_1} P_F\Big(\mathbf{m}^{(g)} + \sum_{k=1}^{n-1} \varepsilon_k v_k; \mathbf{s}, \mathbf{t}\Big),$$

the constant terms taken innermost first, $|\varepsilon_1| \ll \cdots \ll |\varepsilon_{n-1}|$*.*

Theorem 16.23 (A wall is closed by its last variable)**.** *For a schedule* $\mathfrak{s} = (g; \varsigma)$ *put* $\mathbf{p} = \mathbf{m}^{(g)}$ *and* $I(\varepsilon) = P_F\big(\mathbf{p} + \sum_k \varepsilon_k v_k; \mathbf{s}, \mathbf{t}\big)$*. A proper* U *is* polar *when* $\kappa_U(\mathbf{p}) \in -\mathbb{N}$*; its* members *are the* k *with* $\varsigma(k) \in U$ *if* $g \notin U$*, and with* $\varsigma(k) \notin U$ *if* $g \in U$*;* $\mathrm{last}(U)$ *is its last member.*

(i) Near 0*,* $I(\varepsilon) = \sum_C f_C(\varepsilon) \big/ \prod_{U \in C} \ell_U(\varepsilon) + H(\varepsilon)$*,* $\ell_U = \pm \sum_{k\ member} \varepsilon_k$*, over the nonempty sets* C *of polar walls that are tails of one order, with* f_C, H *holomorphic; the member sets in one* C *are nested or disjoint.*

(ii) Under $\mathrm{CT}_{\varepsilon_k}$*,* $1/\ell_U$ *is holomorphic at* $\varepsilon_k = 0$ *unless* $k = \mathrm{last}(U)$*; for one polar wall with numerator* f_C *the iterated constant term of* f_C/ℓ_U *is* $\pm\partial_{\varepsilon_a} f_C(0)$*,* $a = \mathrm{last}(U)$*.*

(iii) For a fixed chart, the quasi-integral of a regular schedule depends on the order only through $U \mapsto \mathrm{last}(U)$ *on the polar walls.*

With one regulator ε_D for each class D of a realization, taken in some order of the classes, $\ell_U = \pm \sum_D |U \cap D|\, \varepsilon_D$; a wall is closed by the last class it meets, which contributes $|U \cap D|^{-1} \partial_{\varepsilon_D}$, and the value depends only on the order of the classes, which can be taken from the order of classes (Theorem 13.7).

Proposition 16.24 (The coordinates set the log-scale)**.** *In the coordinates $u=\alpha/\beta$, $\beta_g=1$, with the regulators ε_k entering as $u_{\varsigma(k)}^{\varepsilon_k}$, the regulated function is $e^{-\sum_k \varepsilon_k\lambda_k}I(\varepsilon)$, $\lambda_k=\log\beta_{\varsigma(k)}$, and for one polar wall with numerator f_C and last member a the iterated constant term becomes $\pm\big(\partial_{\varepsilon_a}f_C(0)-\lambda_a f_C(0)\big)$: changing coordinates shifts the finite part by $-\log\beta_{\varsigma(a)}$ times the signed residue of each wall closed by a mark whose gauge differs from the chart's.*

Theorem 16.25 (Residue at a wall)**.** *Let ω be projective, S a proper bunch with room R, $g\in R$ and $\alpha_S=\rho u$. In this statement write $K_j^{[l]}=K_{j,S}^{(d_j(S)+l)}(u,\alpha_R)$ and $\Psi_j^{[l]}=\Psi_{j,S}^{(d_j^*(S)+l)}(u,\alpha_R)$ for the level and colevel letters of Definition 12.16 counted from their floors, so that $K_j(\rho u,\alpha_R)=\rho^{d_j(S)}\sum_{l\ge0}\rho^l K_j^{[l]}$ and $\Psi_j(\rho u,\alpha_R)=\rho^{d_j^*(S)}\sum_{l\ge0}\rho^l\Psi_j^{[l]}$. At points of $\kappa_S=-q$, $q\in\mathbb{N}$, where every other proper wall is positive,*

$$\operatorname*{Res}_{\kappa_S=-q}P_F(\mathbf{m};\mathbf{s},\mathbf{t})=\int_{\alpha_g=1}\int_{\Delta_S}u^{\mathbf{m}|_S-\mathbf{1}}\alpha_R^{\mathbf{m}|_R-\mathbf{1}}\prod_j\big(K_j^{[0]}\big)^{-s_j}\big(\Psi_j^{[0]}\big)^{-t_j}\,[\rho^q]h\;d\omega_S\,d\alpha_{R-g},$$

where

$$h=\prod_j\Big(\sum_l\rho^lK_j^{[l]}/K_j^{[0]}\Big)^{-s_j}\Big(\sum_l\rho^l\Psi_j^{[l]}/\Psi_j^{[0]}\Big)^{-t_j},$$

$$[\rho^q]\Big(1+\sum_{l\ge1}\rho^lX_l\Big)^{-s}=\sum_{\sum_l ln_l=q}(-1)^{|\mathbf{n}|}\frac{\Gamma(s+|\mathbf{n}|)}{\Gamma(s)}\prod_l\frac{X_l^{n_l}}{n_l!}.$$

If the weights factor on the bottom levels, then with the faces *of the wall, the families*

$$F^S=\big((\mathcal{B}_j/R;\,s_j,0),\;(\mathcal{B}_j|S;\,0,t_j)\big)_j\ \text{on } S,\qquad F^R=\big((\mathcal{B}_j|R;\,s_j,0),\;(\mathcal{B}_j/S;\,0,t_j)\big)_j\ \text{on } R$$

(Definition 7.5), the residue at $\kappa_S=0$ is the product of their periods at the masses $\mathbf{m}|_S$ and $\mathbf{m}|_R$; both faces are balanced, the walls of F^S are the κ_U, $U\subseteq S$, and those of F^R are the $\kappa_{S\cup U}$, $U\subseteq R$, on the wall. Here P_F is the meromorphic function of Lemma 16.9; on a connected family with real data and $s_j,t_j\ge0$, not all zero, it is the normaliser of the distribution of Theorem 16.17(i).

Proposition 16.26 (A molecule at a nonpositive wall)**.** *Let a molecule carry real data with $s_j,t_j\ge0$ and target $\boldsymbol{\tau}$, and let S be a proper bunch with room R, $\alpha_S=\rho u$ on a chart $\alpha_g=1$, $g\in R$, with $H(\rho)=H(\rho;u,\alpha_R)$ the native completion $W\,d\alpha_{\boldsymbol{\tau}}$ divided by $\rho^{\kappa_S(\boldsymbol{\tau})-1}d\rho\,d\omega_S\,d\alpha_{R-g}$ and $H_l=[\rho^l]H$ as in Theorem 16.25.*

(i) Along the collapse of S, $\Phi(y_0-\lambda\mathbf{1}_S)-\langle\boldsymbol{\tau},y_0-\lambda\mathbf{1}_S\rangle=\lambda\,\kappa_S(\boldsymbol{\tau})+O(1)$ as $\lambda\to\infty$, the left side being the negative logarithm of the density in $y=\log\alpha$ (Theorem 8.19); so the density does not decay along the collapse exactly when $\kappa_S(\boldsymbol{\tau})\le0$, and then the form is not integrable at $\rho=0$.

(ii) With $\langle\cdot\rangle$ the integral over u and α_R, if every other proper wall at $\boldsymbol{\tau}$ is positive, $\kappa_S(\boldsymbol{\tau})$ is not a nonpositive integer, and $L\in\mathbb{N}$ has $\kappa_S(\boldsymbol{\tau})+L>0$,

$$P_F(\boldsymbol{\tau};\mathbf{s},\mathbf{t})=\sum_{l<L}\frac{\langle H_l\rangle}{\kappa_S(\boldsymbol{\tau})+l}+\int_0^1\rho^{\kappa_S(\boldsymbol{\tau})-1}\Big(\langle H\rangle-\sum_{l<L}\rho^l\langle H_l\rangle\Big)d\rho+\int_1^\infty\rho^{\kappa_S(\boldsymbol{\tau})-1}\langle H\rangle\,d\rho,$$

the continuation of the period past the wall of S; its poles at $\kappa_S=-q$ have the residues $\langle H_q\rangle$ of Theorem 16.25. When the weights factor on the bottom levels, $\langle H_0\rangle$ is the product of the integrals of the faces F^S at $\boldsymbol{\tau}|_S$ and F^R at $\boldsymbol{\tau}|_R$, whose imbalances are $\kappa_S(\boldsymbol{\tau})$ and $-\kappa_S(\boldsymbol{\tau})$: the leading term is the compound of Proposition 16.12.

Corollary 16.27 (The vertex)**.** *At $S = \mathcal{E} - e$, with e neither a loop nor a coloop in any table, the face F^R is the single mark e and contributes* 1*, and*

$$\langle H_0 \rangle = \int_{\Delta_{\mathcal{E}-e}} u^{\boldsymbol{\tau}|_{\mathcal{E}-e}-\mathbf{1}} \prod_j K_{j,/e}(u)^{-s_j} \Psi_{j,\backslash e}(u)^{-t_j} \, d\omega_{\mathcal{E}-e}(u),$$

the integral of the vertex child*: the contractions at e on the basis side and the deletions on the cobasis side. Proposition 16.26(ii) at $S = \mathcal{E} - e$ removes the leading terms of the vertex from the period exactly.*

16.4 The pseudointegral

Definition 16.28 (Period datum; moves)**.** Let a family of tables with positive rational weights have rational exponents and masses and lie on the balance wall. Its *period datum* is the positive orthant of $\mathbb{R}^{\mathcal{E}}$, read projectively, with the form $W \, d\alpha_{\mathbf{m}} = \alpha^{\mathbf{m}-\mathbf{1}} \prod_j K_j^{-s_j} \Psi_j^{-t_j} d\alpha$, algebraic over $\mathbb{Q}$ and homogeneous of degree zero, the hypersurface $\{\prod_j K_j \Psi_j = 0\}$ and the coordinate hyperplanes; the face $\{\alpha_S = 0\}$ carries the wall κ_S (Theorem 8.5). A *move* between period data is a change of variables by a birational map defined over $\mathbb{Q}$ carrying the open domain bijectively onto the open domain, faces to faces and form to form; a product of data; a linear combination; or the boundary term of an exact form.

Definition 16.29 (The pseudointegral over a region)**.** Let F be a family with real data, $s_j, t_j \geq 0$ not all zero, masses $\mathbf{m} > 0$ and weights factoring across its molecules, with form $\omega = W \, d\alpha_{\mathbf{m}}$.

(i) A *region* of ω is a domain $\mathcal{R}$ in coordinates x with a change of variables mapping it bijectively onto a section $\{h = 1\}$ of the orthant, $h > 0$ homogeneous of degree one: a chart $\alpha_g = 1$, the simplex, a bunch section $|\alpha_B| = 1$. The *density* of ω on $\mathcal{R}$ is the function f for which $f(x)\,dx$ is the form that ω induces on the section (Lemma 16.2). A region of the damped form $e^{-|\alpha|}\omega$ is the same with the orthant in place of the section. For a family of tables with positive rational weights and rational data on the balance wall the regions reached from these by moves (Definition 16.28) are domains cut out by polynomial inequalities over $\mathbb{Q}$.

(ii) The *pseudointegral* of ω over a region is

$$\int\!\!\cdots\!\!\int_{\mathcal{R}} f(x)\,dx := \int W \, d\alpha_{\mathbf{m}}$$

(Definition 16.10(iii)), and over a region of the damped form, away from the poles of J_F, it is the continued interest, $J_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \int W \, e^{-|\alpha|} d\alpha_{\mathbf{m}}$ (Definition 8.8), written $\int \alpha^{\mathbf{m}-\mathbf{1}} e^{-|\alpha|} \prod_j K_j^{-s_j} \Psi_j^{-t_j} d\alpha$ when the integrand is displayed. The value belongs to ω: the native completion and the ray of Definition 16.10(iii) are taken in the table's coordinates α, and a presentation (Theorem 16.13) declares them anew and is another form; the region and its coordinates say how the integration is presented, and a density determines ω only together with the family, a chart $\alpha_g = 1$ not seeing the mass m_g and the simplex not seeing a power of $|\alpha|$, the letter of the list $\binom{\mathcal{E}}{1}$ (Proposition 16.3). Divided by the period of the centre, P_{c} on a molecule, it is the pseudoexpectation $\mathsf{E}_{U \sim \mathbb{P}_{\mathrm{c}}}[(\omega_{\boldsymbol{\tau}}/\omega_{\mathrm{c}})(U)]$.

(iii) The pseudointegral of ω is read in the Foreman's order (Definition 16.14). The tree is drawn from the tables at the centre of the table's gauge; on each molecule the measure $d\alpha_{\mathbf{m}}$ is set to $d\alpha_{\boldsymbol{\tau}}$; the bunches are integrated in the Foreman's order, each at once in scale and shape; where the target lies outside a wall the value is the continuation in the masses, and on a

pole hyperplane its constant term along the ray of the masses. The damped form takes no completion, and the Foreman computes it on the ray beyond the target (Theorem 16.15).

Theorem 16.30 (The pseudointegral and the native completion)**.** *Let $\omega = W\,d\alpha_{\mathbf{m}}$ have real data on a connected family, $s_j, t_j \geq 0$ not all zero and $\mathbf{m} > 0$, with target $\boldsymbol{\tau}$.*

(i) With a native gauge $\alpha^\star$ the pseudointegral is read at the realization $\Upsilon = ((s_j,t_j)_j; \alpha^\star)$, whose masses are $\boldsymbol{\tau}$ and whose proper walls are positive. The form $W\,d\alpha_{\boldsymbol{\tau}}$ is positive with convergent period, and every iterated integral of it over every section, in any coordinates, in the Foreman's order and in every other, converges absolutely to

$$\Big\backslash W\,d\alpha_{\mathbf{m}} = \int W\,d\alpha_{\boldsymbol{\tau}} = P_F(\boldsymbol{\tau};\mathbf{s},\mathbf{t}) :$$

no finite part is taken, and the pseudoexpectation is the expectation of a positive function, $\mathsf{E}_{U\sim\mathbb{P}_{\mathrm{c}}}[(\omega_{\boldsymbol{\tau}}/\omega_{\mathrm{c}})(U)] = \mathbb{E}_{U\sim\mathbb{P}_{\mathrm{c}}}[(\omega_{\boldsymbol{\tau}}/\omega_{\mathrm{c}})(U)]$.

(ii) If $\boldsymbol{\tau}$ lies on no pole hyperplane, every regular schedule of the native completion returns the pseudointegral,

$$\mathrm{Reg}^{\mathfrak{s}}\int W\,d\alpha_{\boldsymbol{\tau}} = \Big\backslash W\,d\alpha_{\mathbf{m}} = P_F(\boldsymbol{\tau};\mathbf{s},\mathbf{t}),$$

each iterated integral a finite part (Definition 1.5), and the value does not depend on the order; its quasi-expectation is the pseudoexpectation, $\mathfrak{E}^{\mathfrak{s}}_{U\sim\mathbb{P}_{\mathrm{c}}}[(\omega_{\boldsymbol{\tau}}/\omega_{\mathrm{c}})(U)] = \mathsf{E}_{U\sim\mathbb{P}_{\mathrm{c}}}[(\omega_{\boldsymbol{\tau}}/\omega_{\mathrm{c}})(U)]$.

(iii) On a pole hyperplane $\Big\backslash W\,d\alpha_{\mathbf{m}} = \mathrm{CT}_{\eta=0}\,P_F(\boldsymbol{\tau}+\eta\mathbf{m};\mathbf{s},\mathbf{t})$ exists and depends on $\mathbf{m}$ only through its ray. It takes no chart and no order: its regulator is η, along the ray of the masses, and its section is the simplex that the damping singles out, $P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = J_F(\mathbf{m};\mathbf{s},\mathbf{t})/\Gamma(\kappa_{\mathcal{E}})$ (Theorem 8.7).

Proposition 16.31 (A pole target in other coordinates)**.** *In Theorem 16.30(iii) let $x = \lambda^{-1}\alpha$ be the coordinates of a presentation (Theorem 16.13), $W^\lambda(x) = W(\lambda x)$, and*

$$G_k(\eta) = \int_{\Delta_{\mathcal{E}}} \big(\log|\lambda u|\big)^k\, u^{\boldsymbol{\tau}+\eta\mathbf{m}-\mathbf{1}} W^\lambda(u)\,d\omega_{\mathcal{E}}(u) \qquad (k\in\mathbb{N}),$$

continued in η, so that $G_0(\eta)$ is the integral over the simplex of the presented word W^λ at the masses $\boldsymbol{\tau}+\eta\mathbf{m}$. Each G_k has at $\eta = 0$ a pole of order at most $n-1$, and the presentation has pseudointegral

$$(\lambda^{\mathbf{m}})^{\kappa_{\mathcal{E}}/m_{\mathcal{E}}}\Big(\Big\backslash W\,d\alpha_{\mathbf{m}} - \lambda^{\boldsymbol{\tau}}\sum_{1\leq i+k\leq n-1}\frac{\langle\mathbf{m},\log\lambda\rangle^i}{i!}\,\frac{(-m_{\mathcal{E}})^k}{k!}\,[\eta^{-i-k}]\,G_k\Big),$$

$[\eta^{-i-k}]$ the Laurent coefficient at $\eta = 0$. Off the pole hyperplanes every G_k is holomorphic at 0 and this is Theorem 16.13; on them the finite part is taken in the coordinates of the table, as every finite part is taken in its own coordinate (Lemma 1.9).

Proposition 16.32 (Sections off the balance wall)**.** *Let $\omega = W\,d\alpha_{\mathbf{m}}$ have real data, $s_j, t_j \geq 0$ not all zero, $\mathbf{m} > 0$ and imbalance $\kappa_{\mathcal{E}} \neq 0$.*

(i) The integral of ω over a section $\{h = 1\}$ is the integral over every section of the projective form $h^{-\kappa_{\mathcal{E}}}\omega$, wherever it converges. Over a chart it is the period at the chart completion (Proposition 16.5(i)), over a bunch section $|\alpha_B| = 1$ the period of the family with the list $\binom{B}{1}$, the marks outside B as loops, appended at the exponents $(\kappa_{\mathcal{E}}, 0)$, a multinomial sum of

completions when $-\kappa_{\mathcal{E}} \in \mathbb{N}$ (Proposition 16.5(iii)), and over the simplex, where the proper walls at $\mathbf{m}$ are positive, $P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \Gamma_1^n \begin{bmatrix} \mathbf{m} \\ m_{\mathcal{E}} \end{bmatrix} \mathbb{E}_{U\sim \mathrm{Dir}_{\mathbf{m}}}[W(U)]$ (Proposition 8.12(i)). Different sections integrate different projective forms; the pseudointegral integrates the native completion over all of them.

(ii) The walls of the chart completion at g and of the native completion are

$$\kappa_S(\mathbf{m}^{(g)}) = \kappa_S(\mathbf{m}) - \kappa_{\mathcal{E}}\,\mathbf{1}_S(g), \qquad \kappa_S(\boldsymbol{\tau}) = \kappa_S(\mathbf{m}) - \frac{\kappa_{\mathcal{E}}}{m_{\mathcal{E}}}\, m_S :$$

the snip moves the walls through g by the whole imbalance and leaves the others, and the native completion moves each wall by its share. For $\kappa_{\mathcal{E}} > 0$ a proper wall through g is lower at the chart completion than at the target by $\kappa_{\mathcal{E}}(1 - m_S/m_{\mathcal{E}})$, and one avoiding g is higher by $\kappa_{\mathcal{E}} m_S/m_{\mathcal{E}}$. So a snip can put the walls through g on pole hyperplanes, or past them, while the target is inside every wall.

Theorem 16.33 (Integrals over sections)**.** *Let $\omega = W\, d\alpha_{\mathbf{m}}$ have real data, $s_j, t_j \geq 0$ not all zero and $\mathbf{m} > 0$, and for $h > 0$ homogeneous of degree one let $\int_{h=1}\omega$ denote the integral over the section $\{h = 1\}$ with the measure of Lemma 16.2.*

(i) By Proposition 16.32(i) the integral of ω over a section $\{h = 1\}$ is the integral over the rays of $h^{-\kappa_{\mathcal{E}}}\omega$, and for $\kappa_{\mathcal{E}} \neq 0$, $h \mapsto h^{-\kappa_{\mathcal{E}}}$ carries the sections bijectively onto the positive multipliers of degree $-\kappa_{\mathcal{E}}$. The monomial sections $\{\alpha^w = 1\}$, $w_{\mathcal{E}} = 1$, are the completions, $(\alpha^w)^{-\kappa_{\mathcal{E}}}\omega = W\, d\alpha_{\mathbf{m}-\kappa_{\mathcal{E}} w}$: they act on the measure and keep the word.

(ii) The native completion is the section $\{\alpha^{\mathbf{m}} = 1\}$, the hyperplane $\langle \mathbf{m}, y\rangle = 0$ in $y = \log\alpha$, where the density $e^{\langle \mathbf{m}, y\rangle}$ of $d\alpha_{\mathbf{m}}$ against dy is 1; it is the one monomial section with this property. With a native gauge on a connected family of at least two marks, for every mark g,

$$\int\!\!\!\!\!\!- W\, d\alpha_{\mathbf{m}} = \frac{m_{\mathcal{E}}}{m_g}\int_{\mathbb{R}^{\mathcal{E}-g}} W(e^y)\, dy_{\mathcal{E}-g}, \qquad y_g = -\frac{1}{m_g}\sum_{e\neq g} m_e y_e,$$

and $\mathsf{E}_{U\sim\mathbb{P}_{\mathrm{c}}}[(\omega_{\boldsymbol{\tau}}/\omega_{\mathrm{c}})(U)]$ is this integral over the integral of ω_{c} over the same section, which is P_{c}.

(iii) The simplex $\{|\alpha| = 1\}$ is not a monomial section for $n \geq 2$: its multiplier is $|\alpha|^{-\kappa_{\mathcal{E}}}$, which keeps the measure and multiplies the word by a power of the letter $K_0 = |\alpha|$ of the list $\binom{\mathcal{E}}{1}$. The integral over it is the integral of the projective form $K_0^{-\kappa_{\mathcal{E}}} W\, d\alpha_{\mathbf{m}}$, the family with that table added at the exponents $(\kappa_{\mathcal{E}}, 0)$ (Proposition 16.3, Proposition 16.5(iii) at $B = \mathcal{E}$), and wherever every proper wall at $\mathbf{m}$ is positive it is the period $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ of Proposition 8.12(i), the law $\mathrm{Dir}_{\mathbf{m}}$ there being the law of $\binom{\mathcal{E}}{1}$ at a full basis lean.

(iv) On the balance wall every section reads $\int W\, d\alpha_{\mathbf{m}}$ (Theorem 8.7).

Proposition 16.34 (The centre sets the law)**.** *Let $\omega = W\, d\alpha_{\mathbf{m}}$ have real data on a connected family of $n \geq 2$ marks, $s_j, t_j \geq 0$ not all zero and $\mathbf{m} > 0$, with target $\boldsymbol{\tau}$, centre ω_{c} and law of the centre $\mathbb{P}_{\mathrm{c}}$ (Definition 16.10). For laws $\mathbb{P}, \mathbb{P}'$ with $\mathbb{P}$ absolutely continuous with respect to $\mathbb{P}'$ write $\mathrm{KL}(\mathbb{P}\,\|\,\mathbb{P}') = \mathbb{E}_{U\sim\mathbb{P}}\big[\log\frac{d\mathbb{P}}{d\mathbb{P}'}(U)\big]$, the Kullback–Leibler divergence.*

(i) The native completion is the centre times the departure, $\omega_{\boldsymbol{\tau}} = \frac{\omega_{\boldsymbol{\tau}}}{\omega_{\mathrm{c}}}\,\omega_{\mathrm{c}}$, and with a native gauge the Foreman's law, the shape law $\mathrm{Breta}^{\circ}(F;\boldsymbol{\tau};\mathbf{s},\mathbf{t})$ of the native completion, is the law of the centre reweighted by the departure:

$$\mathrm{Breta}^{\circ}(F;\boldsymbol{\tau};\mathbf{s},\mathbf{t})(du) = \frac{(\omega_{\boldsymbol{\tau}}/\omega_{\mathrm{c}})(u)}{\mathsf{E}_{U\sim\mathbb{P}_{\mathrm{c}}}[(\omega_{\boldsymbol{\tau}}/\omega_{\mathrm{c}})(U)]}\,\mathbb{P}_{\mathrm{c}}(du).$$

(ii) With a native gauge,

$$\log \mathsf{E}_{U\sim\mathbb{P}_{\mathrm{c}}}\Big[\frac{\omega_{\boldsymbol{\tau}}}{\omega_{\mathrm{c}}}(U)\Big] = \mathrm{KL}\big(\mathbb{P}_{\mathrm{c}} \,\big\|\, \mathrm{Breta}^{\circ}(F;\boldsymbol{\tau};\mathbf{s},\mathbf{t})\big) \;\geq\; 0,$$

with equality exactly when $\mathrm{Breta}^{\circ}(F;\boldsymbol{\tau};\mathbf{s},\mathbf{t}) = \mathbb{P}_{\mathrm{c}}$. *So every pseudointegral with a native gauge is at least the period of its centre,* $\int W\, d\alpha_{\mathbf{m}} \geq P_{\mathrm{c}}$, *and among the forms of given strengths* σ_j *with a native gauge the centre has the least value.*

(iii) The pseudoexpectation is kept by the fold: the two forms of Theorem 16.18, at the masses $\mathbf{m}$ *with the exponents* $(\mathbf{s},\mathbf{t})$ *and at the masses* $\lambda(2\sigma\mathbf{1}-\boldsymbol{\tau})$ *with* $(\mathbf{t},\mathbf{s})$, *have one centre and one pseudoexpectation, and the same holds for continued values off the pole hyperplanes where* $2\sigma\mathbf{1}-\boldsymbol{\tau} > 0$.

(iv) Let ω *be the form of a realization at the table's gauge,* $\alpha^{\star} = \mathbf{1}$ *(Definition 9.1). In signed coordinates on* $\mathbf{1}^{\perp}$ *the departure is*

$$\frac{\omega_{\boldsymbol{\tau}}}{\omega_{\mathrm{c}}}(e^{2z}) = \exp\Big(-\sum_j \delta_j \tilde{O}_j(z)\Big), \qquad \tilde{O}_j(z) = O_j(z) - \langle \nabla O_j(0), z\rangle,$$

each $\tilde{O}_j$ *odd with value, gradient and Hessian* 0 *at* 0. *The Foreman's law and the law of the centre have their mode at the table's gauge and the same Hessian of the logarithm of the density there, and the logarithm of their ratio is, up to a constant,* $-\sum_j \delta_j \tilde{O}_j$*: minus the odd part of the centred potential less its linear term, whose Taylor coefficients at the table's gauge are minus the odd rungs of order at least three of the potential, the rungs that vanish at the centre (Proposition 8.21(iii)).*

Proposition 16.35 (The list $\binom{\mathcal{E}}{1}$ as a normaliser)**.** *Let* $\omega = W\, d\alpha_{\mathbf{m}}$ *have real data on a connected family of* $n \geq 2$ *marks,* $s_j, t_j \geq 0$ *not all zero and* $\mathbf{m} > 0$, *so that* W *is homogeneous of degree* $-\tau_{\mathcal{E}}$*; let* $K_0 = |\alpha|$ *be the letter of the list* $\binom{\mathcal{E}}{1}$, *whose bases are the singletons.*

(i) Every completion $W\, d\alpha_{\mathbf{m}'}$, $\mathbf{m}' = \mathbf{m} - \kappa_{\mathcal{E}} w$, *has total mass* $m'_{\mathcal{E}} = \tau_{\mathcal{E}}$. *The native completion is the one whose masses keep the proportions of* $\mathbf{m}$, $\boldsymbol{\tau}/\tau_{\mathcal{E}} = \mathbf{m}/m_{\mathcal{E}}$, *and they are positive, while the chart completion at* g *has the mass* $m_g - \kappa_{\mathcal{E}}$ *at* g.

(ii) For $\mathbf{m}' > 0$ *with* $m'_{\mathcal{E}} = \tau_{\mathcal{E}}$ *the form* $K_0^{-\tau_{\mathcal{E}}} d\alpha_{\mathbf{m}'}$ *is projective, with integral* $\Gamma_1^n \begin{bmatrix} \mathbf{m}' \\ \tau_{\mathcal{E}} \end{bmatrix}$ *over every section: the period of* $\binom{\mathcal{E}}{1}$ *at the full basis lean* $(\tau_{\mathcal{E}}, 0)$, *whose law is* $\mathrm{Dir}_{\mathbf{m}'}$ *(Proposition 16.3). So* $\Gamma_1^n \begin{bmatrix} \boldsymbol{\tau} \\ \tau_{\mathcal{E}} \end{bmatrix} = \int K_0^{-\tau_{\mathcal{E}}} d\alpha_{\mathbf{m}}$*; for a schedule with* $\mathbf{m}^{(g)} > 0$, $\Gamma_1^n \begin{bmatrix} \mathbf{m}^{(g)} \\ \tau_{\mathcal{E}} \end{bmatrix} = \mathrm{Reg}^{\mathfrak{s}} \int K_0^{-\tau_{\mathcal{E}}} d\alpha_{\mathbf{m}}$, *a convergent integral; and with a native gauge*

$$\int W\, d\alpha_{\mathbf{m}} \Big/ \int K_0^{-\tau_{\mathcal{E}}} d\alpha_{\mathbf{m}} = \mathbb{E}_{U\sim\mathrm{Dir}_{\boldsymbol{\tau}}}[W(U)].$$

(iii) With a native gauge, and for continued values off the pole hyperplanes where $2\sigma\mathbf{1}-\boldsymbol{\tau} > 0$, *the fold keeps the pseudointegral and carries the target* $\boldsymbol{\tau}$ *to* $2\sigma\mathbf{1}-\boldsymbol{\tau}$ *(Theorem 16.18), so the quotients of (ii) for* ω *and for its image are* $P_F(\boldsymbol{\tau};\mathbf{s},\mathbf{t})$ *divided by* $\Gamma_1^n \begin{bmatrix} \boldsymbol{\tau} \\ \tau_{\mathcal{E}} \end{bmatrix}$ *and by* $\Gamma_1^n \begin{bmatrix} 2\sigma\mathbf{1}-\boldsymbol{\tau} \\ \tau^*_{\mathcal{E}} \end{bmatrix}$, $\tau^*_{\mathcal{E}} = 2n\sigma - \tau_{\mathcal{E}}$. *The second quotient over the first is* $\Gamma_1^n \begin{bmatrix} \boldsymbol{\tau} \\ \tau_{\mathcal{E}} \end{bmatrix} / \Gamma_1^n \begin{bmatrix} 2\sigma\mathbf{1}-\boldsymbol{\tau} \\ \tau^*_{\mathcal{E}} \end{bmatrix}$, *which is not* 1 *in general. The period of* $\binom{\mathcal{E}}{1}$ *is that of a full basis lean of a table outside the family, and it prices a lean and its mirror differently; the centre, which the fold fixes, prices them alike (Proposition 16.34(iii)).*

(iv) Along the ray of the masses, wherever the proper walls at $\lambda\mathbf{m}$ are positive, the integral of the projective form $K_0^{-(\lambda m_{\mathcal{E}}-\tau_{\mathcal{E}})}W\,d\alpha_{\lambda\mathbf{m}}$ is $\Gamma_1^n\begin{bmatrix}\lambda\mathbf{m}\\ \lambda m_{\mathcal{E}}\end{bmatrix}\,\mathbb{E}_{U\sim\mathrm{Dir}_{\lambda\mathbf{m}}}[W(U)]$ (Theorem 16.33(iii), Proposition 8.12(i)). The power of K_0 vanishes exactly at $\lambda=\tau_{\mathcal{E}}/m_{\mathcal{E}}$, where the form is the native completion $W\,d\alpha_{\boldsymbol{\tau}}$.

Corollary 16.36 (The pseudointegral is the quasi-integral that always exists)**.** *For real data with $s_j,t_j\geq 0$ not all zero, $\mathbf{m}>0$ and weights factoring across the molecules, the pseudointegral $\int W\,d\alpha_{\mathbf{m}}$ and the pseudoexpectation $\mathsf{E}_{U\sim\mathbb{P}_{\mathrm{c}}}[(\omega_{\boldsymbol{\tau}}/\omega_{\mathrm{c}})(U)]$ are defined. On a molecule whose target lies on no pole hyperplane the pseudointegral is the quasi-integral of the native completion and the pseudoexpectation its quasi-expectation, the same along every regular schedule; on a pole hyperplane, where the regular schedules of the native completion can depend on the order (Theorem 16.23), it is the one constant term along the ray of the masses. On each molecule every generalized expectation divides by the one period of its centre, a positive convergent integral (Proposition 8.21); when the molecule has a native gauge, the native completion is the one completion that keeps it (Theorem 16.8(i)). The quasi-integrals of ω itself are Laurent data at its chart completions (Theorem 16.22), which off the balance wall can depend on the chart and on the order.*

The pseudointegral names a procedure as well as a value. Written for a family whose realization is specified later, $\int\cdots\int_{\mathcal{R}}$ commits to the Foreman's order at every realization: the tree is drawn once from the tables, and the realization $((s_j,t_j)_j;\alpha^\star)$ of the point fixes the measure $d\alpha_{\boldsymbol{\tau}}$ and where the contours of the ports run. An iterated integral in another order, or after a snip, computes a quasi-integral and not the pseudointegral, even where the numbers agree; when they agree, that is Theorem 16.30(i)–(ii), not the order that was followed.

On a pole hyperplane the regulator η of the pseudointegral enters as $u^{\eta\mathbf{m}}$, as in Theorem 1.7. Past a wall the pseudointegral normalizes the distribution of Theorem 16.17(i).

Chapter 17

The family as one Laplace transform

On its balance wall a family is one Laplace transform. In the pair coordinates of its data and the signed coordinates of the shape, its period is the Laplace transform, over the tilts, of the even and odd statistics against the offsets (Definition 17.1; for the interest, Theorem 8.2); the Breta shape laws at the points of the balance wall form an exponential family in these coordinates, and every ratio of periods is a moment generating function of the statistics. On the sector of every order the exponent of a question is minus twice its wall at the tilt, the walls of the tails weighted by the differences of the tilt along the order, less the logarithms of the sector letters, which are bounded. The Laplace transform is read through that one reading of the walls: where the exponent is largest and how it falls, how the period behaves at low and at high strength, how far a question can lean, and how fast the tails of the statistics fall.

17.1 Questions and the law of the tilt

Definition 17.1 (Tilts; questions)**.** The space of *tilts* is $\mathcal{T} = \mathbb{R}^{\mathcal{E}}/\mathbb{R}\mathbf{1}$, with the Lebesgue measure dz of a chart $z_g = 0$, which does not depend on g. The *tilt* of a shape $u \in \Delta_{\mathcal{E}}$ is the image in $\mathcal{T}$ of its signed coordinates $\frac{1}{2}\log u$, and a tilt is read at its representative in $\mathbf{1}^{\perp}$ when an odd statistic is applied to it, since $O_j(z + c\mathbf{1}) = O_j(z) + 2c(2r_j - n)$ (Theorem 7.15(iii)). A *question* to a family F is a point of its balance wall with real data, written in its pair coordinates $(\boldsymbol{\mu}_{\perp}; \boldsymbol{\sigma}, \boldsymbol{\delta})$: the data $(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \big(\mathbf{m}_F(\boldsymbol{\mu}_{\perp}; \boldsymbol{\sigma}, \boldsymbol{\delta});\ \boldsymbol{\sigma} + \boldsymbol{\delta},\ \boldsymbol{\sigma} - \boldsymbol{\delta}\big)$ (Definition 8.1). In the coordinates $z = \frac{1}{2}\log u$ of Theorem 8.7,

$$P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = 2^{n-1} \int_{\mathcal{T}} \exp\Big(2\langle \boldsymbol{\mu}_{\perp}, z\rangle - \sum_j \big(\sigma_j E_j(z) + \delta_j O_j(z)\big)\Big)\, dz.$$

When every proper wall is positive, the tilt Z of $U \sim \mathrm{Breta}^{\circ}(F; \mathbf{m}; \mathbf{s}, \mathbf{t})$ has the density

$$2^{n-1} \exp\Big(2\langle \boldsymbol{\mu}_{\perp}, z\rangle - \sum_j \big(\sigma_j E_j(z) + \delta_j O_j(z)\big)\Big) \Big/ P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$$

with respect to dz: this is the *law of the question*. A direction $v = (\dot{\mathbf{m}}; \dot{\mathbf{s}}, \dot{\mathbf{t}})$ of the data is *balanced* when $\dot{m}_{\mathcal{E}} = \sum_j (\dot{s}_j r_j + \dot{t}_j r_j^*)$; its pair coordinates $(c; \mathbf{a}, \mathbf{b})$ have $\dot{\mathbf{m}} = \mathbf{m}_F(c; \mathbf{a}, \mathbf{b})$, $\dot{\mathbf{s}} = \mathbf{a} + \mathbf{b}$ and $\dot{\mathbf{t}} = \mathbf{a} - \mathbf{b}$, and D_v is the derivative along v. The derivatives ∂_{σ_j}, ∂_{δ_j} and $\nabla_{\boldsymbol{\mu}_{\perp}}$ of a function of the question are those along the balanced directions with the pair coordinates $(0; \mathbf{e}_j, \mathbf{0})$, $(0; \mathbf{0}, \mathbf{e}_j)$ and $(\mathbf{e}_e - \frac{1}{n}\mathbf{1}; \mathbf{0}, \mathbf{0})$, that is $(\mathbf{1}; \mathbf{e}_j, \mathbf{e}_j)$, $\big(\frac{2r_j - n}{n}\mathbf{1}; \mathbf{e}_j, -\mathbf{e}_j\big)$ and $\big(\mathbf{e}_e - \frac{1}{n}\mathbf{1}; \mathbf{0}, \mathbf{0}\big)$. The centre of a question is the question $(\sigma\mathbf{1}; \boldsymbol{\sigma}, \boldsymbol{\sigma})$ with the same strengths, the data of the family at the centre

(Definition 9.1), of pair coordinates $(0;\boldsymbol{\sigma},\mathbf{0})$; on a connected family its law is the law of the centre $\mathbb{P}_{\mathrm{c}}$ of Definition 16.10 read on the tilts.

Corollary 17.2 (The Laplace transform of the tilt and the statistics)**.** *Let a question* $(\mathbf{m};\mathbf{s},\mathbf{t})$ *have every proper wall positive. In this statement* $\mathbb{E}$ *is the expectation of* $U\sim\mathrm{Breta}^{\circ}(F;\mathbf{m};\mathbf{s},\mathbf{t})$ *and* Z *is the tilt of* U*. For* $c\in\mathbf{1}^{\perp}\otimes\mathbb{C}$ *and* $\mathbf{a},\mathbf{b}\in\mathbb{C}^N$ *such that the real parts of the shifted data* $\big(\mathbf{m}+\mathbf{m}_F(c;\mathbf{a},\mathbf{b});\,\mathbf{s}+\mathbf{a}+\mathbf{b},\,\mathbf{t}+\mathbf{a}-\mathbf{b}\big)$ *have every proper wall positive,*

$$\mathbb{E}\Big[e^{2\langle c,Z\rangle-\sum_j(a_jE_j(Z)+b_jO_j(Z))}\Big]=\frac{P_F\big(\mathbf{m}+\mathbf{m}_F(c;\mathbf{a},\mathbf{b});\,\mathbf{s}+\mathbf{a}+\mathbf{b},\,\mathbf{t}+\mathbf{a}-\mathbf{b}\big)}{P_F(\mathbf{m};\mathbf{s},\mathbf{t})},$$

analytic in $(c,\mathbf{a},\mathbf{b})$ *there: the shift moves the pair coordinates of the question by* $(c;\mathbf{a},\mathbf{b})$*. So the joint cumulants of order* k *of* $(E_j(Z),O_j(Z))_j$ *are* $(-1)^k$ *times the derivatives of order* k *of* $\log P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ *in* $(\sigma_j,\delta_j)_j$*, and their characteristic function is the same ratio at* $c=0$ *and purely imaginary* $(\mathbf{a},\mathbf{b})$*: the family on the fibre of imaginary exponents over the question.*

Definition 17.3 (The wall at a tilt)**.** For an order π of $\mathcal{E}$ with tails $U_k=\{\pi(k),\dots,\pi(n)\}$, the sector H_π of Lemma 8.3 is read in the tilts as $\{z\in\mathcal{T}:\ z_{\pi(1)}\geq\cdots\geq z_{\pi(n)}\}$. On it the measure dz of Definition 17.1 is the Lebesgue measure in the differences $z_{\pi(k-1)}-z_{\pi(k)}\geq 0$, $2\leq k\leq n$, which at the gauge $\alpha=e^{2z}$ are half the gaps $\log(\alpha_{\pi(k-1)}/\alpha_{\pi(k)})$ of Corollary 8.6. For data on the balance wall the *wall at a tilt* $z\in H_\pi$ is

$$\kappa(z)=\sum_{k=2}^{n}\kappa_{U_k}\big(z_{\pi(k-1)}-z_{\pi(k)}\big),$$

the walls of the tails of π weighted by the differences of z along π, half the walls weighted by the gaps. It does not depend on the order whose sector holds z, the tails with a positive difference being the sets $\{e:\ z_e<z_f\}$ for the $f\in\mathcal{E}$ with $z_f>\min_e z_e$; it is positively homogeneous of degree one and linear on every sector, and $\kappa(-\mathbf{1}_S)=\kappa_S$ for every nonempty proper S, with $-\mathbf{1}_S$ read in $\mathcal{T}$, the direction along which S collapses (Proposition 16.26(i)). In pair coordinates $\kappa(z)$ is linear in the question.

Proposition 17.4 (The exponent of a question reads its walls; the even statistic is least at the table's gauge)**.** *Let a family carry a question* $(\boldsymbol{\mu}_\perp;\boldsymbol{\sigma},\boldsymbol{\delta})$*, its exponents of any signs, and in this statement write* $X(z)=2\langle\boldsymbol{\mu}_\perp,z\rangle-\sum_j\big(\sigma_jE_j(z)+\delta_jO_j(z)\big)$ *for the exponent of the law of the question (Definition 17.1) and* $\kappa(z)$ *for its wall at the tilt* z *(Definition 17.3).*

(i) On the sector H_π *of every order* π*, with the sector letters* $k_{j,\pi},\psi_{j,\pi}$ *of Theorem 8.5(ii) read at the sector coordinates* $q_k=\alpha_{\pi(k)}/\alpha_{\pi(k-1)}=e^{-2(z_{\pi(k-1)}-z_{\pi(k)})}$ *of* $\alpha=e^{2z}$*,*

$$X(z)=-2\kappa(z)-\sum_j\big(s_j\log k_{j,\pi}(q)+t_j\log\psi_{j,\pi}(q)\big).$$

With $h_j(z)=\max_{T\in\mathcal{B}_j}\langle\chi_T,z\rangle$*, the support function of the Newton polytope* $2P_j-\mathbf{1}$ *of* Λ_j *(Theorem 7.18),* $2\kappa(z)=\sum_j\big(s_jh_j(z)+t_jh_j(-z)\big)-2\langle\boldsymbol{\mu}_\perp,z\rangle$ *on* $\mathbf{1}^{\perp}$*, and for* $s_j,t_j\geq 0$ *the wall at a tilt is the support function of* $\mathcal{N}_F-\mathbf{m}$*,* $\mathcal{N}_F$ *the Newton sum of Theorem 8.19(ii). The sector letters are polynomials with nonnegative coefficients, with the constant terms* $\theta_{j,T^+_{j,\pi}}$ *and* $\theta_{j,T^-_{j,\pi}}$ *and the value* $K_j(\mathbf{1})$ *at* $q=\mathbf{1}$ *(Theorem 8.5(ii)), so on the cube they lie in* $[\theta_{j,T^+_{j,\pi}},K_j(\mathbf{1})]$ *and* $[\theta_{j,T^-_{j,\pi}},K_j(\mathbf{1})]$*; with* $\theta_{j,\min}=\min_T\theta_{j,T}$*,* $|X+2\kappa|\leq\sum_j(|s_j|+|t_j|)\max\big(|\log\theta_{j,\min}|,|\log K_j(\mathbf{1})|\big)$*, and for* $s_j,t_j\geq 0$

$$2\kappa(z)+\sum_j(s_j+t_j)\log\theta_{j,\min}\leq-X(z)\leq 2\kappa(z)+\sum_j(s_j+t_j)\log K_j(\mathbf{1}).$$

(ii) $\kappa > 0$ *on* $\mathcal{T} \setminus 0$ *exactly when every proper wall is positive, and then* $\kappa(z) \geq \kappa_{\min}\big(\max_e z_e - \min_e z_e\big)$, $\kappa_{\min}$ *the least proper wall.*

(iii) At the centre of strengths $\boldsymbol{\sigma}$, $\sigma_j \geq 0$, *where* $\boldsymbol{\mu}_\perp = 0$ *and* $\boldsymbol{\delta} = 0$, *the exponent is minus the centred potential* $\sum_j \sigma_j E_j$ *(Proposition 8.21) and* $2\kappa(z) = \sum_j \sigma_j \operatorname{wd}_j(z)$, *with* $\operatorname{wd}_j(z) = h_j(z) + h_j(-z)$ *the width of* $2P_j - \mathbf{1}$ *in the direction* z, *twice the width of* P_j, *so that* $\operatorname{wd}_j(\mathbf{1}_S) = 2c_j(S)$. *Every* E_j *is convex and even,* $E_j(z) \geq E_j(0) = 2\log K_j(\mathbf{1})$, *and*

$$\sum_j \sigma_j \operatorname{wd}_j(z) + 2\sum_j \sigma_j \log\theta_{j,\min} \leq \sum_j \sigma_j E_j(z) \leq \sum_j \sigma_j \operatorname{wd}_j(z) + 2\sum_j \sigma_j \log K_j(\mathbf{1}).$$

If the family is connected, $\sum_j \sigma_j E_j$ *is strictly convex on* $\mathcal{T}$ *and* $\sum_j \sigma_j \operatorname{wd}_j > 0$ *on* $\mathcal{T} \setminus 0$.

Theorem 17.5 (The two ends of strength)**.** *Let a question* $q = (\boldsymbol{\mu}_\perp; \boldsymbol{\sigma}, \boldsymbol{\delta})$ *of a family have every proper wall positive, and for* $\lambda \in \mathbb{C}$ *with* $\operatorname{Re}\lambda > 0$ *read the data* λq *of pair coordinates* $(\lambda\boldsymbol{\mu}_\perp; \lambda\boldsymbol{\sigma}, \lambda\boldsymbol{\delta})$, *a question when* λ *is real, whose walls* $\lambda\kappa_S$ *have positive real parts; in this statement* $P_F(\lambda q)$ *is its period,* $2^{n-1}\int_{\mathcal{T}} e^{\lambda X(z)}dz$ *by the change of variables of Definition 17.1 with the powers of the positive letters principal (Theorem 8.7), and* X *and* κ *are those of* q *(Proposition 17.4).*

(i) Low strength. *As* $\lambda \downarrow 0$,

$$\lambda^{n-1}P_F(\lambda q) \to \sum_\pi \prod_{k=2}^{n} \kappa_{U_k}^{-1} = (n-1)!\,\operatorname{vol}\{z \in \mathcal{T} :\ \kappa(z) \leq 1\},$$

and

$$\lambda^{n-1}P_F(\lambda q) = \sum_\pi \prod_{k=2}^{n} \kappa_{U_k}^{-1}\Big(1 - \lambda\sum_j \big(s_j \log\theta_{j,T^+_{j,\pi}} + t_j \log\theta_{j,T^-_{j,\pi}}\big)\Big) + o(\lambda),$$

with the greedy bases $T^\pm_{j,\pi}$ *of Lemma 8.3: the walls set the period at low strength, and the weights enter at the next order, through the greedy bases.*

(ii) High strength, in the half-plane. *Let* $s_j, t_j \geq 0$. *Then* $-X$ *is strictly convex on* $\mathcal{T}$, *its unique critical point* $z^\star$ *is the native gauge of every question* λq, $\lambda > 0$, *and as* $|\lambda| \to \infty$ *with* $\operatorname{Re}\lambda \geq \lambda_0$ *for a fixed* $\lambda_0 > 0$, *in particular as* $\lambda \to +\infty$ *and along* $\lambda = \lambda_0 + i\eta$, $|\eta| \to \infty$,

$$P_F(\lambda q) = 2^{n-1}e^{\lambda X(z^\star)}\Big(\frac{2\pi}{\lambda}\Big)^{\frac{n-1}{2}} \det\big(-\nabla^2 X(z^\star)\big)^{-\frac{1}{2}}\big(1 + O(|\lambda|^{-1})\big),$$

the power principal and the Hessian taken on a chart $z_g = 0$, *where it is rung two of the still of the realization* $\big((s_j, t_j)_j; e^{2z^\star}\big)$ *of the active tables (Definition 9.4) with the row and the column of* g *deleted. At the centre of strengths* $\boldsymbol{\sigma}$, $z^\star = 0$, $X(0) = -2\sum_j \sigma_j \log K_j(\mathbf{1})$, *and on the chart* $z_g = 0$, $-\nabla^2 X(0) = 8\sum_j \sigma_j \big(\kappa_{j,\mathbf{1}}(X_e, X_f)\big)_{e,f\neq g}$.

Remark 17.6 (The volume of the walls is the volume of a polar body). At the centre of strengths $\boldsymbol{\sigma}$, $\sigma_j \geq 0$, Proposition 17.4(iii) gives $2\kappa(z) = \sum_j \sigma_j \operatorname{wd}_j(z)$, and $\operatorname{wd}_j(z) = h_j(z) + h_j(-z)$, with h_j the support function of $2P_j - \mathbf{1}$ and P_j the base polytope of table j (Theorem 7.18), is twice the support function of $P_j - P_j$ at z. So κ is the support function of the centrally symmetric polytope $\mathcal{Q} = \sum_j \sigma_j(P_j - P_j)$, a Minkowski sum in $\mathbf{1}^\perp$, read on $\mathcal{T} = \mathbb{R}^{\mathcal{E}}/\mathbb{R}\mathbf{1}$, and $\{z \in \mathcal{T} :\ \kappa(z) \leq 1\}$ is its polar body $\mathcal{Q}^\circ = \{z :\ \langle x, z\rangle \leq 1 \text{ for every } x \in \mathcal{Q}\}$, bounded when every proper wall is positive (Proposition 17.4(ii)). By Theorem 17.5(i), $\sum_\pi \prod_{k=2}^n \kappa_{U_k}^{-1} = (n-1)!\operatorname{vol}(\mathcal{Q}^\circ)$: the volume V_1 of the direction of the centre ray at the strengths $\boldsymbol{\sigma}$ (Proposition 39.34), whose walls are those of this question, is $(n-1)!$ times the volume of the polar body of $\sum_j \sigma_j(P_j - P_j)$.

At low strength the walls alone set the period, through the volume of the region where the wall at a tilt is at most one, and the weights enter at the next order through the greedy bases. At high strength the period concentrates at the native gauge, where it is a Gaussian integral whose Hessian is rung two of the still.

Proposition 17.7 (How far a question can lean; the values of the statistics)**.** *For every family and every nonempty proper S put $\varepsilon_j^{\perp}(S) = \varepsilon_j(S) - |S|\frac{2r_j - n}{n}$, so that $\varepsilon_j^{\perp}(\mathcal{E} \setminus S) = -\varepsilon_j^{\perp}(S)$, and for a question $(\boldsymbol{\mu}_{\perp}; \boldsymbol{\sigma}, \boldsymbol{\delta})$ let*

$$\kappa_S^{\mathbf{E}}(\boldsymbol{\sigma}) = \sum_j \sigma_j c_j(S), \qquad \kappa_S^{\mathbf{O}}(\boldsymbol{\mu}_{\perp}, \boldsymbol{\delta}) = \mu_{\perp,S} - \sum_j \delta_j \varepsilon_j^{\perp}(S),$$

the even and the odd part of the wall at S: on the balance wall $\kappa_S = \kappa_S^{\mathbf{E}} + \kappa_S^{\mathbf{O}}$ and $\kappa_{\mathcal{E}\setminus S} = \kappa_S^{\mathbf{E}} - \kappa_S^{\mathbf{O}}$, and the fold, which negates the odd part (Theorem 16.18), swaps the two. So a question is inside its walls exactly when $|\kappa_S^{\mathbf{O}}(\boldsymbol{\mu}_{\perp}, \boldsymbol{\delta})| < \kappa_S^{\mathbf{E}}(\boldsymbol{\sigma})$ for every S. When the centre of strengths $\boldsymbol{\sigma}$ is inside its walls, the slope *of an odd direction $(c, \mathbf{b}) \in \mathbf{1}^{\perp} \times \mathbb{R}^N$ at $\boldsymbol{\sigma}$ is*

$$\ell_{\boldsymbol{\sigma}}^*(c, \mathbf{b}) = \min\Big\{ \frac{\kappa_S^{\mathbf{E}}(\boldsymbol{\sigma})}{|\kappa_S^{\mathbf{O}}(c, \mathbf{b})|} : \ \kappa_S^{\mathbf{O}}(c, \mathbf{b}) \neq 0 \Big\},$$

$\ell_{\boldsymbol{\sigma}}^* = \infty$ if every $\kappa_S^{\mathbf{O}}(c, \mathbf{b})$ vanishes; it is homogeneous of degree one in $\boldsymbol{\sigma}$, and even and positively homogeneous of degree -1 in $(c, \mathbf{b})$. The questions of strengths $\boldsymbol{\sigma}$ inside their walls are those whose odd part has $\ell_{\boldsymbol{\sigma}}^*(\boldsymbol{\mu}_{\perp}, \boldsymbol{\delta}) > 1$, an open convex polyhedron symmetric under the fold, bounded exactly when no nonzero odd direction has $\kappa_S^{\mathbf{O}}(c, \mathbf{b}) = 0$ for every S. For one connected table at offsets zero they form the wedge $\sigma > 0$, $|\delta| < \ell_1^*(0,1)\,\sigma$, with $\ell_1^*(0,1) = \min\{c(S)/|\varepsilon^{\perp}(S)| : \ \varepsilon^{\perp}(S) \neq 0\}$.

(i) For the tilt Z of $U \sim \mathrm{Breta}^{\circ}(F; \sigma\mathbf{1}; \boldsymbol{\sigma}, \boldsymbol{\sigma})$, the centre of strengths $\boldsymbol{\sigma}$, and real $c \in \mathbf{1}^{\perp}$, $\mathbf{a}, \mathbf{b} \in \mathbb{R}^N$, the expectation of $e^{2\langle c, Z\rangle - \sum_j (a_j E_j(Z) + b_j O_j(Z))}$ is finite exactly when every proper wall of the question $(c; \boldsymbol{\sigma} + \mathbf{a}, \mathbf{b})$ is positive, $|\kappa_S^{\mathbf{O}}(c, \mathbf{b})| < \kappa_S^{\mathbf{E}}(\boldsymbol{\sigma} + \mathbf{a})$ for every S, and it is then the ratio of the periods of that question and of the centre (Corollary 17.2); in particular $\mathbb{E}_{U \sim \mathrm{Breta}^{\circ}(F; \sigma\mathbf{1}; \boldsymbol{\sigma}, \boldsymbol{\sigma})}\big[e^{2\langle c, Z\rangle - \sum_j b_j O_j(Z)}\big]$ is finite exactly when $\ell_{\boldsymbol{\sigma}}^*(c, \mathbf{b}) > 1$.

(ii) For a question inside its walls with $|\delta_j| \leq \sigma_j$ the native gauge $z^{\star}$ minimizes $-2\langle \boldsymbol{\mu}_{\perp}, z\rangle + \sum_j (\sigma_j E_j + \delta_j O_j)$ on $\mathbf{1}^{\perp}$, so $\big(z^{\star}; E_j(z^{\star}), O_j(z^{\star})\big)_j$ is the point of the set of values $\{(z; E_j(z), O_j(z))_j : \ z \in \mathbf{1}^{\perp}\}$ of the statistics at which $-2\langle \boldsymbol{\mu}_{\perp}, x\rangle + \sum_j (\sigma_j y_j + \delta_j w_j)$ is least; at the centre it is $\big(0; 2\log K_j(\mathbf{1}), 0\big)_j$.

Proposition 17.8 (The tails of the statistics are read at the walls)**.** *Let a question q of a family have every proper wall positive, let Z be the tilt of $U \sim \mathrm{Breta}^{\circ}(F; \mathbf{m}; \mathbf{s}, \mathbf{t})$ at its data, and for a real balanced direction v of pair coordinates $(c; \mathbf{a}, \mathbf{b})$ (Definition 17.1) let $Y = 2\langle c, Z\rangle - \sum_j \big(a_j E_j(Z) + b_j O_j(Z)\big)$. On the balance wall the walls are linear in the pair coordinates, $\kappa_S(q + \lambda v) = \kappa_S(q) + \lambda \kappa_S(v)$ with $\kappa_S(v) = \kappa_S^{\mathbf{E}}(\mathbf{a}) + \kappa_S^{\mathbf{O}}(c, \mathbf{b})$ (Proposition 17.7). Let*

$$\lambda^* = \min\Big\{ \frac{\kappa_S(q)}{-\kappa_S(v)} : \ \kappa_S(v) < 0 \Big\},$$

the value of λ at which the ray $q + \lambda v$, $\lambda > 0$, first meets a wall, with $\lambda^* = \infty$ if no $\kappa_S(v)$ is negative. For real $\lambda \geq 0$, $\mathbb{E}[e^{\lambda Y}]$ is finite exactly for $\lambda < \lambda^*$, where it is the ratio of the periods of the questions $q + \lambda v$ and q (Corollary 17.2); if $\lambda^* < \infty$,

$$\mathbb{P}(Y > x) = e^{-\lambda^* x + o(x)} \qquad (x \to \infty),$$

and if $\lambda^* = \infty$, Y is bounded above. Under the law of the centre of strengths $\boldsymbol{\sigma}$ an odd direction, of pair coordinates $(c; \mathbf{0}, \mathbf{b})$, has $\lambda^* = \ell_{\boldsymbol{\sigma}}^*(c, \mathbf{b})$ for Y and for $-Y$ alike.

The period of a question is a Laplace transform in the tilts, so the shape laws form an exponential family whose natural parameters are the offsets and the pair coordinates of the exponents and whose statistics are the tilt and the even and odd statistics E_j, O_j. On the sector of each order the exponent of a question is minus twice its wall at the tilt, the walls of the tails weighted by the differences of the tilt along the order, up to the bounded sector letters. So the walls alone fix how the period blows up as the strength goes to zero, the weights entering only at the next order and only through the greedy bases; at high strength, real or complex with its real part bounded below, the period is read at the native gauge of the ray. At a centre the exponent is minus the centred potential $\sum_j \sigma_j E_j$, which is convex, smallest at the table's gauge and within a constant of the widths of the Newton polytopes. A question can lean only as far as its strengths allow: the odd part of every wall is bounded by its even part, the slope of its odd part exceeds one, and the same slope bounds the exponential moments of the odd statistics at the centre; along every direction the tail of a statistic falls at the rate of the first wall the direction meets. Integrating over the simplex is integrating against the list $\binom{\mathcal{E}}{1}$ at a full basis lean, so every Dirichlet expectation of letters is a ratio of periods (Proposition 16.3).

Chapter 18

The Breta law and the port on the balance wall

18.1 The laws

Theorem 18.1 (The pseudointegral is a normalizer)**.** *Let F be connected on $n \geq 2$ marks with real data, $s_j, t_j \geq 0$, not all zero, and $\mathbf{m} > 0$, a native gauge $\alpha^\star$, target $\boldsymbol{\tau}$ and form $\omega = W\, d\alpha_{\mathbf{m}}$.*

(i) $\int W\, d\alpha_{\mathbf{m}} = P_F(\boldsymbol{\tau}; \mathbf{s}, \mathbf{t})$ is the normalizer of $\mathrm{Breta}^\circ(F; \boldsymbol{\tau}; \mathbf{s}, \mathbf{t})$*, and the pseudoexpectation $\mathsf{E}_{U \sim \mathbb{P}_{\mathrm{c}}}[(\omega_{\boldsymbol{\tau}}/\omega_{\mathrm{c}})(U)] = \int W\, d\alpha_{\mathbf{m}}/P_{\mathrm{c}}$ is the normalizer of its density against the law of the centre (Proposition 16.34(i)). With $\phi_{\mathbf{m}'}$ the joint law of $\big(K_1(U), \dots, K_N(U), \Psi_1(U), \dots, \Psi_N(U)\big)$ for $U \sim \mathrm{Dir}_{\mathbf{m}'}$, both periods are stacked Gammas of masses over their total times Trailmoments (Proposition 8.12(i)):*

$$\mathsf{E}_{U \sim \mathbb{P}_{\mathrm{c}}}\big[(\omega_{\boldsymbol{\tau}}/\omega_{\mathrm{c}})(U)\big] = \frac{\Gamma_1^n \begin{bmatrix} \boldsymbol{\tau} \\ \tau_{\mathcal{E}} \end{bmatrix} \big(\mathsf{T}_{(\mathbf{s},\mathbf{t});I_{2N}}[\mathrm{id}]\, \phi_{\boldsymbol{\tau}}\big)\big((0,\infty)^{2N}\big)}{\Gamma_1^n \begin{bmatrix} \sigma\mathbf{1} \\ n\sigma \end{bmatrix} \big(\mathsf{T}_{(\boldsymbol{\sigma},\boldsymbol{\sigma});I_{2N}}[\mathrm{id}]\, \phi_{\sigma\mathbf{1}}\big)\big((0,\infty)^{2N}\big)}.$$

(ii) In the coordinates $y = \log u$ modulo $\mathbb{R}\mathbf{1}$ the law $\mathrm{Breta}^\circ(F; \boldsymbol{\tau}; \mathbf{s}, \mathbf{t})$ *has density proportional to $e^{\langle \boldsymbol{\tau}, y\rangle - \Phi(y)}$, whose unique mode is $\log \alpha^\star$.*

(iii) (Cremona) If $U \sim \mathrm{Breta}^\circ(F; \mathbf{m}; \mathbf{s}, \mathbf{t})$ on the balance wall, then $U^{-1}/|U^{-1}| \sim \mathrm{Breta}^\circ(F; 2\sigma\mathbf{1} - \mathbf{m}; \mathbf{t}, \mathbf{s})$.

(iv) (The even–odd pair) On the balance wall the inversion of (iii) carries $\mathrm{Breta}^\circ(F; \mathbf{m}; \mathbf{s}, \mathbf{t})$ *at the data $(\boldsymbol{\mu}_\perp; \boldsymbol{\sigma}, \boldsymbol{\delta})$ to the law at $(-\boldsymbol{\mu}_\perp; \boldsymbol{\sigma}, -\boldsymbol{\delta})$; at $(0; \boldsymbol{\sigma}, \mathbf{0})$ it fixes the law, and with Z the signed coordinate of U the odd statistics $(O_j(Z))_j$ have a law symmetric under $O \mapsto -O$. The joint Laplace transform of the even and odd statistics is Corollary 17.2.*

Proposition 18.2 (The mark relation of the Breta shape law)**.** *Let F have real data, masses $\mathbf{m}$ on the balance wall and every proper wall positive, and in this statement write $\mathbf{u}(\alpha) = \sum_j \big(s_j R_j(\alpha) + t_j R_j^*(\alpha)\big)$ for the usage at α and $\mathbb{E}$ for the expectation of $U \sim \mathrm{Breta}^\circ(F; \mathbf{m}; \mathbf{s}, \mathbf{t})$. For $Y = \log U$ modulo $\mathbb{R}\mathbf{1}$, every mark e and every observable g, a smooth function of degree 0 in α such that g and $\partial_{y_e} g$ grow at most exponentially at a rate below the walls,*

$$\mathbb{E}\big[(m_e - \mathbf{u}_e(U))\, g(U) + \partial_{y_e} g(U)\big] = 0.$$

At $g=1$ the masses are the mean usage, $\mathbb{E}[\mathbf{u}(U)]=\mathbf{m}$; with a native gauge $\alpha^\star$ the usage equals the target $\boldsymbol{\tau}=\mathbf{m}$ at the mode $\log\alpha^\star$ (Theorem 18.1(ii)).

Proposition 18.3 (Scale and shapes along a bunch)**.** *For a proper bunch B with room R, masses $\mathbf{m}>0$ and every proper wall of positive real part,*

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t})=\Gamma_{1}^{|B|}\begin{bmatrix}\mathbf{m}|_B\\ m_B\end{bmatrix}\Gamma_{1}^{|R|}\begin{bmatrix}\mathbf{m}|_R\\ m_R\end{bmatrix}$$
$$\times\,\mathbb{E}_{(U'_B,U'_R)\sim \mathrm{Dir}_{\mathbf{m}|_B}\otimes \mathrm{Dir}_{\mathbf{m}|_R}}\Big[\int_0^\infty x^{m_B-1}(1+x)^{-\kappa_{\mathcal{E}}}\prod_j K_j(xU'_B,U'_R)^{-s_j}\Psi_j(xU'_B,U'_R)^{-t_j}\,dx\Big],$$

the inner integral being the scale integral of the family with the list $\binom{\mathcal{E}}{1}$ appended at the exponents $(\kappa_{\mathcal{E}},0)$, whose letter at (xU'_B,U'_R) is $1+x$ (Proposition 16.3); on the balance wall it is $\mathrm{Sc}_B(U'_B,U'_R;\mathbf{m};\mathbf{s},\mathbf{t})$ (Theorem 15.3), and the display is Corollary 16.6 at $h=|\alpha_R|$. For real data with every proper wall positive and $U\sim\mathrm{Breta}^\circ(F;\mathbf{m};\mathbf{s},\mathbf{t})$, with the internal shapes $V_B=U_B/|U_B|$ and $V_R=U_R/|U_R|$ and the totals $|U_B|+|U_R|=1$ (Theorem 3.12), the scale $\rho=|U_B|/|U_R|$ of B given the internal shapes has density proportional to $\rho^{m_B-1}(1+\rho)^{-\kappa_{\mathcal{E}}}\prod_j K_j(\rho V_B,V_R)^{-s_j}\Psi_j(\rho V_B,V_R)^{-t_j}$.

Theorem 18.4 (Structure of the Breta law)**.** *Let $X\sim\mathrm{Breta}(F;\mathbf{m};\mathbf{s},\mathbf{t})$; in this statement $\mathbb{E}$ is the expectation of X.*

(i) $|X|\sim\mathrm{Gamma}_{\kappa_{\mathcal{E}}}$ *and* $X/|X|\sim\mathrm{Breta}^\circ(F;\mathbf{m};\mathbf{s},\mathbf{t})$*, independently.*

(ii) The laws form an exponential family with respect to $e^{-|\alpha|}d\alpha/\alpha^{\mathbf{1}}$, with statistics $(\log X_e)_e$ and $(-\log K_j(X),-\log\Psi_j(X))_j$, natural parameters $(\mathbf{m},\mathbf{s},\mathbf{t})$ and log-partition $\log J_F(\mathbf{m};\mathbf{s},\mathbf{t})$: $\mathbb{E}\log X_e=\partial_{m_e}\log J_F(\mathbf{m};\mathbf{s},\mathbf{t})$, $\mathbb{E}\log(K_j\Psi_j)(X)=-D_{(\mathbf{0};\mathbf{e}_j,\mathbf{e}_j)}\log J_F(\mathbf{m};\mathbf{s},\mathbf{t})$, $\mathbb{E}\log(K_j/\Psi_j)(X)=-D_{(\mathbf{0};\mathbf{e}_j,-\mathbf{e}_j)}\log J_F(\mathbf{m};\mathbf{s},\mathbf{t})$, D_v the derivative along the direction v of the data, the masses fixed, and the covariances are second derivatives.

(iii) $\mathbb{E}[X^{\mathbf{k}}]=J_F(\mathbf{m}+\mathbf{k};\mathbf{s},\mathbf{t})/J_F(\mathbf{m};\mathbf{s},\mathbf{t})$ *and* $\mathbb{E}\big[\prod_j K_j(X)^{-a_j}\Psi_j(X)^{-b_j}\big]=J_F(\mathbf{m};\mathbf{s}+\mathbf{a},\mathbf{t}+\mathbf{b})/J_F(\mathbf{m};\mathbf{s},\mathbf{t})$.

Theorem 18.5 (The race representation)**.** *Let $X\sim\mathrm{Breta}(F;\mathbf{m};\mathbf{s},\mathbf{t})$. Given $X=\alpha$, run for each table j a* basis race*, the basis T ringing with intensity $\theta_{j,T}\alpha^T$, and a* cobasis race*, with intensity $\theta_{j,T}\alpha^{\mathcal{E}\setminus T}$, all clocks independent; let Y_j and Y_j^* be the first ringing times and T_j, T'_j the winners. In this statement $\mathbb{E}$ and $\mathbb{P}$ are taken over the clocks of the races at α.*

(i) In each race the time and the winner are independent: $K_j(\alpha)Y_j\sim\mathrm{Gamma}_1$ and $T_j\sim\mathbb{P}_{j,\alpha}$; $\Psi_j(\alpha)Y_j^*\sim\mathrm{Gamma}_1$ and $T'_j\sim\mathbb{P}^*_{j,\alpha}$.

(ii) $K_j(\alpha)^{-s_j}\Psi_j(\alpha)^{-t_j}=\mathbb{E}\big[Y_j^{s_j}(Y_j^*)^{t_j}\big]/\big(\Gamma(1+s_j)\Gamma(1+t_j)\big)$.

(iii) With $\mathrm{g}_j=-\log(K_jY_j)$ and $\mathrm{g}'_j=-\log(\Psi_jY_j^*)$, independent, $-\log(Y_jY_j^*)=\log(K_j\Psi_j)+\mathrm{g}_j+\mathrm{g}'_j$ and $-\log(Y_j/Y_j^*)=\log(K_j/\Psi_j)+\mathrm{g}_j-\mathrm{g}'_j$, and, for real a,b with $1+a\pm b>0$, $\mathbb{E}\big[e^{-a(\mathrm{g}_j+\mathrm{g}'_j)-b(\mathrm{g}_j-\mathrm{g}'_j)}\big]=\Gamma(1+a+b)\,\Gamma(1+a-b)$.

(iv) $\mathbb{P}(Y_j<Y_j^*)=K_j/(K_j+\Psi_j)=1/(1+e^{-O_j(z)})$, $\alpha=e^{2z}$.

(v) $D=\chi_{T_j}-\chi_{T'_j}$ has $\mathbb{E}[e^{\langle w,D\rangle}]=e^{E_j(z+w)-E_j(z)}$: the even statistic E_j is the cumulant function of the difference of the two winners (by (i), Theorem 7.16 for table j).

The two exponents of a table are the two clocks of its races: its even letter reads the sum $\mathrm{g}_j+\mathrm{g}'_j$ of the two logarithmic clocks of (iii) and its odd letter their difference, so that the pair coordinates (σ_j,δ_j) are the exponents of $\mathrm{g}_j+\mathrm{g}'_j$ and $\mathrm{g}_j-\mathrm{g}'_j$.

Theorem 18.6 (Conjugacy)**.** *Let* $X \sim \mathrm{Breta}(F;\mathbf{m};\mathbf{s},\mathbf{t})$.

(i) Given the winner T *of the* j*-th basis race, its time unobserved,* $X \sim \mathrm{Breta}(F;\mathbf{m}+\mathbf{1}_T;\mathbf{s}+\mathbf{e}_j,\mathbf{t})$*; given the winner* T' *of the* j*-th cobasis race,* $X \sim \mathrm{Breta}(F;\mathbf{m}+\mathbf{1}_{\mathcal{E}\setminus T'};\mathbf{s},\mathbf{t}+\mathbf{e}_j)$*. Both keep* $\kappa_{\mathcal{E}}$*.*

(ii) Under the joint law of X *and the races of Theorem 18.5,* $\mathbb{P}(T_j = T) = \theta_{j,T} P_F(\mathbf{m}+\mathbf{1}_T;\mathbf{s}+\mathbf{e}_j,\mathbf{t})/P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ *and* $\mathbb{P}(T'_j = T') = \theta_{j,T'} P_F(\mathbf{m}+\mathbf{1}_{\mathcal{E}\setminus T'};\mathbf{s},\mathbf{t}+\mathbf{e}_j)/P_F(\mathbf{m};\mathbf{s},\mathbf{t})$*, each summing to one.*

(iii) Given the time $Y_j = \lambda$ *as well,* X *has the density of* $\mathrm{Breta}(F;\mathbf{m}+\mathbf{1}_T;\mathbf{s},\mathbf{t})$ *multiplied by* $e^{-\lambda K_j(\alpha)}$ *and renormalized: the kernel terms* $\lambda\theta_{j,T}\alpha^T$ *join those of* $e^{-|\alpha|}$*, and the law exists only on the orthant.*

Corollary 18.7 (Conjugacy for the continued period)**.** *For every family and every table* j *of it, with its bases* $\mathcal{B}_j$ *and weights* θ_j*,*

$$\sum_{T\in\mathcal{B}_j} \theta_{j,T}\, P_F(\mathbf{m}+\mathbf{1}_T;\mathbf{s}+\mathbf{e}_j,\mathbf{t}) = P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \sum_{T'\in\mathcal{B}_j} \theta_{j,T'}\, P_F(\mathbf{m}+\mathbf{1}_{\mathcal{E}\setminus T'};\mathbf{s},\mathbf{t}+\mathbf{e}_j)$$

as identities of meromorphic functions of the masses and the exponents (Lemma 16.9), and so on the balance wall: the identities of Theorem 18.6(ii) hold for the continued values of Theorem 16.17.

Theorem 18.8 (The winners of a tensorminental table)**.** *If table* j *is tensorminental of tensor rank* q *with slices* $A^{(k)}$*, then for a bunch* B *with room* R *and at a gauge as in Theorem 7.23, the pattern* $T_j \cap B$ *of the basis winner has the generating function* $\sum_{k,l} w_{kl} \det\big(I+(D_x-I)\Pi^{(kl)}_{BB}\big)$ *of that theorem, and the cobasis winner's is the same with the slices of the dual multivector. Conditioning on the winner's pattern leaves tables with multivectors of tensor rank at most* q *on the room.*

Proposition 18.9 (The period along a ray of data)**.** *Let* F *be connected, let* $(\boldsymbol{\tau};\mathbf{s},\mathbf{t})$ *be real data on its balance wall with* $\boldsymbol{\tau} > 0$*,* $s_j, t_j \geq 0$ *not all zero, and a native gauge* $\alpha^\star$*, let* $(\mathbf{m}_0;\mathbf{s}_0,\mathbf{t}_0)$ *be complex data on the balance wall, and in this statement write* $W_0 = \prod_j K_j^{-s_{0,j}} \Psi_j^{-t_{0,j}}$*. As* $\lambda \to +\infty$ *the data* $(\mathbf{m}_0+\lambda\boldsymbol{\tau};\mathbf{s}_0+\lambda\mathbf{s},\mathbf{t}_0+\lambda\mathbf{t})$ *have every proper wall of positive real part, and, with* Φ *the potential at* $(\mathbf{s},\mathbf{t})$ *and a chart* g*,*

$$P_F(\mathbf{m}_0+\lambda\boldsymbol{\tau};\mathbf{s}_0+\lambda\mathbf{s},\mathbf{t}_0+\lambda\mathbf{t}) \sim (\alpha^\star)^{\mathbf{m}_0} W_0(\alpha^\star)\Big(\frac{2\pi}{\lambda}\Big)^{\frac{n-1}{2}} \det\big(\nabla^2\Phi(\log\alpha^\star)\big)^{-1/2}_{(g)}\, e^{-\lambda(\Phi(\log\alpha^\star)-\langle\boldsymbol{\tau},\log\alpha^\star\rangle)},$$

(g*) deleting the row and the column of* g*, where* $\nabla^2\Phi$ *is* $\frac{1}{4}$ *times rung two of the still and* $(\alpha^\star)^{\mathbf{m}_0}W_0(\alpha^\star)$ *does not depend on the scale of* $\alpha^\star$*. At* $(\mathbf{m}_0;\mathbf{s}_0,\mathbf{t}_0) = 0$ *the display is the leading term of Theorem 17.5(ii) at real* λ *for the question of the data* $(\boldsymbol{\tau};\mathbf{s},\mathbf{t})$*. For real* $(\mathbf{m}_0;\mathbf{s}_0,\mathbf{t}_0)$*, under* $\mathrm{Breta}^\circ(F;\mathbf{m}_0+\lambda\boldsymbol{\tau};\mathbf{s}_0+\lambda\mathbf{s},\mathbf{t}_0+\lambda\mathbf{t})$*,* $\sqrt{\lambda}(Y-\log\alpha^\star)$ *tends to the centred normal law on* $\mathbb{R}^{\mathcal{E}}/\mathbb{R}\mathbf{1}$ *with covariance* $(\nabla^2\Phi)^{-1}$*,* $Y = \log U$*.*

A base point added to the data moves the ray off the origin: along $(\mathbf{m}_0+\lambda\boldsymbol{\tau};\mathbf{s}_0+\lambda\mathbf{s},\mathbf{t}_0+\lambda\mathbf{t})$, with complex $(\mathbf{m}_0;\mathbf{s}_0,\mathbf{t}_0)$ on the balance wall, the leading term of Theorem 17.5(ii) gains the factor $(\alpha^\star)^{\mathbf{m}_0}\prod_j K_j(\alpha^\star)^{-s_{0,j}}\Psi_j(\alpha^\star)^{-t_{0,j}}$ at the native gauge $\alpha^\star = e^{2z^\star}$.

Definition 18.10 (Skeleton law)**.** For coefficients $\xi_\ell \in \mathbb{C}\setminus(-\infty,0]$, $\ell \in J = \{0,\dots,L\}$, closed under conjugation, real nonzero letter exponents w_ℓ, equal on conjugate coefficients, with total

$|\mathbf{w}|$, and $0<\kappa<|\mathbf{w}|$, the *Skeleton law* $\mathrm{Skel}_{\mathbf{w},\kappa}(\boldsymbol{\xi})$ is the law on $(0,\infty)$ with density

$$y^{\kappa-1}\prod_{\ell}(y+\xi_\ell)^{-w_\ell}\Big/\Gamma_{\,|J|}^{\,2}\begin{bmatrix}\kappa,\ |\mathbf{w}|-\kappa\\ \mathbf{w}\end{bmatrix}\ \mathsf{B}^{\{J\}}_{\mathbf{w},\,|\mathbf{w}|-\kappa;\,I_J}(\boldsymbol{\xi}),$$

its normalizer being Proposition 15.1; the density is positive, and integrable exactly when $0<\kappa<|\mathbf{w}|$.

Theorem 18.11 (The Skeleton law)**.** *(i) Under* $\mathrm{Breta}^{\circ}(F;\mathbf{m};\mathbf{s},\mathbf{t})$*, the scale of a proper bunch* B *given the internal shapes of* B *and of its room has the law* $\mathrm{Skel}_{\mathbf{w},\kappa_B}(\boldsymbol{\xi})$*:* $\boldsymbol{\xi}$ *the joint spectrum of* B *at that point and* $\mathbf{w}$ *its letter exponents of Theorem 15.3, and off the balance wall the coefficient* 1 *besides, with the letter exponent* $\kappa_{\mathcal{E}}$*, added to the letter exponent of* 1 *when* 1 *is a point of the joint spectrum; coefficients of letter exponent zero are discarded.*

(ii) For $Y\sim\mathrm{Skel}_{\mathbf{w},\kappa}(\boldsymbol{\xi})$ *and* $-\kappa<\operatorname{Re}k<|\mathbf{w}|-\kappa$*,*

$$\mathbb{E}_{Y\sim\mathrm{Skel}_{\mathbf{w},\kappa}(\boldsymbol{\xi})}[Y^k]=\Gamma_{\,2}^{\,2}\begin{bmatrix}\kappa+k,\ |\mathbf{w}|-\kappa-k\\ \kappa,\ |\mathbf{w}|-\kappa\end{bmatrix}\frac{\mathsf{B}^{\{J\}}_{\mathbf{w},\,|\mathbf{w}|-\kappa-k;\,I_J}(\boldsymbol{\xi})}{\mathsf{B}^{\{J\}}_{\mathbf{w},\,|\mathbf{w}|-\kappa;\,I_J}(\boldsymbol{\xi})},$$

the quotient of the values of Proposition 15.1 at the indices $\kappa+k$ *and* κ*, read as that quotient when a letter exponent is not positive; and* $1/Y\sim\mathrm{Skel}_{\mathbf{w},|\mathbf{w}|-\kappa}(\boldsymbol{\xi}^{-1})$*.*

(iii) With real coefficients, positive letter exponents and a point $r\geq\max_\ell\xi_\ell$ *of the axis,* Y *is the mixture over* $\mathbf{n}\in\mathbb{N}^J$ *of* $rY_{\mathbf{n}}$*,* $Y_{\mathbf{n}}\sim\mathrm{Skel}_{|\mathbf{w}|+|\mathbf{n}|,\kappa}(1)$ *the law with the one coefficient* 1*, mixed in proportion to* $\prod_{\ell\in J}\frac{(w_\ell)_{n_\ell}}{n_\ell!}g_\ell^{n_\ell}\Gamma_{\,1}^{\,2}\begin{bmatrix}\kappa,\ |\mathbf{w}|+|\mathbf{n}|-\kappa\\ |\mathbf{w}|+|\mathbf{n}|\end{bmatrix}$*,* $g_\ell=1-\xi_\ell/r$ *the spectral gaps at* r *of Theorem 15.6; at* $r=\max_\ell\xi_\ell$ *the largest coefficient drops out.*

(iv) In the situation of (i) on the balance wall, with $s_j,t_j\geq0$*: given* $Y\leq1$*,* Y *is the mixture of the first coordinates of the laws* $\mathrm{Dir}_{(\kappa_B+k,|\mathbf{n}|+1)}$*, and given* $Y\geq1$*,* $1/Y$ *is the mixture of the first coordinates of* $\mathrm{Dir}_{(\kappa_B^{\mathrm{top}}+k,|\mathbf{n}|+1)}$*, mixed in proportion to the terms of Theorem 15.9(ii); the two sectors carry probabilities proportional to the sector Trailmoments of that theorem at the indices* κ_B *and* κ_B^{top}*.*

18.2 The port on the balance wall

Definition 18.12 (Wall contour; joint period)**.** On the balance wall, with $\operatorname{Re}s_j>0$ or $s_j=0$, and $\operatorname{Re}t_j>0$ or $t_j=0$, for every j, a *wall contour* at a bunch B puts the shares of Theorem 15.15 of the letters with nonzero exponent on real parts $c_{j,p},c'_{j,p}>0$ with $\sum_p c_{j,p}=\operatorname{Re}s_j$, $\sum_p c'_{j,p}=\operatorname{Re}t_j$ and real odd load equal to the real part of the offset on the bunch, $\sum_{j,p}\frac{c_{j,p}-c'_{j,p}}{2}\chi_p(e)=\operatorname{Re}\mu_e$; equivalently the real part of every mass of the bunch is carried exactly, $\operatorname{Re}\mathrm{load}_e=\operatorname{Re}m_e$. The *fibre integral at* B is the fibre integral (Definition 4.1) with the pins $|\mathbf{a}_j|=s_j$, $|\mathbf{b}_j|=t_j$ and $\langle\boldsymbol{\delta}\rangle_e=\mu_e$, $e\in B$. For a family $G=((\mathcal{B}_i,\theta_i);a_i,b_i)_i$ whose molecules are $R_1,\dots,R_q$, the *joint period* $P_G^{\otimes}(\mathbf{m};\mathbf{a},\mathbf{b})$ is the integral of $\alpha^{\mathbf{m}-\mathbf{1}}\prod_i K_i(\alpha)^{-a_i}\Psi_i(\alpha)^{-b_i}$ over $\alpha\in\prod_{k=1}^q\Delta_{R_k}$ against $\prod_k d\omega_{R_k}$, wherever it converges; when the weights factor across the molecules it is the product of the molecules' periods.

Theorem 18.13 (The port on the balance wall)**.** *Let* F *have data on the balance wall with* $\operatorname{Re}s_j>0$ *or* $s_j=0$*, and* $\operatorname{Re}t_j>0$ *or* $t_j=0$*, for every* j*, let* $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ *converge, and let* B *be a proper bunch with room* R*; put* $z=\frac12\log\alpha$*.*

(i) The bunch factor $\Xi_B(\alpha_R;\boldsymbol{\mu}|_B;\mathbf{s},\mathbf{t}) = \int_{\mathbb{R}^B_{>0}} \alpha_B^{\boldsymbol{\mu}|_B-\mathbf{1}} \prod_j \Lambda_j(z)^{-s_j}\Lambda_j(-z)^{-t_j}\, d\alpha_B$ *converges for every* α_R, $P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \int_{\Delta_R} v^{\boldsymbol{\mu}|_R-\mathbf{1}}\, \Xi_B(v;\boldsymbol{\mu}|_B;\mathbf{s},\mathbf{t})\, d\omega_R(v)$, *and on every wall contour*

$$\Xi_B(\alpha_R;\boldsymbol{\mu}|_B;\mathbf{s},\mathbf{t}) = \int_{|\mathbf{a}_j|=s_j,\ |\mathbf{b}_j|=t_j,\ \langle\boldsymbol{\delta}\rangle=\boldsymbol{\mu}|_B} \prod_j \Gamma_{|\operatorname{pat}_j(B)|}\begin{bmatrix}\mathbf{a}_j\\ s_j\end{bmatrix}\Gamma_{|\operatorname{pat}_j(B)|}\begin{bmatrix}\mathbf{b}_j\\ t_j\end{bmatrix} \times \prod_{j,p}\Lambda_{j,(p)}(z_R)^{-a_{j,p}}\Lambda_{j,(p)}(-z_R)^{-b_{j,p}}.$$

(ii) Let $R_1,\dots,R_q$ *be the molecules of the children and* $\kappa_{R_i}(\mathbf{a},\mathbf{b})$ *the wall at* R_i *of the children* $F_B(\mathbf{a},\mathbf{b})$ *with the masses* $\mathbf{m}|_R$ *(Definition 8.1); as* R_i *is a molecule,* $\kappa_{R_i}(\mathbf{a},\mathbf{b}) = m_{R_i} - \sum_{j,p}\big(a_{j,p}r_{j,(p)}(R_i) + b_{j,p}(|R_i| - r_{j,(p)}(R_i))\big)$, *with* $r_{j,(p)}$ *the rank function of the child* (j,p). *Let* $\mathcal{X}$ *be the fibre of the shares cut by the pins* $|\mathbf{a}_j| = s_j$, $|\mathbf{b}_j| = t_j$, $\langle\boldsymbol{\delta}\rangle = \boldsymbol{\mu}|_B$ *and* $\kappa_{R_1} = \cdots = \kappa_{R_{q-1}} = 0$, *with* $|B|+q-1$ *pins beyond the share sums;* $\kappa_{R_q} = 0$ *holds on it. On a wall contour with* $\operatorname{Re}\kappa_{R_i} = 0$ *for* $i < q$ *at which* $P^{\otimes}_{F_B(\mathbf{c},\mathbf{c}')}(\operatorname{Re}\mathbf{m}|_R;\mathbf{c},\mathbf{c}')$ *converges,*

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \int_{\mathcal{X}} \prod_j \Gamma_{|\operatorname{pat}_j(B)|}\begin{bmatrix}\mathbf{a}_j\\ s_j\end{bmatrix}\Gamma_{|\operatorname{pat}_j(B)|}\begin{bmatrix}\mathbf{b}_j\\ t_j\end{bmatrix}\, P^{\otimes}_{F_B(\mathbf{a},\mathbf{b})}(\mathbf{m}|_R;\mathbf{a},\mathbf{b}).$$

(iii) The native split of the real parts $(\operatorname{Re}\mathbf{m};\operatorname{Re}\mathbf{s},\operatorname{Re}\mathbf{t})$, *which have a native gauge, is a wall contour whose real parts are those of the points of* $\mathcal{X}$, *and* $P^{\otimes}$ *converges there; for real data it is the native split, and it lies on the fibre.*

The bunch is integrated on its orthant, scale and shape at once: writing $\alpha_B = \rho u$ before opening the letters would split the $|B|$ pins into a pin on the scale and a stacked Gamma over the shape whose indices sum to zero, carrying $1/\Gamma(0) = 0$, and neither has a value alone. For the same reason $B = \mathcal{E}$ is excluded: the imaginary part of the odd load then lies in the hyperplane $\sum_{e\in\mathcal{E}}\operatorname{Im}\langle\boldsymbol{\delta}\rangle_e = \operatorname{Im}\mu_{\mathcal{E}}$, the scaling mode, and one mark stays in the room.

Lemma 18.14 (Connected tables have connected children)**.** *If some table with* $s_j + t_j > 0$ *is connected, then at every bunch the children at a split with positive shares form a connected family.*

At the masses $\boldsymbol{\tau}+\eta\mathbf{m}$ the port on the orthant carries the stacked Gamma with the upper entries $\nu_e = \mu_e - \langle\boldsymbol{\delta}\rangle_e$, $e \in B$, and κ_{R_i}, and the lower entry $\eta m_{\mathcal{E}}$; its $|B|+q$ upper entries sum to $\eta m_{\mathcal{E}}$ and have real parts positive multiples of η on the wall contour of the native split (Theorem 18.13(iii)); as $\eta \to 0$ it tends to $(2\pi)^{|B|+q-1}$ times the delta of the pins. So the port on the balance wall is the limit of the Foreman procedure on the ray (Theorem 16.15): the Gammas are the pins.

Proposition 18.15 (Peeling a molecule)**.** *In Theorem 18.13 with a native gauge, let* R_1 *be a molecule of the children and* $g \in R_1$. *Each child letter is* $\sum_X \alpha_{R_1}^X K_{[X]}(\alpha_{R\setminus R_1})$ *over the bases* X *of its restriction to* R_1, *with* $K_{[X]}$ *the letter on* $R\setminus R_1$ *with the bases* Y *and the weights* $\theta_{X\cup Y}$ *(for* Ψ, $\alpha_{R_1}^{R_1\setminus X}\Psi_{[X]}$*). Opening these sums with one share per part,* $P^{\otimes}$ *is the fibre integral with the* $|R_1|-1$ *pins* $\operatorname{load}_e = m_e$, $e \in R_1 - g$, *of the stacked Gammas of these shares against the joint period of the new children on the remaining molecules; the pin at* g *holds by the balance of* R_1, *the native split lies on the fibre, and the joint period converges there. With weights multiplicative across* R_1 *every* $K_{[X]}$ *is a multiple of one letter and this is the factorization of Theorem 18.13(ii).*

Corollary 18.16 (Atoms on the balance wall)**.** *In Theorem 18.13, fix g. On a wall contour for $\mathcal{E}-g$, with one share per basis and letter,*

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \int_{|\mathbf{a}_j|=s_j,\ |\mathbf{b}_j|=t_j,\ \langle\boldsymbol{\delta}\rangle=\boldsymbol{\mu}|_{\mathcal{E}-g}} \prod_j \Gamma_{1}^{|\mathcal{B}_j|}\begin{bmatrix}\mathbf{a}_j\\ s_j\end{bmatrix}\Gamma_{1}^{|\mathcal{B}_j|}\begin{bmatrix}\mathbf{b}_j\\ t_j\end{bmatrix}\prod_{j,T}\theta_{j,T}^{-a_{j,T}-b_{j,T}},$$

independent of g; the pin at g holds by itself.

Running the ports on the balance wall down to rooms of one mark writes $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ as an iterated fibre integral with $n-1$ pins in all; with one share per pattern and letter its dimension is $\sum(|\mathcal{B}_j|-1)-(n-1)$, one term for each active letter, j its table, independent of the tree when no letter is split across molecules.

Proposition 18.17 (The pins reach every integer point)**.** *In Corollary 18.16 take one share for each basis and each active letter, the K_j with $s_j\neq 0$ and the Ψ_j with $t_j\neq 0$, and write the pins in the shares as the share sums $|\mathbf{a}_j|=s_j$, $|\mathbf{b}_j|=t_j$ of the active letters and the loads $\mathrm{load}_e=m_e$, $e\in\mathcal{E}-g$ (Definition 12.24). Let every two marks be joined by a sequence of marks in which any two consecutive marks lie in a common circuit of a table with an active letter. Then the pins map the integer points of the share space onto the integer points of their target. So at integer exponents and masses the fibre has integer points, its integer points are $x_0+\Lambda$ for one of them x_0 and the lattice Λ of the integer points of its directions, which has the rank of the dimension of the fibre, and a basis of Λ gives integral coordinates on the fibre in which the integer points are exactly the points with integer coordinates.*

Corollary 18.18 (Closure)**.** *If the weights of a form $W\,d\alpha_{\mathbf{m}}$ with real data, $s_j,t_j\geq 0$ not all zero, factor across its molecules and every molecule has a native gauge, $\int W\,d\alpha_{\mathbf{m}}$ is a product over the molecules of iterated fibre integrals over affine fibres of share space, with integrands products of stacked Gammas of the shares and monomials in the weights, $n-1$ pins on a molecule of n marks. The period of each molecule at its target is also the nonnegative series of Corollary 15.11 and of Theorem 15.13. Every quasi-integral is an iterated constant term of the continuation of the share integral of Theorem 15.15 at its chart completion.*

What a closed form is. Definition 1.1(vi) writes final answers as words, and Closure writes the period of every family as one, in the stacked Gamma, monomials in the weights and fibre integrals alone. That such a word is a closed form is checked against the criterion by which any function is counted as one.

Definition 18.19 (Closed form)**.** A function is *named* when it is given by an integral or a series of fixed shape whose calculus is known: where it converges, how it continues in its data, where its poles lie, how it grows, and how it is evaluated to any precision. An *alphabet* is a finite set of named functions with fixed operations. A value is *in closed form* relative to an alphabet when it is a finite expression in it, and an alphabet is *closed on a class* of values when every value of the class is in closed form relative to it. The *serif alphabet* is exp, log, the stacked Gamma and the serif family, with the operations of a word, and a *serif word* is a word in it (Definition 1.1(vi)).

This is the criterion on which Γ and the Beta integral are counted as closed forms, and with them the classical functions listed among the Aliases: each is an integral or a series of fixed shape whose calculus is known. An integral counts as unevaluated when its shape varies with its input, as the letters K_j and Ψ_j of a family vary with its tables, and it is evaluated when it is carried to an integral of fixed shape, which is what the atom formula does (Corollary 18.16).

Proposition 18.20 (The serif word is the closed form of the periods)**.** *In the terms of Definition 18.19:*

(i) The stacked Gamma is named: it is a quotient of values of Γ*, which is the Gramma of one scale,* $\Gamma(\nu) = \mathsf{G}_{\nu;(1)}(1)$*, and it is meromorphic in its entries. The Gramma converges exactly on* $\mathcal{T}_t$ *and is holomorphic there. The fibre integral is a fixed operation: it is fixed by its pins and does not depend on its admissible real point.*

(ii) The alphabet of the stacked Gamma, with monomials in the data and fibre integrals over affine fibres of share space, is closed on the periods of the convergent families on the balance wall with $\operatorname{Re} s_j > 0$ *or* $s_j = 0$ *and* $\operatorname{Re} t_j > 0$ *or* $t_j = 0$ *for every* j*, and on the pseudointegrals of Corollary 18.18: each is a fibre integral, or a product of iterated fibre integrals, of products of stacked Gammas of the shares and monomials in the weights.*

(iii) On the word the calculus of every such period is read: its convergence at the walls (Theorem 8.7), its continuation in all its data (Corollary 18.18), its native gauge, where its integrand is largest (Theorem 8.19), the integer points of its fibre and its closings (Proposition 18.17, Theorem 4.5), and its nonnegative series (Corollary 15.11, Theorem 15.13).

(iv) The series of stacked Gammas are readings of words. For $k > 0$ *and* $0 < \mathsf{m} < 2$ *let* F_{m} *be the family on* $\{1,2\}$ *of two copies of* $\binom{[2]}{1}$*, the first with the weights* 1 *at the exponents* $(k,0)$*, the second with the weight* 1 *on the basis* $\{1\}$ *and* m *on the basis* $\{2\}$ *at the exponents* $(0,k)$*. At the masses* (k,k)*,*

$$P_{F_{\mathsf{m}}}\big((k,k);(k,0),(0,k)\big) = \frac{1}{2\pi i}\int_{\operatorname{Re} x = k/2} \Gamma_{\substack{4\\2}}\begin{bmatrix} x,\ x,\ k-x,\ k-x \\ k,\ k \end{bmatrix}\, \mathsf{m}^{x-k}\, dx$$
$$= \sum_{j\ge 0} \Gamma_{\substack{2\\1}}\begin{bmatrix} k+j,\ k+j \\ 2k+j \end{bmatrix} \frac{(1-\mathsf{m})^j}{j!}.$$

For $n \ge 1$*,* $-1 < z < 0$ *and* $-1 < c < 0$*,*

$$\sum_{j\ge 1} \frac{z^j}{j^n} = \frac{z}{2\pi i}\int_{\operatorname{Re} s = c} \Gamma_{\substack{2\\0}}\big[-s,\ 1+s\big]\, \Big(\Gamma_{\substack{1\\1}}\begin{bmatrix} 1+s \\ 2+s \end{bmatrix}\Big)^n (-z)^s\, ds,$$

and the integral, which converges for every $z < 0$*, continues the series to every* $z < 0$*.*

So the serif word is the closed form of the periods by the criterion that makes Γ one: its functions are named on the grounds on which Γ is, the alphabet is closed on the periods, their calculus is read on the word, and the classical closed forms are among its readings (Aliases). Along a ray the values of a family satisfy one recurrence and span a space of finite dimension (Theorem 38.31); twists and product weights multiply the integrand by a monomial in the loads (Theorem 25.12(ii), Proposition 26.20); and down the hinge tree each cell enters through the period of its own hinge minors at the loads of its marker (Theorem 22.4), on the centre ray of a table with norms on its marks through its own word (Proposition 42.26). Smaller alphabets fail already on a class: no function whose continuations span a local system with a unipotent subgroup of finite index in its monodromy is a nonzero period of the pencil of a class of at least three marks (Corollary 42.30). That a value has no closed form in a smaller alphabet is a statement about that alphabet.

Corollary 18.21 (The marginal law of the shape)**.** *In Theorem 18.13 let* $U \sim \mathrm{Breta}^{\circ}(F;\mathbf{m};\mathbf{s},\mathbf{t})$*, with the internal shapes* $V_B = U_B/|U_B|$ *and* $V_R = U_R/|U_R|$ *of* B *and* R *(Proposition 18.3).*

(i) $\mathbb{E}_{U'\sim \mathrm{Dir}_{\mathbf{m}|_B}}\big[\,\mathrm{Sc}_B(U',v;\mathbf{m};\mathbf{s},\mathbf{t})\big] = v^{-\sigma\mathbf{1}}\,\Xi_B(v;\boldsymbol{\mu}|_B;\mathbf{s},\mathbf{t})/\Gamma_{|B|\atop 1}\begin{bmatrix}\mathbf{m}|_B\\ m_B\end{bmatrix}$.

(ii) *Given* $V_R = v$, *for* $\mathbf{k}\in\mathbb{C}^B$ *with* $|\mathbf{k}| = 0$, $\mathbb{E}_{U\sim \mathrm{Breta}^\circ(F;\mathbf{m};\mathbf{s},\mathbf{t})}[V_B^{\mathbf{k}} \mid V_R = v] = \Xi_B(v;\boldsymbol{\mu}|_B + \mathbf{k};\mathbf{s},\mathbf{t})/\Xi_B(v;\boldsymbol{\mu}|_B;\mathbf{s},\mathbf{t})$, *the bunch factor at shifted offsets, whose fibre is* $\langle\boldsymbol{\delta}\rangle = \boldsymbol{\mu}|_B + \mathbf{k}$.

(iii) V_R *has density proportional to* $v^{\boldsymbol{\mu}|_R-\mathbf{1}}\,\Xi_B(v;\boldsymbol{\mu}|_B;\mathbf{s},\mathbf{t})$, *the fibre mixture of the children's shape laws in proportion to the stacked Gammas times* $P_{F_B(\mathbf{a},\mathbf{b})}(\mathbf{m}|_R;\mathbf{a},\mathbf{b})$ *when the children are connected (Lemma 18.14).*

(iv) *Given both shapes, the scale of* B *has the Skeleton law of Theorem 18.11(i).*

18.3 Cycles

Definition 18.22 (Cycle of a family)**.** A *cycle* of a family is a bunch C that is a circuit of one of its tables. That table's cobasis polynomial has floor one on C, and on its bottom colevel the letter is linear on C; a letter linear on a bunch gives the bunch the *kernel* e^{-h}, h the letter divided by the sum of its coefficients (Theorem 18.23(ii) below).

Theorem 18.23 (A cycle carries its own kernel)**.** *Let* F *have real data with* $s_j, t_j \geq 0$, $\kappa_{\mathcal{E}} = 0$, $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ *convergent, and* $C \neq \mathcal{E}$ *a circuit of table* j_0 *with* $t_{j_0} > 0$ *and room* R.

(i) *The patterns of table* j_0 *on* C *of colevel one are exactly* $p_e = C - e$, $e \in C$, *and the child at* p_e *is the contraction* $\mathcal{B}_{j_0}/C$ *on* R *with the weights* $\theta_{j_0,p_e\cup X}$. *So* $\Psi_{j_0} = \Psi^\flat + \Psi^\sharp$ *with* $\Psi^\flat = \sum_{e\in C}\alpha_e\Psi_{j_0,(p_e)}(\alpha_R)$ *linear in* α_C. *The circuits are the only bunches whose colevel-one patterns are one per mark.*

(ii) *With* $G(\alpha_R) = \sum_{e\in C}\Psi_{j_0,(p_e)}(\alpha_R)$ *and* $h = \Psi^\flat/G$, *if the family with* $\Psi_{j_0}^{-t_{j_0}}$ *replaced by* $(\Psi^\flat)^{-c}(\Psi^\sharp)^{-(t_{j_0}-c)}$ *converges, then on* $\mathrm{Re}\,\beta = c$

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \frac{1}{\Gamma(t_{j_0})}\int_{\beta+\beta'=t_{j_0}}\Gamma(\beta') \times\int_{\mathbb{R}^{\mathcal{E}}_{>0}}\alpha^{\mathbf{m}-\mathbf{1}}e^{-h(\alpha)}G(\alpha_R)^{-\beta}\Psi^\sharp(\alpha)^{-\beta'}K_{j_0}^{-s_{j_0}}\prod_{j\neq j_0}K_j^{-s_j}\Psi_j^{-t_j}\,d\alpha.$$

When the colevel-one children are multiples ϑ_e *of one letter, as for unit weights and for determinantal tables, the kernel is* $e^{-\langle\vartheta,\alpha_C\rangle/|\vartheta|}$.

(iii) *On a wall contour at* C *the pins at the marks of* C *hold exactly when* $b_{j_0,p_e} = m_e - \lambda_e$, λ_e *the load on* e *of all the other shares, and* $\sum_{j,p}\big(a_{j,p}(|p| - d_j(C)) + b_{j,p}(|C\setminus p| - d_j^*(C))\big) = \kappa_C$, *the coefficients being the excesses of the level and the colevel of* p *in table* j *(Definition 12.16); the fibre integral at* C *is over the other shares with the single pin that their total excess is the wall of the cycle, the Gammas* $\Gamma(m_e - \lambda_e)$ *of the cycle standing in the places of the* $\Gamma(b_{j_0,p_e})$.

Dually, a cocircuit has floor one in the basis polynomial, and its bottom level gives its kernel.

Corollary 18.24 (A table that is one circuit)**.** *Let* $F = ((\mathcal{B},\theta);s,t)$ *with* $s,t > 0$, *where the bases of* $\mathcal{B}$ *are the sets* $\mathcal{E} - e$, $e\in\mathcal{E}$, *with the weights* θ_e; *let the masses lie on the balance wall,* $m_{\mathcal{E}} = (n-1)s + t$, *with* $m_S > s(|S|-1)$ *for every nonempty proper* S, *and put* $\nu_e = m_e - s$. *Then*

$$P_F(\mathbf{m};s,t) = \frac{\prod_e\theta_e^{-\nu_e}}{\Gamma(s)\Gamma(t)}\int_0^\infty y^{s-1}\prod_{e\in\mathcal{E}}\mathsf{G}_{\nu_e;(1,-1)}\big(1,\theta_e^2 y\big)\,dy$$

$$= \frac{\prod_e \theta_e^{-\nu_e}}{\Gamma(s)\Gamma(t)} \int_{\sum_e a_e = s} \prod_{e \in \mathcal{E}} \Gamma(a_e)\, \Gamma(a_e + \nu_e)\, \theta_e^{-2a_e} \, :$$

the cobasis polynomial $\Psi(\alpha) = \langle \theta, \alpha \rangle$ is linear on the whole set, which so carries its own kernel (Definition 18.22), and the fibre of the atom formula (Corollary 18.16), of dimension $n-1$, closes to one scale.

Chapter 19

Bunches of width one: pooling and cleaning

A bunch whose bases meet it on two levels only is seen by its room as one mark: the room reads the bunch through two ratios of polynomials on its marks, one for each Foreman polynomial, and the bunch is a table on its own marks and one more. A bunch of width one is read as a mark of its room, its shape integrated while its scale is kept, its walls glued, and its scale closed at a wall, at the gauge and on the totals of the bunch and the room. Cleaning, the repeated pooling of such bunches, is a move between period data and has one result.

19.1 Bunches of width one

Definition 19.1 (Parallel and series bunches)**.** A *parallel bunch* of a table (a parallel class) is a set of at least two marks, none a loop, no two of which lie in a common basis; a *series bunch* (a series class) is a set of at least two marks, none a coloop, every basis containing all but at most one of them. A bunch B of width $c(B) = r(B) - d(B)$ (Definition 7.12, Theorem 7.13) has its patterns on the $c(B)+1$ levels $d(B), \dots, r(B)$ (Theorem 12.7), and its room has the same width.

Definition 19.2 (Hinge values; their ratio)**.** Let a bunch B of a table $(\mathcal{B}, \theta)$ have width one, the weights factoring across B and its room R, $\theta_T = \theta'_{T\cap B}\,\theta''_{T\cap R}$, so that $\mathcal{B}|B$ and $\mathcal{B}/R$ carry θ' and $\mathcal{B}|R$ and $\mathcal{B}/B$ carry θ'' (Definition 7.5). The *hinge value of B by K* and its *hinge value by Ψ* are

$$\gamma_B^K = \frac{K_{\mathcal{B}|B}}{K_{\mathcal{B}/R}}, \qquad \gamma_B^\Psi = \frac{\Psi_{\mathcal{B}/R}}{\Psi_{\mathcal{B}|B}},$$

functions of α_B homogeneous of degree one, the values at which K and Ψ see the bunch replaced by one mark, and their *ratio*

$$\varrho_B = \frac{\gamma_B^\Psi}{\gamma_B^K} = \frac{\mathbf{E}_{\mathcal{B}/R}}{\mathbf{E}_{\mathcal{B}|B}},$$

the quotient of the even letters $\mathbf{E} = K\Psi$ (Definition 8.18) of the two tables on B, is homogeneous of degree zero, a function of the shape $u = \alpha_B/|\alpha_B|$ alone. The room has width one as well, and its hinge values are those of R as a bunch: $\gamma_R^K = K_{\mathcal{B}|R}/K_{\mathcal{B}/B}$, $\gamma_R^\Psi = \Psi_{\mathcal{B}/B}/\Psi_{\mathcal{B}|R}$ and $\varrho_R = \mathbf{E}_{\mathcal{B}/B}/\mathbf{E}_{\mathcal{B}|R}$. Statements about hinge values and their ratios are read at one fixed factorization. For table j of a family they are $\gamma_{j,B}^K$, $\gamma_{j,B}^\Psi$ and $\varrho_{j,B}$, each table with its own factorization.

Proposition 19.3 (Hinge values of parallel and series bunches)**.** *A parallel or series bunch has width at most one, and width zero exactly when it is a union of molecules. Let a parallel bunch B of width one have its weights factoring across B and R (Definition 19.2); then $\mathcal{B}/R$ has the single basis $\varnothing$, with the weight $\theta'_{\varnothing}$, and $\mathcal{B}|B$ the singletons, with the weights $\theta'_{\{e\}}$, and in this statement write $w_e = \theta'_{\{e\}}/\theta'_{\varnothing}$. So $K_{\mathcal{B}/R} = \theta'_{\varnothing}$, $K_{\mathcal{B}|B} = \theta'_{\varnothing} \sum_{e\in B} w_e\alpha_e$, $\Psi_{\mathcal{B}|B} = \theta'_{\varnothing}\, e_{|B|}(\alpha_B) \sum_{e\in B} w_e\alpha_e^{-1}$ and $\Psi_{\mathcal{B}/R} = \theta'_{\varnothing}\, e_{|B|}(\alpha_B)$, and*

$$\gamma_B^K = \sum_{e\in B} w_e\alpha_e, \qquad \gamma_B^\Psi = \Big(\sum_{e\in B} w_e\alpha_e^{-1}\Big)^{-1} :$$

K adds the marks of the class with the factors w_e and Ψ combines them as reciprocals with the same factors. A series bunch B of width one, its weights factoring, swaps the two roles: $\mathcal{B}|B$ has the single basis B, with the weight θ'_B, and $\mathcal{B}/R$ the sets $B-e$, with the weights θ'_{B-e}; with $w_e = \theta'_{B-e}/\theta'_B$, $K_{\mathcal{B}|B} = \theta'_B\, e_{|B|}(\alpha_B)$, $K_{\mathcal{B}/R} = \theta'_B\, e_{|B|}(\alpha_B) \sum_e w_e\alpha_e^{-1}$, $\Psi_{\mathcal{B}|B} = \theta'_B$ and $\Psi_{\mathcal{B}/R} = \theta'_B \sum_e w_e\alpha_e$, so $\gamma_B^\Psi = \sum_e w_e\alpha_e$ and $\gamma_B^K = \big(\sum_e w_e\alpha_e^{-1}\big)^{-1}$. In a list, the case used for cleaning (Definition 19.35 below), with the factorization $\theta' = \theta'' = 1$, every w_e is 1, and a pair with the shape $(x, 1-x)$ has $\varrho_B = x(1-x)$ when it is parallel and $\varrho_B = 1/(x(1-x))$ when it is in series.

Theorem 19.4 (A bunch of width one is one mark to its room)**.** *Let a bunch B of a table $(\mathcal{B},\theta)$ have width one, the weights factoring across B and R, $\theta_T = \theta'_{T\cap B}\,\theta''_{T\cap R}$, and let g be a new mark. The* cell of the bunch $\mathcal{B}_B^+$ *is the table on $B+g$ whose bases avoiding g are those of $\mathcal{B}|B$ and whose bases through g are the $X+g$, $X\in\mathcal{B}/R$, with the weights θ'; the* cell of the room $\mathcal{B}_R^+$ *is the table on $R+g$ whose bases avoiding g are those of $\mathcal{B}|R$ and whose bases through g are the $Y+g$, $Y\in\mathcal{B}/B$, with the weights θ''. Both are tables, lists when $(\mathcal{B},\theta)$ is one, in which g, the* hinge, *is neither a loop nor a coloop, and the bases of $\mathcal{B}$ are theirs glued along g with g on exactly one side:*

$$\mathcal{B} = \{X\sqcup Y:\ X\in\mathcal{B}|B,\ Y\in\mathcal{B}/B\}\ \sqcup\ \{X\sqcup Y:\ X\in\mathcal{B}/R,\ Y\in\mathcal{B}|R\}.$$

With the first argument of the polynomials of a cell the variable of its hinge and the hinge values of Definition 19.2,

$$K(\alpha) = K_{\mathcal{B}/R}(\alpha_B)\, K_{\mathcal{B}_R^+}\big(\gamma_B^K(\alpha_B),\alpha_R\big), \qquad \Psi(\alpha) = \Psi_{\mathcal{B}|B}(\alpha_B)\, \Psi_{\mathcal{B}_R^+}\big(\gamma_B^\Psi(\alpha_B),\alpha_R\big).$$

Conversely, if $K(\alpha) = \sum_{l=0}^k A_l(\alpha_B)\, C_l(\alpha_R)$ with every C_l homogeneous, then $c(B)\le k$; in particular $K(\alpha) = A(\alpha_B)\big(C_0(\alpha_R) + G(\alpha_B)\, C_1(\alpha_R)\big)$ with C_0 and C_1 homogeneous gives $c(B)\le 1$.

The deletions and the contractions of the hinge are the four minors $\mathcal{B}_B^+\setminus g = \mathcal{B}|B$ and $\mathcal{B}_B^+/g = \mathcal{B}/R$, $\mathcal{B}_R^+\setminus g = \mathcal{B}|R$ and $\mathcal{B}_R^+/g = \mathcal{B}/B$ of the table. So the hinge values of B are those of B in its own cell, and across a bunch of width one the bunch and the room see each other as one mark: the room reads the hinge at $\alpha_g = \gamma_B^K(\alpha_B)$ in K and at $\alpha_g = \gamma_B^\Psi(\alpha_B)$ in Ψ.

Corollary 19.5 (The scale of a bunch of width one is that of one mark)**.** *Along the scale of a bunch B of width one of a table whose weights factor across B and R, each Foreman polynomial has one Skeleton value, the room's hinge value over the bunch's:*

$$\operatorname{spec}_B^K(\alpha) = \Big\{\frac{\gamma_R^K(\alpha_R)}{\gamma_B^K(\alpha_B)}\Big\} = \Big\{\frac{K_{\mathcal{B}/R}(\alpha_B)\, K_{\mathcal{B}|R}(\alpha_R)}{K_{\mathcal{B}|B}(\alpha_B)\, K_{\mathcal{B}/B}(\alpha_R)}\Big\},$$
$$\operatorname{spec}_B^\Psi(\alpha) = \Big\{\frac{\gamma_R^\Psi(\alpha_R)}{\gamma_B^\Psi(\alpha_B)}\Big\} = \Big\{\frac{\Psi_{\mathcal{B}|B}(\alpha_B)\, \Psi_{\mathcal{B}/B}(\alpha_R)}{\Psi_{\mathcal{B}/R}(\alpha_B)\, \Psi_{\mathcal{B}|R}(\alpha_R)}\Big\},$$

the Skeleton value of the hinge as a one-mark bunch of the cell of the room (Corollary 15.4), read at $\alpha_g = \gamma_B^K(\alpha_B)$, respectively at $\alpha_g = \gamma_B^\Psi(\alpha_B)$. The value of K over that of Ψ is $\varrho_B(\alpha_B)/\varrho_R(\alpha_R)$, the even letters of the minors of the level $d(B)$ over those of the level $r(B)$, and their product is the same quotient of the odd letters.

Lemma 19.6 (One hinge value of any degree is width at most one)**.** *Let B be a bunch of a table $(\mathcal{B}, \theta)$ with the room R, and suppose that on the open orthant*

$$K(\alpha) = A(\alpha_B)\, P\big(\alpha_R, \gamma(\alpha_B)\big),$$

with A and γ positive functions of α_B, homogeneous, γ of degree one, and P a polynomial in α_R and one more variable with real coefficients, of any degree in that variable. Then $c(B) \le 1$. Conversely, when the weights factor across B and R and $c(B) \le 1$, K has this form: at width zero with P free of its last variable, and at width one with $A = K_{\mathcal{B}/R}$, $\gamma = \gamma_B^K$ and $P(\alpha_R, y) = K_{\mathcal{B}_R^+}(y, \alpha_R)$ (Theorem 19.4). The same holds for Ψ, the basis polynomial of the dual table, in which B has the same width.

Proposition 19.7 (The freedom of the factorization)**.** *Let a bunch B of a table $(\mathcal{B}, \theta)$ have width one, the weights factoring across B and R, $\theta_T = \theta'_{T\cap B}\, \theta''_{T\cap R}$. The factorization is fixed up to one positive constant on each of the two levels: multiplying θ' by λ_d on the patterns of the level $d(B)$ and by λ_r on those of the level $r(B)$, and dividing θ'' by λ_d and by λ_r on the room sides of the bases of these levels, multiplies the hinge values γ_B^K and γ_R^K by $c = \lambda_r/\lambda_d$, γ_B^Ψ and γ_R^Ψ by c^{-1}, and the ratios ϱ_B and ϱ_R by c^{-2} (Definition 19.2), and leaves γ_R^K/γ_B^K, $\gamma_R^\Psi/\gamma_B^\Psi$ and ϱ_B/ϱ_R unchanged. In a family each table has its own two constants.*

19.2 Pooling

Theorem 19.8 (Pooling integrates the shape and keeps the scale)**.** *Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$ be a family and B a bunch of width one in every table, the weights of every table factoring across B and R, and read $\alpha_B = \rho u$, $\rho > 0$, $u \in \Delta_B$ (Lemma 2.7). For $u \in \Delta_B$ the* pooled family *$F_{B\to g}(u)$ is the family on $R + g$ with, for every j, two tables with the bases of the cell of the room $\mathcal{B}_{j,R}^+$ (Theorem 19.4): the first with its weights multiplied by $\gamma_{j,B}^K(u)$ on its bases through g and the exponents $(s_j, 0)$, the second with its weights multiplied by $\gamma_{j,B}^\Psi(u)$ on its bases avoiding g and the exponents $(0, t_j)$. Its letters are $K_{\mathcal{B}_{j,R}^+}\big(\gamma_{j,B}^K(u)\alpha_g, \alpha_R\big)^{-s_j}$ and $\Psi_{\mathcal{B}_{j,R}^+}\big(\gamma_{j,B}^\Psi(u)\alpha_g, \alpha_R\big)^{-t_j}$; listing the N first tables and then the N second ones, its exponents are $(\mathbf{s}, \mathbf{0})$ and $(\mathbf{0}, \mathbf{t})$. To* pool *B is to pass from F to its pooled families $F_{B\to g}(u)$, keeping the letters $K_{\mathcal{B}_j/R}$ and $\Psi_{\mathcal{B}_j|B}$ of the shape of B, its cell kernel (Chapter 22), and the hinge values of every table. Give the hinge the mass κ_B, the wall of B. Then $F_{B\to g}(u)$ has the imbalance of F, and*

$$J_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \int_{\Delta_B} u^{\mathbf{m}|_B - \mathbf{1}} \prod_j K_{\mathcal{B}_j/R}(u)^{-s_j} \Psi_{\mathcal{B}_j|B}(u)^{-t_j} \times J_{F_{B\to g}(u)}\big((\kappa_B, \mathbf{m}|_R); (\mathbf{s}, \mathbf{0}), (\mathbf{0}, \mathbf{t})\big)\, d\omega_B(u),$$

both sides converging together; the same holds with P for J, on the balance wall as well.

The port (Theorem 15.15) integrates the scale and the shape of a bunch together; pooling integrates the shape of a bunch of width one and keeps its scale, which becomes the hinge of the room. For a list the pooled families again have weights that factor across every bunch of R and

across every bunch containing g, so poolings can be repeated. Proposition 18.3 is the same split with the scale integral left whole. Read backwards, pooling is gluing: the table is its cell of the bunch substituted into its cell of the room at the hinge (Proposition 21.3), and every cell of a substitution is pooled at once by Theorem 22.3.

19.3 Walls glue

Theorem 19.9 (Walls glue)**.** *Let a bunch B of a table $(\mathcal{B},\theta)$ have width one, the weights factoring across B and R, with the cells $\mathcal{B}_B^+$ and $\mathcal{B}_R^+$ of Theorem 19.4. For $S_B \subseteq B$ and $S_R \subseteq R$ the counts of the table glue from those of the cells, the hinge counted on exactly one side, as in the gluing of the bases:*

$$d(S_B \sqcup S_R) = \min\left\{d_{\mathcal{B}_B^+}(S_B+g) + d_{\mathcal{B}_R^+}(S_R),\ d_{\mathcal{B}_B^+}(S_B) + d_{\mathcal{B}_R^+}(S_R+g)\right\},$$
$$d^*(S_B \sqcup S_R) = \min\left\{d^*_{\mathcal{B}_B^+}(S_B+g) + d^*_{\mathcal{B}_R^+}(S_R),\ d^*_{\mathcal{B}_B^+}(S_B) + d^*_{\mathcal{B}_R^+}(S_R+g)\right\}.$$

For a family $F = ((\mathcal{B}_j,\theta_j);s_j,t_j)_{j=1}^N$ with masses $\mathbf{m}$, B having width one in every table and the weights of every table factoring across B and R:

(i) the walls of the pooled family $F_{B\to g}(u)$ at the masses $(\kappa_B,\mathbf{m}|_R)$ are walls of F: its wall at S_R is κ_{S_R} and its wall at S_R+g is $\kappa_{B\sqcup S_R}$;

(ii) the density $u^{\mathbf{m}|_B-\mathbf{1}}\prod_j K_{\mathcal{B}_j/R}(u)^{-s_j}\Psi_{\mathcal{B}_j|B}(u)^{-t_j}$ of the cell kernel of B has at the face $u_{S_B}=0$ of Δ_B the wall of F, $m_{S_B} - \sum_j \left(s_j\, d_{\mathcal{B}_j/R}(S_B) + t_j\, d^*_{\mathcal{B}_j|B}(S_B)\right) = \kappa_{S_B}$;

(iii) on the balance wall, with the cell families $G_B = ((\mathcal{B}_{j,B}^+,\theta_j');s_j,t_j)_j$ at the masses $(\mathbf{m}|_B, 2\sigma-\kappa_B)$ and $G_R = ((\mathcal{B}_{j,R}^+,\theta_j'');s_j,t_j)_j$ at the masses $(\kappa_B,\mathbf{m}|_R)$, σ the total strength, whose walls are written $\kappa_S^{G_B}$ and $\kappa_S^{G_R}$, both cell families lie on their balance walls and every wall of a cell family is a wall of F,

$$\kappa_{S_B}^{G_B} = \kappa_{S_B},\qquad \kappa_{S_B+g}^{G_B} = \kappa_{S_B\sqcup R},\qquad \kappa_{S_R}^{G_R} = \kappa_{S_R},\qquad \kappa_{S_R+g}^{G_R} = \kappa_{B\sqcup S_R};$$

if moreover $s_j,t_j\geq 0$ and every active letter reads B alike, its hinge value a constant multiple of one function γ on Δ_B, as when one letter is active, every wall of F is glued from walls of the cell families,

$$\kappa_{S_B\sqcup S_R} = \min\left\{\kappa_{S_B}^{G_B} + \kappa_{S_R}^{G_R},\ \kappa_{S_B+g}^{G_B} + \kappa_{S_R+g}^{G_R}\right\},$$

and F has every proper wall positive exactly when both cell families do.

19.4 Full leans

Theorem 19.10 (Pooling factors at one hinge value)**.** *Let $F = ((\mathcal{B}_j,\theta_j);s_j,t_j)_{j=1}^N$ have real exponents and be on the balance wall with every proper wall positive, and let a bunch B have width one in every table, the weights of every table factoring across B and R. Suppose that every active letter reads B alike, its hinge value a constant multiple of one function γ on Δ_B, the factorizations being chosen so that every constant is 1: every active letter has the one hinge value γ. (A change of the factorization of table j multiplies $\gamma_{j,B}^K$ by a positive constant and $\gamma_{j,B}^\Psi$ by its inverse (Proposition 19.7). So a table with one active letter can always be so normalized, and when every table is at a full lean the hypothesis is a condition across the tables alone; one table with both letters*

active can be so normalized exactly when ϱ_B is constant.) Then $0 < \kappa_B < 2\sigma$, σ the total strength (Definition 8.1), and, with the cell families $G_B = ((\mathcal{B}^+_{j,B}, \theta'_j); s_j, t_j)_j$ and $G_R = ((\mathcal{B}^+_{j,R}, \theta''_j); s_j, t_j)_j$,

$$\Gamma_{\!1}^{\,2}\begin{bmatrix}\kappa_B, & 2\sigma-\kappa_B\\ & 2\sigma\end{bmatrix} P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = P_{G_B}\big((\mathbf{m}|_B, 2\sigma-\kappa_B);\mathbf{s},\mathbf{t}\big)\, P_{G_R}\big((\kappa_B, \mathbf{m}|_R);\mathbf{s},\mathbf{t}\big),$$

both cell families on their balance walls with every proper wall positive. One table at the exponents $(0,t)$ or $(s,0)$ has one active letter, and then 2σ is t, respectively s.

When every active letter has one hinge value, as for one table at a full lean, where one letter is active, the hinge carries the mass κ_B in the room and $2\sigma - \kappa_B$ in the bunch, and the period of the family is the product of the periods of its two cell families divided by the Beta corner of the hinge.

Proposition 19.11 (Pooling a realization)**.** *Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$ be a family, B a bunch of width one in every table, the weights of every table factoring across B and R, and let $\Upsilon = ((s_j, t_j)_j; \alpha)$ be a realization of F with masses $\boldsymbol{\tau}$ (Definition 9.1); write $\alpha_B = \rho u$, $\rho > 0$, $u \in \Delta_B$ (Lemma 2.7), and read the two tables of index j of the pooled family $F_{B\to g}(u)$ of Theorem 19.8 as one table with two systems of weights at the exponents (s_j, t_j) (Definition 8.1). Then $((s_j, t_j)_j; (\rho, \alpha_R))$ is a realization of $F_{B\to g}(u)$, with the masses $\big(\tau_B - \sum_j (s_j d_j(B) + t_j d^*_j(B)),\ \boldsymbol{\tau}|_R\big)$, the first at the hinge: pooling sends a realization to a realization, and the mass of the hinge is the wall κ_B at the masses $\boldsymbol{\tau}$. With one table at the exponents $(0,t)$ the letter Ψ of $F_{B\to g}(u)$ at (ρ, α_R) is that of the cell of the room $(\mathcal{B}^+_R, \theta'')$ at $(\gamma^\Psi_B(\alpha_B), \alpha_R)$, and $((0,t); (\gamma^\Psi_B(\alpha_B), \alpha_R))$ is a realization of $(\mathcal{B}^+_R, \theta'')$ with the masses $(\tau_B - t\, d^*(B),\ \boldsymbol{\tau}|_R)$.*

Proposition 19.12 (Hinge values that agree)**.** *Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$ have real exponents and be on the balance wall with every proper wall positive, and let a bunch B have width one in every table, the weights of every table factoring across B and R. Suppose that every active letter reads B alike, its hinge value a constant multiple of one function γ on Δ_B: $\gamma^K_{j,B} = c_j\gamma$ whenever $s_j \neq 0$ and $\gamma^\Psi_{j,B} = c^*_j\gamma$ whenever $t_j \neq 0$, with constants $c_j, c^*_j > 0$; put $c_j = 1$ when $s_j = 0$ and $c^*_j = 1$ when $t_j = 0$. Let $G^{\mathbf{c}}_R$ be the pooled family of Theorem 19.8 with these constants in place of the hinge values: for every j the table $\mathcal{B}^+_{j,R}$ with its weights multiplied by c_j on its bases through g, at the exponents $(s_j, 0)$, and with its weights multiplied by c^*_j on its bases avoiding g, at the exponents $(0, t_j)$. Then*

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = P_{G^{\mathbf{c}}_R}\big((\kappa_B, \mathbf{m}|_R); (\mathbf{s},\mathbf{0}), (\mathbf{0},\mathbf{t})\big) \times \int_{\Delta_B} u^{\mathbf{m}|_B - \mathbf{1}} \prod_j K_{\mathcal{B}_j/R}(u)^{-s_j}\, \Psi_{\mathcal{B}_j|B}(u)^{-t_j}\, \gamma(u)^{-\kappa_B}\, d\omega_B(u) :$$

the shape and the room separate at every pair of exponents. For one table with ϱ_B constant, a factorization with $\varrho_B = 1$ (Proposition 19.7) gives $c = c^* = 1$ and $\gamma = \gamma^K_B$, and $G^{\mathbf{c}}_R$ is then $((\mathcal{B}^+_R, \theta''); s, t)$.

19.5 Partial leans

Theorem 19.13 (Gluing across a bunch of width one)**.** *Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$ have real data with $s_j, t_j \geq 0$, $s_j + t_j > 0$, and masses $\mathbf{m}$ on the balance wall with every proper wall positive, and let a bunch B have width one in every table, the weights factoring across B and R. In table j call*

$d_j(B)$ *the* level d *and* $r_j(B) = d_j(B) + 1$ *the* level r. Level shares $\mathbf{a} = (a_j^d, a_j^r)_j$ *and* $\mathbf{b} = (b_j^d, b_j^r)_j$ *split the exponents over the two levels,* $a_j^d + a_j^r = s_j$ *and* $b_j^d + b_j^r = t_j$, *a letter of exponent zero being opened by nothing, its two level shares* 0*; they are the shares of Definition 12.24 summed over the patterns of each level, and their pair shares (Definition 12.24) are the* even share $\sigma_j^\ell = \frac{1}{2}(a_j^\ell + b_j^\ell)$ *and the* odd share $\delta_j^\ell = \frac{1}{2}(a_j^\ell - b_j^\ell)$, $\ell \in \{d, r\}$. *The* bunch family *and the* room family *are*

$$F^{\text{bunch}}(\mathbf{a}, \mathbf{b}) = \big((\mathcal{B}_j/R;\, a_j^d, b_j^d),\ (\mathcal{B}_j|B;\, a_j^r, b_j^r)\big)_j \quad \text{on } B,$$
$$F^{\text{room}}(\mathbf{a}, \mathbf{b}) = \big((\mathcal{B}_j|R;\, a_j^d, b_j^d),\ (\mathcal{B}_j/B;\, a_j^r, b_j^r)\big)_j \quad \text{on } R:$$

each level carries one table of the bunch and one of the room, at the same shares. The scale of B *pins the shares of the minors it multiplies,*

$$\sum_j \big(a_j^r + b_j^d\big) = \kappa_B, \qquad \textit{equivalently} \qquad \sum_j \delta_j^d = \tfrac{1}{2}\Big(\sum_j s_j - \kappa_B\Big),$$

and, for pattern shares with these level sums, equivalently $\sum_{e\in B}\langle\boldsymbol{\delta}\rangle_e = \mu_B$, *the sum over the bunch of the pins* $\langle\boldsymbol{\delta}\rangle_e = \mu_e$ *of a wall contour (Definition 18.12). On this pin both families lie on their balance walls at* $\mathbf{m}|_B$ *and* $\mathbf{m}|_R$, *and on every contour on which the stacked Gammas below have arguments of positive real part and both periods converge absolutely,*

$$P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = 2^{N-1} \int_{\sum_j \delta_j^d = \frac{1}{2}(\sum_j s_j - \kappa_B)} \prod_j \Gamma_{\!\!\begin{smallmatrix}4\\2\end{smallmatrix}}\!\begin{bmatrix} a_j^d,\ b_j^d,\ a_j^r,\ b_j^r \\ s_j,\ t_j \end{bmatrix} \times P_{F^{\text{bunch}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_B; \mathbf{a}, \mathbf{b})\, P_{F^{\text{room}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_R; \mathbf{a}, \mathbf{b}),$$

the fibre integral (Definition 4.1) in the pair coordinates $(\sigma_j^d, \delta_j^d)_j$, *with* $\sigma_j^r = \sigma_j - \sigma_j^d$ *and* $\delta_j^r = \delta_j - \delta_j^d$*: its dimension is* $2N - 1$, *and its* N *even shares* σ_j^d *are free. This display needs every* s_j *and* t_j *positive; in general, with* p *the number of active letters,*

$$P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \int_{\sum_j (a_j^r + b_j^d) = \kappa_B} \prod_{s_j \neq 0} \Gamma_{\!\!\begin{smallmatrix}2\\1\end{smallmatrix}}\!\begin{bmatrix} a_j^d,\ a_j^r \\ s_j \end{bmatrix} \prod_{t_j \neq 0} \Gamma_{\!\!\begin{smallmatrix}2\\1\end{smallmatrix}}\!\begin{bmatrix} b_j^d,\ b_j^r \\ t_j \end{bmatrix} \times P_{F^{\text{bunch}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_B; \mathbf{a}, \mathbf{b})\, P_{F^{\text{room}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_R; \mathbf{a}, \mathbf{b}),$$

the share integral (Definition 4.1) over the shares a_j^r, $s_j \neq 0$, *and* b_j^d, $t_j \neq 0$, *of the minors that the scale of* B *multiplies, pinned by their sum* κ_B, *of dimension* $p - 1$*; with every exponent positive it is the display above, and at* $p = 1$ *it is the value at the one admissible point. For one table with* $s, t > 0$ *the odd share is fixed,* $2\delta^d = s - \kappa_B = \delta\,(1 + \varepsilon(B)) - \mu_B$, *and the even share alone is free: on a line* $\operatorname{Re}\sigma^d = \sigma_*^d$ *of such a contour,*

$$P_F(\mathbf{m}; s, t) = \frac{1}{2\pi i} \int_{\operatorname{Re}\sigma^d = \sigma_*^d} \Gamma_{\!\!\begin{smallmatrix}4\\2\end{smallmatrix}}\!\begin{bmatrix} a^d,\ b^d,\ a^r,\ b^r \\ s,\ t \end{bmatrix} P_{F^{\text{bunch}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_B; \mathbf{a}, \mathbf{b})\, P_{F^{\text{room}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_R; \mathbf{a}, \mathbf{b})\, d\sigma^d.$$

Swapping B *and* R *swaps the two levels and leaves the formula unchanged.*

The scale of the bunch is opened letter by letter, one share on each level of each letter; the scale integrates to the pin, and what is left is the form of the bunch family on its simplex times the form of the room family on its own. The level shares are the pattern shares of the port (Theorem 15.15) summed over each level: at width one the children of the level d are all $\mathcal{B}_j|R$ and those of the level

r all $\mathcal{B}_j/B$, up to constant factors of their weights (Theorem 12.19), so the room family is the children of the port with equal children merged. At the level shares $(a_j^d, b_j^d, a_j^r, b_j^r) = (s_j, 0, 0, t_j)$, on the wall $\kappa_B = 0$, the two families are the faces of Theorem 16.25. Left unopened on the room, as in Theorem 19.8, the shape enters the pooled family only through the hinge values of B by its letters, and a rescaling of the hinge variable absorbs one of them: the shares that separate the shape from the room are one fewer than the hinge values of B by the active letters counted up to constant factors, none when every active letter reads B alike (Proposition 19.12), as for one table at a full lean (Theorem 19.10).

Corollary 19.14 (One Skeleton value pins the share)**.** *Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$ have real exponents and be on the balance wall with every proper wall positive, and let a bunch B have width one in every table, the weights factoring across B and R. Suppose that every active letter reads B alike, its hinge value a constant multiple of one function γ on Δ_B, and reads R alike with the same constant, its hinge value of R that constant times one function γ_R on Δ_R: the active letters have the one Skeleton value $\gamma_R(v)/\gamma(u)$ on the scale of B at every gauge $(u, v) \in \Delta_B \times \Delta_R$ (Corollary 19.5). Then $0 < \kappa_B < 2\sigma$, σ the total strength, and for all level shares $(\mathbf{a}, \mathbf{b})$ of Theorem 19.13, those of the inactive letters 0, with $a_j^d + a_j^r = s_j$, $b_j^d + b_j^r = t_j$ and $\sum_j (a_j^r + b_j^d) = \kappa_B$,*

$$P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \Gamma_{\!\!\begin{smallmatrix}2\\1\end{smallmatrix}}\!\begin{bmatrix}\kappa_B, & 2\sigma - \kappa_B\\ & 2\sigma\end{bmatrix} P_{F^{\mathrm{bunch}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_B; \mathbf{a}, \mathbf{b})\, P_{F^{\mathrm{room}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_R; \mathbf{a}, \mathbf{b}),$$

the product of the two periods not depending on the level shares: the Beta corner of the hinge times the periods of the bunch family and the room family. One active letter has one Skeleton value: for one table at $(0, t)$, at the level shares $(a^d, b^d, a^r, b^r) = (0, \kappa_B, 0, t - \kappa_B)$, the two periods are those of the forms $u^{\mathbf{m}|_B - \mathbf{1}} \Psi_{\mathcal{B}/R}^{-\kappa_B} \Psi_{\mathcal{B}|B}^{-(t-\kappa_B)}$ on Δ_B and $v^{\mathbf{m}|_R - \mathbf{1}} \Psi_{\mathcal{B}|R}^{-\kappa_B} \Psi_{\mathcal{B}/B}^{-(t-\kappa_B)}$ on Δ_R, and at $(s, 0)$, at the level shares $(s - \kappa_B, 0, \kappa_B, 0)$, the same holds with the letters of K.

Lemma 19.15 (Slopes and the range of the ratios)**.** *In Theorem 19.13 with every s_j and t_j positive, the even share σ_j^d of table j enters the two families only through $\big(\varrho_{j,B}(u)/\varrho_{j,R}(v)\big)^{-\sigma_j^d}$, $(u, v) \in \Delta_B \times \Delta_R$, the ratio of the hinge values of the bunch over that of the room in table j (Definition 19.2). The wall at S of either family is affine in the shares, with the* slope *in σ_j^d the width of S in the table of the level d of table j less its width in the table of the level r of table j: with r_j^+ the rank function of the cell of table j on the side of S,*

$$\begin{aligned} &\big[r_j^+(S + g) - r_j^+(S)\big] + \big[r_j^+(B \setminus S + g) - r_j^+(B \setminus S)\big] - 1 \qquad (S \subseteq B),\\ &1 - \big[r_j^+(S + g) - r_j^+(S)\big] - \big[r_j^+(R \setminus S + g) - r_j^+(R \setminus S)\big] \qquad (S \subseteq R). \end{aligned}$$

$\sup_{\Delta_B} \varrho_{j,B} < \infty$ exactly when no slope of table j on B is positive and $\inf_{\Delta_B} \varrho_{j,B} > 0$ exactly when none on B is negative; $\inf_{\Delta_R} \varrho_{j,R} > 0$ exactly when no slope of table j on R is positive and $\sup_{\Delta_R} \varrho_{j,R} < \infty$ exactly when none on R is negative. So a wall of either family falls as σ_j^d moves toward the level d only if $\sup \varrho_{j,B} / \inf \varrho_{j,R} = \infty$, and as it moves toward the level r only if $\inf \varrho_{j,B} / \sup \varrho_{j,R} = 0$. These conditions, like the quotient $\varrho_{j,B}/\varrho_{j,R}$, do not depend on the factorization. For one table the index j is omitted.

A wall that falls as the even share moves toward the level being closed on is therefore the same thing as the two levels coming to overlap at that wall (Proposition 19.25): the quotient ϱ_B/ϱ_R of the even letters of the two levels, below one where the closing starts, is unbounded near the face where the wall sits.

19.6 Closing at a wall and closing at the gauge

A share between the levels of a letter can be closed in two places. *At the gauge* every letter is expanded about its value at a point of the scale; the terms are nonnegative and nothing is asked of the Skeleton values. That closing is Theorem 15.9, and it closes every letter on the scale at once. *At a wall* a letter is expanded about one of its two extreme coefficients, the other coefficients entering as integer powers; the terms then separate over the bunch and the room, and the expansion holds as far as the letters are separated along the scale. The closing at a wall holds for any number of letters and any width; across a bunch of width one it is a lattice of products of periods of the bunch family and the room family, and it stops where the values no longer stand in one order, which for one table is where the two levels overlap (Proposition 19.25).

Definition 19.16 (Letters on the scale)**.** Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^{N}$ have real masses and real exponents of either sign, let B be a proper bunch with room R, and read $\alpha_B = \rho u$ with $u \in \Delta_B$. At the gauge (u, α_R) the *letters on the scale* of B are the $2N$ polynomials in ρ

$$\rho^{-d_j(B)} K_j(\rho u, \alpha_R) = \sum_{l=0}^{c_j(B)} \rho^l \, K_{j,B}^{(d_j(B)+l)}(u, \alpha_R), \qquad \rho^{-d_j^*(B)} \Psi_j(\rho u, \alpha_R) = \sum_{l=0}^{c_j(B)} \rho^l \, \Psi_{j,B}^{(d_j^*(B)+l)}(u, \alpha_R),$$

with the letter exponents s_j and t_j: their coefficients are the level and colevel letters of Definition 12.16 counted from their floors, and divided by their values at $\rho = 1$ they are the Skeleton polynomials $\mathsf{Q}_{j,B}^{K}(\rho; (u, \alpha_R))$ and $\mathsf{Q}_{j,B}^{\Psi}(\rho; (u, \alpha_R))$ (Definition 12.10). Listed as $L_i(\rho) = \sum_{l=0}^{c_i} \rho^l L_i^{(l)}$, $i = 1, \dots, 2N$, with the letter exponent w_i and the width $c_i = c_j(B)$ of their table, every coefficient is positive (Theorem 12.7), a letter of width zero is constant, and the scale integral of Theorem 15.3 at the gauge (u, α_R) is

$$\mathrm{Sc}_B(u, \alpha_R; \mathbf{m}; \mathbf{s}, \mathbf{t}) = \int_0^\infty \rho^{\kappa_B - 1} \prod_i L_i(\rho)^{-w_i} \, d\rho,$$

convergent exactly when $0 < \kappa_B < \sum_i w_i c_i$, where $\sum_i w_i c_i = \kappa_B + \kappa_B^{\mathrm{top}}$.

Definition 19.17 (Letters read from an end of the scale; separated groups)**.** Fix $\lambda \in (0, 1)$. A letter $L(\rho) = \sum_{l=0}^{c} \rho^l L^{(l)}$ with positive coefficients is *read from the bottom up to a* when $\sum_{l \ge 1} a^l L^{(l)} \le \lambda \, L^{(0)}$, and *read from the top down to a* when $\sum_{l < c} a^l L^{(l)} \le \lambda \, a^c L^{(c)}$. A partition of the letters on the scale of B into *groups* $\mathcal{G}_1, \dots, \mathcal{G}_q$ is *separated* by the scales $0 < a_1 < \cdots < a_{q-1}$ when every letter of $\mathcal{G}_k$ is read from the bottom up to a_{k-1} (for $k \ge 2$) and from the top down to a_k (for $k \le q-1$); a letter whose exponent is a nonpositive integer is a polynomial factor of the integrand, may be put in any group, and nothing is asked of it. A group $\mathcal{G}$ has the product $f_{\mathcal{G}} = \prod_{i \in \mathcal{G}} L_i^{-w_i}$, the *scale degree* $w_{\mathcal{G}} = \sum_{i \in \mathcal{G}} w_i c_i$, and the *bottom* and *top coefficients* $\beta_{\mathcal{G},n}^{\downarrow}$ and $\beta_{\mathcal{G},n}^{\uparrow}$,

$$f_{\mathcal{G}}(\rho) = \sum_{n \ge 0} \beta_{\mathcal{G},n}^{\downarrow} \, \rho^n \quad (\rho \text{ small}), \qquad f_{\mathcal{G}}(\rho) = \rho^{-w_{\mathcal{G}}} \sum_{n \ge 0} \beta_{\mathcal{G},n}^{\uparrow} \, \rho^{-n} \quad (\rho \text{ large}).$$

Below the scale a a letter read from the bottom is its lowest coefficient up to the factor $1 + \lambda$, and above a a letter read from the top is its top term $\rho^c L^{(c)}$ up to the same factor. At width one, $L(\rho) = L^{(0)} + \rho L^{(1)}$ has the single Skeleton value $\xi = L^{(0)}/L^{(1)}$ (Corollary 19.5); it is read from the bottom up to a exactly when $a \le \lambda \xi$ and from the top down to a exactly when $a \ge \xi/\lambda$. So single letters of width one with the values $\xi_1, \dots, \xi_q$ are separated, by $a_k = \sqrt{\xi_k \xi_{k+1}}$, exactly when $\xi_k \le \lambda^2 \xi_{k+1}$ for every k: their values stand in one order with room between them.

Theorem 19.18 (The scale closes between separated groups)**.** *At the gauge (u, α_R) let the letters on the scale of B be separated into groups $\mathcal{G}_1, \dots, \mathcal{G}_q$, let $0 < \kappa < \sum_i w_i c_i$, and suppose $\kappa - \sum_{k' \le k} w_{\mathcal{G}_{k'}} \notin \mathbb{Z}$ for $1 \le k < q$. For $1 \le k \le q$ and $\mathbf{n} = (n_{k'})_{k' \ne k} \in \mathbb{N}^{q-1}$ put*

$$\nu_k(\mathbf{n}) = \kappa - \sum_{k'<k} \left(w_{\mathcal{G}_{k'}} + n_{k'} \right) + \sum_{k'>k} n_{k'}.$$

(i)

$$\int_0^\infty \rho^{\kappa-1} \prod_i L_i(\rho)^{-w_i} \, d\rho = \sum_{k=1}^{q} \sum_{\mathbf{n}} \prod_{k'<k} \beta^{\uparrow}_{\mathcal{G}_{k'}, n_{k'}} \prod_{k'>k} \beta^{\downarrow}_{\mathcal{G}_{k'}, n_{k'}} \ \mathrm{Reg} \int_0^\infty \rho^{\nu_k(\mathbf{n})-1} f_{\mathcal{G}_k}(\rho) \, d\rho;$$

at $\kappa = \kappa_B$ the left side is $\mathrm{Sc}_B(u, \alpha_R; \mathbf{m}; \mathbf{s}, \mathbf{t})$.

(ii) The series converges absolutely, and the sum of the absolute values of its terms is at most C times the left side, where C depends only on λ, the letter exponents, the widths, κ and the distances of the numbers $\kappa - \sum_{k' \le k} w_{\mathcal{G}_{k'}}$ from $\mathbb{Z}$.

(iii) $\beta^{\downarrow}_{\mathcal{G},n} = \prod_{i \in \mathcal{G}} \left(L_i^{(0)} \right)^{-w_i} [\rho^n] \prod_{i \in \mathcal{G}} \left(1 + \sum_{l \ge 1} \rho^l L_i^{(l)} / L_i^{(0)} \right)^{-w_i}$: the bottom coefficients of a group are the integrand of Theorem 16.25 for the residue at $\kappa_B = -n$, taken for the letters of the group alone; the top coefficients are the same with the coefficients $L_i^{(c_i)}$ in place of $L_i^{(0)}$, for the residue at $\kappa_B^{\mathrm{top}} = -n$.

Each group in turn keeps the scale. The groups that lie above it on the scale are read from the bottom, the groups below it from the top, and what is left to integrate is the keeping group alone, at an index shifted by the integers of the others, and as a finite part when that index has left the interval $(0, w_{\mathcal{G}})$ in which the group's own integral converges. The coefficients are the wall residues the family already has: for each letter read, a power of its extreme coefficient times a polynomial in its other coefficients. Every coefficient of K_j is a sum of the pattern terms $u^p K_{j,(p)}(\alpha_R)$ and every coefficient of Ψ_j of the terms $u^{B \setminus p} \Psi_{j,(p)}(\alpha_R)$, so the children enter with their pattern index, as in the record of a peel (Definition 14.2).

Corollary 19.19 (Two groups: the walls of one against the continuation of the other)**.** *Let the letters be separated into a lower group $\mathcal{L}$ and an upper group $\mathcal{U}$, with $0 < \kappa < \sum_i w_i c_i$ and $\kappa - w_{\mathcal{L}} \notin \mathbb{Z}$. Then*

$$\int_0^\infty \rho^{\kappa-1} f_{\mathcal{L}} f_{\mathcal{U}} \, d\rho = \sum_{n \ge 0} \beta^{\downarrow}_{\mathcal{U},n} \, \mathrm{Reg} \int_0^\infty \rho^{\kappa+n-1} f_{\mathcal{L}} \, d\rho + \sum_{n \ge 0} \beta^{\uparrow}_{\mathcal{L},n} \, \mathrm{Reg} \int_0^\infty \rho^{\kappa - w_{\mathcal{L}} - n - 1} f_{\mathcal{U}} \, d\rho.$$

For any group, $\mathrm{Reg} \int_0^\infty \rho^{\nu-1} f_{\mathcal{G}} \, d\rho$ is the value at ν of a meromorphic function, and at a pole of that function its constant term there (Theorem 1.7); the poles are at most simple and lie among the points $\nu = -n$, of residue $\beta^{\downarrow}_{\mathcal{G},n}$, and $\nu = w_{\mathcal{G}} + n$, of residue $-\beta^{\uparrow}_{\mathcal{G},n}$, $n \in \mathbb{N}$; the two families of points meet only when $w_{\mathcal{G}} \in -\mathbb{N}$, and at a common point the two residues add.

The scale integral of a product closes on the walls of each factor. The residues of the upper group at the wall of B are paired with the scale integral of the lower group continued past its top, and the residues of the lower group at the top wall with the scale integral of the upper group continued past its bottom. No bound on a moved contour is used: both expansions hold on the stretch of the scale between the groups, and the scale is divided there.

Theorem 19.20 (Joint closing across a bunch of width one)**.** *Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^{N}$ have real data, its masses on the balance wall with $P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$ convergent, and let a bunch B have width at most one in every table, the weights factoring across B and R. A table in which B has width zero is the direct sum of its restrictions to B and to R (Proposition 7.9); its two letters on the scale are constants, and it enters the bunch family and the room family of Theorem 19.13 as those restrictions with its own exponents. For the N' tables in which B has width one the letters on the scale (Definition 19.16) are, on $\Delta_B \times \Delta_R$,*

$$K_{\mathcal{B}_j/R}(u)K_{\mathcal{B}_j|R}(v) + \rho\, K_{\mathcal{B}_j|B}(u)K_{\mathcal{B}_j/B}(v), \qquad \Psi_{\mathcal{B}_j|B}(u)\Psi_{\mathcal{B}_j/B}(v) + \rho\, \Psi_{\mathcal{B}_j/R}(u)\Psi_{\mathcal{B}_j|R}(v),$$

of the letter exponents s_j and t_j, with the Skeleton values of Corollary 19.5; in each the coefficient multiplying ρ is its scale coefficient*, the level letter of the level r for K_j and the colevel letter of the level d for Ψ_j, and the other its* constant coefficient*. Suppose the $2N'$ letters can be listed as $\ell = 1, \dots, 2N'$, with letter exponents w_ℓ and Skeleton values ξ_ℓ, so that for some $\vartheta < 1$*

$$\xi_\ell \le \vartheta\, \xi_{\ell+1} \quad \text{on } \Delta_B \times \Delta_R \qquad (1 \le \ell < 2N'),$$

and that $\kappa_B - \sum_{\ell' \le \ell} w_{\ell'} \notin \mathbb{Z}$ for $1 \le \ell < 2N'$. For a letter i and $\mathbf{n} = (n_\ell)_{\ell \ne i} \in \mathbb{N}^{2N'-1}$ put $\nu_i(\mathbf{n}) = \kappa_B - \sum_{\ell<i}(w_\ell + n_\ell) + \sum_{\ell>i} n_\ell$, and let $(\mathbf{a}, \mathbf{b})_{i,\mathbf{n}}$ be the level shares in which

- *a letter $\ell < i$ has its constant coefficient at $-n_\ell$ and its scale coefficient at $w_\ell + n_\ell$,*
- *a letter $\ell > i$ has its scale coefficient at $-n_\ell$ and its constant coefficient at $w_\ell + n_\ell$,*
- *the letter i has its scale coefficient at $\nu_i(\mathbf{n})$ and its constant coefficient at $w_i - \nu_i(\mathbf{n})$.*

Then:

(i) at every $(\mathbf{a}, \mathbf{b})_{i,\mathbf{n}}$ the bunch family and the room family lie on their balance walls and their periods converge;

(ii) with both periods at $(\mathbf{a}, \mathbf{b}) = (\mathbf{a}, \mathbf{b})_{i,\mathbf{n}}$,

$$P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \sum_{i=1}^{2N'} \sum_{\mathbf{n} \in \mathbb{N}^{2N'-1}} \prod_{\ell \ne i} \frac{(-1)^{n_\ell}(w_\ell)_{n_\ell}}{n_\ell!}\, \Gamma^{\,2}_{\,1}\!\begin{bmatrix} \nu_i(\mathbf{n}),\ w_i - \nu_i(\mathbf{n}) \\ w_i \end{bmatrix} \times P_{F^{\mathrm{bunch}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_B; \mathbf{a}, \mathbf{b})\, P_{F^{\mathrm{room}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_R; \mathbf{a}, \mathbf{b}),$$

where the stacked Gamma is 0 when $w_i \in -\mathbb{N}$; when no letter exponent lies in $-\mathbb{N}$ the coefficient is $\prod_{\ell \ne i} \frac{(-1)^{n_\ell}}{n_\ell!}\, \Gamma^{\,2N'+1}_{\,2N'}\!\begin{bmatrix} (w_\ell + n_\ell)_{\ell \ne i},\ \nu_i(\mathbf{n}),\ w_i - \nu_i(\mathbf{n}) \\ (w_\ell)_\ell \end{bmatrix}$;

(iii) the series converges absolutely, the absolute values of all its terms add up to at most $C\, P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$, and those with $|\mathbf{n}| = M$ to at most $C'(1+M)^D \vartheta^M\, P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$, where C, C' and D depend only on ϑ, the exponents and κ_B.

The $2N'$ Skeleton values stand in one order on the whole shape domain, and each letter in turn keeps the scale. A letter whose value lies below the keeper's is read from the top of the scale, so its constant coefficient is opened; a letter whose value lies above is read from the bottom, so its scale coefficient is opened: each letter opens the one of its two terms that is the smaller at the keeper's place on the scale. An opened coefficient sits at the share $-n$, which puts the n-th power of that coefficient into the forms of the two families, a moment; the keeper carries the Beta corner $\Gamma^{\,2}_{\,1}\!\left[\begin{smallmatrix} \nu,\ w-\nu \\ w \end{smallmatrix}\right]$ of a linear letter (Proposition 15.1 with one coefficient), continued when ν

has left $(0, w)$. So closing across the bunch pairs moments of the bunch family with moments of the room family on $2N'$ lattices of dimension $2N'-1$, the free shares of Theorem 19.13 closed at once. Nothing is asked of the walls of the two families, (i) being a conclusion, and nothing uniform in $\mathbf{n}$ is needed beyond (iii), which bounds the whole lattice by the period itself.

The values are quotients of hinge values, the room's over the bunch's by each letter (Corollary 19.5). The value of K_j over that of Ψ_j is $\varrho_{j,B}(u)/\varrho_{j,R}(v)$, the even letters of its two levels, and their product is the corresponding quotient of the odd letters: the two values of a table sit on either side of the geometric mean set by its odd letters, at the distance set by its even letters. The N' quotients of even letters and the $N'-1$ quotients of the products of one table by those of another are what the N' even shares and the $N'-1$ free odd shares of Theorem 19.13 carry; for one table only ϱ_B/ϱ_R is left.

Corollary 19.21 (Closing the even share)**.** *For one table in Theorem 19.13 let $f(\sigma^d)$ be the integrand of its one-table display.*

(i) If $\sup_{\Delta_B}\varrho_B < \inf_{\Delta_R}\varrho_R$, then $P_F(\mathbf{m};s,t) = \sum \operatorname{Res} f$ over the poles of the Gamma pair $\Gamma(a^d)\Gamma(b^d)$ of the level d, at $\sigma^d=\delta^d-n$ and $\sigma^d=-\delta^d-n$, $n\in\mathbb{N}$, the n-th terms of the size $n^{s+t-2}\big(\sup\varrho_B/\inf\varrho_R\big)^n$; every period at these points converges, and when $2\delta^d\notin\mathbb{Z}$ the n-th terms are at most $C(1+n)^D\big(\sup\varrho_B/\inf\varrho_R\big)^n P_F(\mathbf{m};s,t)$, with C and D depending only on that ratio, the exponents and κ_B (Theorem 19.20(i),(iii) with one table, its letters listed as K, then Ψ). If $\inf_{\Delta_B}\varrho_B > \sup_{\Delta_R}\varrho_R$, then $P_F(\mathbf{m};s,t) = -\sum\operatorname{Res} f$ over the poles of the Gamma pair of the level r, at $\sigma^r=\pm\delta^r-n$. The share closes toward the level whose even letter is the smaller.

(ii) At $\sigma^d=\delta^d-n$ the level shares are $(a^d,b^d,a^r,b^r)=(2\delta^d-n,\,-n,\,s-2\delta^d+n,\,t+n)$, and the residue is

$$\frac{(-1)^n}{n!}\Gamma^{\,3}_{\,2}\!\left[\begin{matrix}2\delta^d-n,\ s-2\delta^d+n,\ t+n\\ s,\ t\end{matrix}\right] P_{F^{\mathrm{bunch}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_B;\mathbf{a},\mathbf{b})\,P_{F^{\mathrm{room}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_R;\mathbf{a},\mathbf{b}),$$

where $P_{F^{\mathrm{bunch}}(\mathbf{a},\mathbf{b})} = \int_{\Delta_B} u^{\mathbf{m}|_B-\mathbf{1}} K_{\mathcal{B}/R}^{-2\delta^d} K_{\mathcal{B}|B}^{-(s-2\delta^d)} \Psi_{\mathcal{B}|B}^{-t}\,\varrho_B^n\,d\omega_B$ is the n-th moment of ϱ_B against a form that does not depend on n, and $P_{F^{\mathrm{room}}(\mathbf{a},\mathbf{b})}$ likewise the n-th moment of ϱ_R^{-1}. At $\sigma^d=-\delta^d-n$ the level shares are $(-n,\,-2\delta^d-n,\,s+n,\,t+2\delta^d+n)$, and the same holds with the form $\Psi_{\mathcal{B}/R}^{2\delta^d}K_{\mathcal{B}|B}^{-s}\Psi_{\mathcal{B}|B}^{-t-2\delta^d}$ on B and its counterpart on R. Closing pairs the moments of the ratios ϱ_B and ϱ_R of the bunch and of the room. The two lattices of a level meet exactly when $2\delta^\ell\in\mathbb{Z}$, at the centre exactly when $\mu_B\in\mathbb{Z}$. At a common point, where $\Gamma(a^d)$ sits at $-k$ and $\Gamma(b^d)$ at $-n$, the pole is double: with $h=\Gamma^{\,2}_{\,2}\!\left[\begin{matrix}s+k,\ t+n\\ s,\ t\end{matrix}\right] P_{F^{\mathrm{bunch}}(\mathbf{a},\mathbf{b})}P_{F^{\mathrm{room}}(\mathbf{a},\mathbf{b})}$,

$$\operatorname{Res} f = \frac{(-1)^{n+k}}{n!\,k!}\,h\,\Big((\log\Gamma)'(n+1)-(\log\Gamma)'(t+n)+(\log\Gamma)'(k+1)-(\log\Gamma)'(s+k) \\ +\partial_{\sigma^d}\log\big(P_{F^{\mathrm{bunch}}(\mathbf{a},\mathbf{b})}P_{F^{\mathrm{room}}(\mathbf{a},\mathbf{b})}\big)\Big).$$

At integer exponents the two differences of $(\log\Gamma)'$ are heads, finite sums of reciprocals (Proposition 5.13), and $(\log\Gamma)'(j+1)=-(\mathsf{T}_{1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((j,\infty))$ for $j\in\mathbb{N}$ (Proposition 5.14).

Closed on a lattice, the even share writes the period as a row over finitely many data of the room whenever the room's periods along the lattice satisfy a recurrence of finite order: the room's initial periods, and at a meeting of the two lattices their derivatives, against sums along the lattice of the bunch's data and the room's fundamental solutions (Proposition 43.10).

Off resonance every pole is simple and the closed value is a sum over two lattices of products of moments of the two ratios ϱ_B and ϱ_R, with stacked Gamma coefficients: no heads. Each lattice's series has a pole where the two lattices of the level meet, from $\Gamma(2\delta^d - n)$ and $\Gamma(-2\delta^d - n)$, and their sum tends to the double-pole residues of (ii); the heads at the centre are this meeting. When the ranges of the even letters of the two levels overlap, the quotient $\varrho_B(u)/\varrho_R(v)$ taking values on both sides of 1, neither closing of (i) applies; the residues of a family at one of its walls are those of Theorem 16.25, periods of the family's faces.

Corollary 19.22 (Joint closing, nested)**.** *In Theorem 19.20 let B' be a bunch of the bunch family, of width at most one in each of its tables, with factoring weights, and let the letters of the bunch family on the scale of B' have their Skeleton values in one order with a ratio $\vartheta' < 1$. Then at every $(\mathbf{a},\mathbf{b})_{i,\mathbf{n}}$ at which the non-integrality condition of Theorem 19.20 holds for the bunch family at B', $P_{F^{\mathrm{bunch}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_B;\mathbf{a},\mathbf{b})$ is given by Theorem 19.20 for the family $F^{\mathrm{bunch}}(\mathbf{a},\mathbf{b})$ at B'; likewise for the room family at a bunch of R. Continuing down a tree of splits of width one, each node splitting its family at a bunch of width one into the bunch family and the room family, with the values ordered at every node, $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ is a nested lattice sum of stacked Gammas and of the periods of the families at the leaves, each leaf at exponents shifted by the integers of the lattices above it. The sum is taken from the leaves up, and at each node it converges absolutely at that node's own root rate.*

The tree of the nesting is a tree of splits of width one and not the Foreman tree of Definition 14.4: a node may be any bunch of width one at which the values are ordered. At a lattice point of the node above, a letter of the family below sits at an exponent $-n$ or $w+n$; the letters below are the same letters at shifted powers, and the next split applies to them because whether the values are in one order is read off the tables. Nothing uniform in the outer integers is used: at each lattice point the inner sum is an identity. The constant C of Theorem 19.20(iii) at an inner node depends on the exponents there and grows at most geometrically in the outer integers; that matters only for summing in another order. The multiple series converges absolutely when the outer ratio ϑ beats that growth, and otherwise the sum is the iterated one.

Proposition 19.23 (Values in one order without room)**.** *In Theorem 19.20 let $\xi_\ell < \xi_{\ell+1}$ on $\Delta_B \times \Delta_R$ for every ℓ, with no $\vartheta < 1$. For $0 < \zeta < 1$ let $P^{(\zeta)}$ be the integral obtained from $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ by multiplying the constant coefficient of the ℓ-th letter by $\zeta^{-\ell}$; it is the period of the family in which K_j and Ψ_j are read from two copies of table j whose level weights are scaled accordingly. Then every period of Theorem 19.20(i) converges, and with $A_{i,\mathbf{n}}$ the term of index $(i,\mathbf{n})$ of the series of Theorem 19.20(ii) and $x_i = \sum_{\ell>i} \ell w_\ell + i\sum_{\ell\le i} w_\ell - i\kappa_B$,*

$$P^{(\zeta)} = \sum_{i,\mathbf{n}} \zeta^{\,x_i + \sum_\ell |\ell - i|\, n_\ell} A_{i,\mathbf{n}} \quad \textit{absolutely}, \qquad P^{(\zeta)} \to P_F(\mathbf{m};\mathbf{s},\mathbf{t}) \ \ (\zeta \uparrow 1).$$

So the lattice sum of Theorem 19.20(ii) is summable to the period by scaling the level weights, and equals the period whenever it converges absolutely.

Proposition 19.24 (The same shares closed at the gauge)**.** *Let $F = ((\mathcal{B}_j,\theta_j);s_j,t_j)_{j=1}^N$ have complex exponents and masses $\mathbf{m}$ and let a bunch B have width one in every table, the weights factoring across B and R, with $\operatorname{Re}\kappa_B > 0$ and $\operatorname{Re}\kappa_B^{\mathrm{top}} > 0$. Write the Skeleton polynomials at the gauge $(u,v) \in \Delta_B \times \Delta_R$ as*

$$\mathsf{Q}^K_{j,B}\big(x;(u,v)\big) = \pi_{j,d} + \pi_{j,r}\,x, \qquad \mathsf{Q}^\Psi_{j,B}\big(x;(u,v)\big) = \pi^*_{j,r} + \pi^*_{j,d}\,x,$$

the chances of the two levels under the basis law and the cobasis law at (u,v), each the sum over its level of the pattern probabilities of Definition 12.25. Then, with $M=|\mathbf{n}|+|\mathbf{n}'|$,

$$\mathrm{Sc}_B(u,v;\mathbf{m};\mathbf{s},\mathbf{t}) = \prod_j K_j(u,v)^{-s_j}\Psi_j(u,v)^{-t_j} \sum_{\mathbf{n},\mathbf{n}'\in\mathbb{N}^N} \prod_j \frac{(s_j)_{n_j}(t_j)_{n'_j}}{n_j!\,n'_j!} \\ \times \Big(\prod_j \pi_{j,r}^{n_j}\pi_{j,d}^{*\,n'_j}\ \Gamma_{\,1}^{\,2}\begin{bmatrix}\kappa_B,\ M+1\\ \kappa_B+M+1\end{bmatrix} + \prod_j \pi_{j,d}^{n_j}\pi_{j,r}^{*\,n'_j}\ \Gamma_{\,1}^{\,2}\begin{bmatrix}\kappa_B^{\mathrm{top}},\ M+1\\ \kappa_B^{\mathrm{top}}+M+1\end{bmatrix}\Big),$$

a series converging absolutely, of nonnegative terms when the data are real with $s_j,t_j\ge 0$, whatever the order of the Skeleton values: it is Theorem 15.9 at width one, whose exceedance polynomials are the constants $\pi_{j,r}$, $\pi^*_{j,d}$ on the bunch and $\pi_{j,d}$, $\pi^*_{j,r}$ on the room. Without the prefactor the terms with M fixed add up in absolute value to at most $\frac{(\sum_j(|s_j|+|t_j|))_M}{M!}\big(\lambda_B^M/\operatorname{Re}\kappa_B+\lambda_R^M/\operatorname{Re}\kappa_B^{\mathrm{top}}\big)$, with $\lambda_B=\max_j(\pi_{j,r},\pi^*_{j,d})<1$ and $\lambda_R=\max_j(\pi_{j,d},\pi^*_{j,r})<1$.

At the gauge every letter is closed about its value at one point of the scale, both levels together. The lattice has one index for each letter, and what is raised to the powers are the chances of the levels at that point. Nothing is asked of the order of the values, and the root rate is the largest chance of a level. The price is that the closed letters $K_j(u,v)$ and $\Psi_j(u,v)$ stay in front, so the terms do not separate over the bunch and the room; integrated over the shapes on their ordering sectors the same closing is Corollary 15.11, with Theorem 15.14 past the walls.

Proposition 19.25 (Overlapping levels)**.** *In Theorem 19.13 with one table let $s,t>0$ and $2\delta^d = s-\kappa_B\notin\mathbb{Z}$, and let $\mathcal{M}(x)$ be the integral over $\Delta_B\times\Delta_R$ of*

$$u^{\mathbf{m}|_B-\mathbf{1}}v^{\mathbf{m}|_R-\mathbf{1}}\big(K_{\mathcal{B}/R}(u)K_{\mathcal{B}|R}(v)\big)^{\kappa_B-s}\big(K_{\mathcal{B}|B}(u)K_{\mathcal{B}/B}(v)\big)^{-\kappa_B}\big(\Psi_{\mathcal{B}|B}(u)\Psi_{\mathcal{B}/B}(v)\big)^{-t}\Big(\frac{\varrho_B(u)}{\varrho_R(v)}\Big)^x.$$

The terms of the two lattices of the level d in Corollary 19.21(ii) are $A_n=a_n\mathcal{M}(n)$ and $A'_n=a'_n\mathcal{M}(n+2\delta^d)$, with

$$a_n = \Gamma_{\,2}^{\,2}\begin{bmatrix}2\delta^d,\ 1-2\delta^d\\ s,\ t\end{bmatrix}\Gamma_{\,2}^{\,2}\begin{bmatrix}t+n,\ \kappa_B+n\\ 1+n,\ 1-2\delta^d+n\end{bmatrix},$$
$$a'_n = -\Gamma_{\,2}^{\,2}\begin{bmatrix}2\delta^d,\ 1-2\delta^d\\ s,\ t\end{bmatrix}\Gamma_{\,2}^{\,2}\begin{bmatrix}s+n,\ t+2\delta^d+n\\ 1+n,\ 1+2\delta^d+n\end{bmatrix}.$$

Suppose these integrals converge for every n. If $\varrho_B(u)>\varrho_R(v)$ on a set of positive measure, then $|A_n+A'_n|\to\infty$; likewise for the level r if $\varrho_B(u)<\varrho_R(v)$ on a set of positive measure. So when the two levels overlap*, both sets having positive measure, the lattices of neither level sum to the period by convergent periods.*

The two lattices of a level have opposite signs and coefficients whose ratio tends to -1. When $\sup\varrho_B<\inf\varrho_R$ each of them converges by itself. When $\varrho_B(u)<\varrho_R(v)$ throughout with $\sup\varrho_B=\inf\varrho_R$ neither need converge; the moments at n and at $n+2\delta^d$ then agree to leading order, so the two lattices cancel to that order, and Proposition 19.23 sums them to the period by scaling the level weights. Past that, the two lattices part and the series diverges. By Lemma 19.15 the overlap reaches a wall when ϱ_B/ϱ_R is unbounded, and then the periods themselves stop converging along the lattice. An overlap is closed on the totals of the bunch and the room (Section 19.7), and, read in one scale, on the lattice of continued periods of a level whenever the reach of the bunch on its side lies below the decay of the other (Theorem 20.39).

Proposition 19.26 (Between groups at the wall, inside a group at the gauge)**.** *In Theorem 19.18 fix a group $\mathcal{G}$, an index ν with $\nu \notin -\mathbb{N}$ and $\nu - w_{\mathcal{G}} \notin \mathbb{N}$, and a point ρ_0 of the scale. For the letter i of K_j in $\mathcal{G}$ put $\mathsf{Q}_i = \mathsf{Q}^K_{j,B}(\cdot;(\rho_0 u, \alpha_R))$ and $\mathsf{Q}_i^\top = \mathsf{Q}^K_{j,R}(\cdot;(\rho_0 u, \alpha_R))$, and for that of Ψ_j the same with Ψ; then $\mathsf{Q}_i(x) = L_i(x\rho_0)/L_i(\rho_0)$ and $\mathsf{Q}_i^\top(x) = x^{c_i}\mathsf{Q}_i(1/x)$ (Proposition 12.11(i),(ii)), and*

$$\operatorname{Reg}\int_0^\infty \rho^{\nu-1} f_{\mathcal{G}}(\rho)\,d\rho = \rho_0^\nu f_{\mathcal{G}}(\rho_0)\Big(\operatorname{Reg}\int_0^1 x^{\nu-1}\prod_{i\in\mathcal{G}}\mathsf{Q}_i(x)^{-w_i}dx + \operatorname{Reg}\int_0^1 x^{w_{\mathcal{G}}-\nu-1}\prod_{i\in\mathcal{G}}\mathsf{Q}_i^\top(x)^{-w_i}dx\Big).$$

Each of the two finite parts is the series of Theorem 15.9(ii) for these polynomials, absolutely convergent, with its Beta corners continued as in Theorem 15.14. So for every separated partition every share of the scale is closed: between the groups on the lattices of Theorem 19.18, inside a group at the gauge. With one group this is Theorem 15.9; with single letters of width one in one order it is Theorem 19.20.

A group that cannot be split, because the values of its letters do not stand in one order, is kept as one Breta of one bunch (Proposition 15.1); it is closed about a point of the scale, where no order is needed, and the letters outside it are closed about its ends. The two closings do not compete: the wall closing does as much as the scale separates, and the gauge closing does the rest. When its index lies in $(0, w_{\mathcal{G}})$ and its letter exponents are nonnegative, a group read on the totals of the bunch and the room closes about constant references, its terms pairing the bunch with the room at width one (Section 19.7).

19.7 The scale on the totals

The scale of a bunch is the quotient of two totals, that of the bunch and that of the room, and the two totals lie on the simplex $\Delta_{\{B,R\}}$ of the two blocks (Theorem 3.12). Read there, a letter on the scale is homogeneous in the totals, with its level or colevel letters as coefficients. At width one it is linear, with its constant coefficient at one vertex of the simplex and its scale coefficient at the other, and its Skeleton value is the point of the scale where its two terms are equal. The free shares of Theorem 19.13 are the share side of this integral over the totals, the pin being the shape integral over the totals (Theorem 3.9), and the lattices of Section 19.6 close them. The integral over the totals can also be closed as it stands. On the simplex a linear letter is at most the larger of its two coefficients, whatever their ratio, so it closes about a constant reference with nonnegative terms, which pair moments of the bunch with moments of the room. No order of the values is asked, and the overlap that stops the lattices of a level (Proposition 19.25) is not seen.

Definition 19.27 (The totals and their letters)**.** The *totals* of a bunch B and its room R are the point $x = (x_B, x_R)$ of the shape simplex $\Delta_{\{B,R\}}$ of the two blocks. Let $\mathbf{m}^{\mathrm{tot}} = (m_B^{\mathrm{tot}}, m_R^{\mathrm{tot}})$ have positive entries, let ϕ be a nonnegative measure on $\Delta_B \times \Delta_R$, and let finitely many *letters on the totals*

$$\widehat{L}_i(x) = \sum_{l=0}^{c_i} x_B^{\,l}\, x_R^{\,c_i-l} L_i^{(l)}, \qquad i = 1, \dots, q,$$

with letter exponents $w_i \in \mathbb{R}$, have coefficients $L_i^{(l)} \geq 0$ that are measurable functions of the shapes $(u, v) \in \Delta_B \times \Delta_R$, each letter positive on the interior of $\Delta_{\{B,R\}}$ at ϕ-almost every shape. The

integral over the totals at the shapes (u, v) is the inner integral below, over $\Delta_{\{B,R\}}$, and its integral against ϕ is the Trailmoment on the source $\Delta_{\{B,R\}} \times \Delta_B \times \Delta_R$ (Definition 5.1) with the coefficient function $(x, u, v) \mapsto (\widehat{L}_i(x))_i$ and the input $x^{\mathbf{m}^{\mathrm{tot}}-\mathbf{1}} d\omega(x)\, \phi(du, dv)$, read over the whole source,

$$\begin{aligned}\big(\mathsf{T}_{\mathbf{w};I_q}[(\widehat{L}_i)_i]\; x^{\mathbf{m}^{\mathrm{tot}}-\mathbf{1}} d\omega(x)\, \phi(du, dv)\big)\big(\Delta_{\{B,R\}} \times \Delta_B \times \Delta_R\big)& \\ = \int_{\Delta_B \times \Delta_R} \int_{\Delta_{\{B,R\}}} x^{\mathbf{m}^{\mathrm{tot}}-\mathbf{1}} \prod_i \widehat{L}_i(x)^{-w_i}\, d\omega(x)\, \phi(du, dv),&\end{aligned}$$

wherever it converges; its kernel $\mathsf{Z}_{\mathbf{w};I_q}((\widehat{L}_i)_i) = \prod_i \widehat{L}_i^{-w_i}$ is the product of the one-scale kernels $\mathsf{Z}_{w_i;(1)}(\widehat{L}_i)$ (Definition 2.12, Theorem 5.21(i)). For one linear letter $x_R L^{(0)} + x_B L^{(1)}$ the integral over the totals is the Breta with the one bunch $\{B, R\}$, the shape index $\mathbf{m}^{\mathrm{tot}}$, the scale index w and the unit configuration (Definition 3.1):

$$\int_{\Delta_{\{B,R\}}} x^{\mathbf{m}^{\mathrm{tot}}-\mathbf{1}} \big(x_B L^{(1)} + x_R L^{(0)}\big)^{-w} d\omega(x) = \mathsf{B}^{\{\{B,R\}\}}_{\mathbf{m}^{\mathrm{tot}},\, w;\, I_{\{B,R\}}}\big(L^{(1)}, L^{(0)}\big).$$

Theorem 19.28 (The scale on the totals)**.** *At the gauge (u, α_R) let $\kappa_B > 0$ and $\kappa_B^{\mathrm{top}} > 0$, and read every letter on the scale of B (Definition 19.16) on the totals,*

$$\widehat{L}_i(x) = x_R^{c_i} L_i(x_B/x_R) = \sum_{l=0}^{c_i} x_B^{\,l}\, x_R^{\,c_i - l} L_i^{(l)},$$

a letter of width zero being a constant on the totals.

(i) At every point $\rho_0 > 0$ of the scale, which may depend on the shapes,

$$\mathrm{Sc}_B(u, \alpha_R; \mathbf{m}; \mathbf{s}, \mathbf{t}) = \rho_0^{\kappa_B} \int_{\Delta_{\{B,R\}}} x_B^{\kappa_B - 1} x_R^{\kappa_B^{\mathrm{top}} - 1} \prod_i \widehat{L}_i(\rho_0 x_B,\ x_R)^{-w_i}\, d\omega(x),$$

both sides converging together. At $\rho_0 = 1$ and $\alpha_R = v \in \Delta_R$ the point $(\rho u, v)$ is projectively $(x_B u, x_R v) \in \Delta_{\mathcal{E}}$, whose totals on the blocks B and R are x_B and x_R (Theorem 3.12), with $\rho = x_B/x_R$. On the balance wall $P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$ is the Trailmoment of Definition 19.27 for the letters $\widehat{L}_i$ at $\mathbf{m}^{\mathrm{tot}} = (\kappa_B, \kappa_B^{\mathrm{top}})$ with $\phi = u^{\mathbf{m}|_B - \mathbf{1}} v^{\mathbf{m}|_R - \mathbf{1}} d\omega_B(u)\, d\omega_R(v)$; both sides converge together.

(ii) Let B have width at most one in every table, the weights factoring across B and R; write the letters of width one $L_i(\rho) = L_i^{(0)} + \rho L_i^{(1)}$, with their constant and scale coefficients and their Skeleton values $\xi_i = L_i^{(0)}/L_i^{(1)}$ (Theorem 19.20), and fix one of them, i_0. At the point $\rho_0 = \xi_{i_0}$ the two terms of i_0 are equal and its letter on the totals is the constant $L_{i_0}^{(0)}$. The products in the displays run over the letters of width one, and both right sides carry the further factor $\prod L_i^{-w_i}$ over the constant letters of the tables of width zero:

$$\begin{aligned}\mathrm{Sc}_B(u, v; \mathbf{m}; \mathbf{s}, \mathbf{t}) &= \big(L_{i_0}^{(0)}\big)^{\kappa_B - w_{i_0}} \big(L_{i_0}^{(1)}\big)^{\kappa_B^{\mathrm{top}} - w_{i_0}} \\ &\qquad \times \int_{\Delta_{\{B,R\}}} x_B^{\kappa_B - 1} x_R^{\kappa_B^{\mathrm{top}} - 1} \prod_{i \neq i_0} \big(x_R L_i^{(0)} L_{i_0}^{(1)} + x_B L_{i_0}^{(0)} L_i^{(1)}\big)^{-w_i}\, d\omega(x) \\ &= \xi_{i_0}^{\kappa_B} \prod_i \big(L_i^{(0)}\big)^{-w_i} \int_{\Delta_{\{B,R\}}} x_B^{\kappa_B - 1} x_R^{\kappa_B^{\mathrm{top}} - 1} \prod_{i \neq i_0} \Big(x_R + x_B \frac{\xi_{i_0}}{\xi_i}\Big)^{-w_i} d\omega(x).\end{aligned}$$

On the balance wall $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ is the Trailmoment of Definition 19.27 for these linear letters at $\mathbf{m}^{\rm tot}=(\kappa_B,\kappa_B^{\rm top})$, with ϕ of (i) multiplied by $(L_{i_0}^{(0)})^{\kappa_B-w_{i_0}}(L_{i_0}^{(1)})^{\kappa_B^{\rm top}-w_{i_0}}$ and by the further factor of the constant letters: the coefficients of each linear letter are the constant coefficient of one letter times the scale coefficient of the other, and their ratio is the ratio of the two Skeleton values.

(iii) In (ii) let every $w_i>0$, and open each linear letter by Corollary 4.4, with the share ν_i on $x_BL_{i_0}^{(0)}L_i^{(1)}$ and $w_i-\nu_i$ on $x_RL_i^{(0)}L_{i_0}^{(1)}$, on a contour with $0<\operatorname{Re}\nu_i<w_i$ and $\kappa_B-w_{i_0}<\sum_{i\neq i_0}\operatorname{Re}\nu_i<\kappa_B$. The integral over the totals is then the Beta corner $\Gamma_{\begin{smallmatrix}2\\1\end{smallmatrix}}\left[\begin{smallmatrix}\nu_{i_0},&w_{i_0}-\nu_{i_0}\\&w_{i_0}\end{smallmatrix}\right]$ of the letter i_0 at $\nu_{i_0}=\kappa_B-\sum_{i\neq i_0}\nu_i$, so that the shares on the scale coefficients add to κ_B identically, and, with the further factor of (ii) on the right,

$$\mathrm{Sc}_B(u,v;\mathbf{m};\mathbf{s},\mathbf{t})=\int_{\sum_i\nu_i=\kappa_B}\prod_i\Gamma_{\begin{smallmatrix}2\\1\end{smallmatrix}}\left[\begin{smallmatrix}\nu_i,&w_i-\nu_i\\&w_i\end{smallmatrix}\right]\big(L_i^{(0)}\big)^{-(w_i-\nu_i)}\big(L_i^{(1)}\big)^{-\nu_i},$$

the share side of the scale integral with one share per letter (Corollary 15.5). Integrated over the shapes it is Theorem 19.13: the pin of the shares is the shape integral over the totals.

The scale integral is the integral over the totals, and the shares of Theorem 19.13 are its share side: opening every letter but one leaves over the totals the Beta corner of the last, and the pin is what that integral asks of the shares. The point ρ_0 is free. At $\rho_0=1$ the totals are those of Theorem 3.12, the coordinates of a node in Theorem 20.15; at the value of a letter that letter leaves the integral, and for one table a single linear letter is left.

Corollary 19.29 (One table: the even share on the totals)**.** *For one table in Theorem 19.13 write, on $\Delta_B\times\Delta_R$,*

$$\mathbf{E}^d=\mathbf{E}_{\mathcal{B}/R}(u)\,\mathbf{E}_{\mathcal{B}|R}(v),\qquad \mathbf{E}^r=\mathbf{E}_{\mathcal{B}|B}(u)\,\mathbf{E}_{\mathcal{B}/B}(v)$$

for the even letters of the two levels, so that $\mathbf{E}^d/\mathbf{E}^r=\varrho_B(u)/\varrho_R(v)$, and let $2\delta^d=s-\kappa_B$ and $2\delta^r=\kappa_B-t$; here $\kappa_B^{\rm top}=s+t-\kappa_B$. Then

$$\begin{aligned}\mathrm{Sc}_B(u,v;\mathbf{m};s,t)&=\big(K_{\mathcal{B}/R}(u)K_{\mathcal{B}|R}(v)\big)^{-2\delta^d}\big(K_{\mathcal{B}|B}(u)K_{\mathcal{B}/B}(v)\big)^{-2\delta^r}\,\mathsf{B}^{\{\{B,R\}\}}_{(\kappa_B,\kappa_B^{\rm top}),\,t;\,I_{\{B,R\}}}\big(\mathbf{E}^d,\mathbf{E}^r\big)\\&=\big(\Psi_{\mathcal{B}/R}(u)\Psi_{\mathcal{B}|R}(v)\big)^{2\delta^d}\big(\Psi_{\mathcal{B}|B}(u)\Psi_{\mathcal{B}/B}(v)\big)^{2\delta^r}\,\mathsf{B}^{\{\{B,R\}\}}_{(\kappa_B,\kappa_B^{\rm top}),\,s;\,I_{\{B,R\}}}\big(\mathbf{E}^r,\mathbf{E}^d\big),\end{aligned}$$

and $\mathsf{B}^{\{\{B,R\}\}}_{(\kappa_B,\kappa_B^{\rm top}),t;I_{\{B,R\}}}(\mathbf{E}^d,\mathbf{E}^r)=(\mathbf{E}^r)^{-t}\,\mathsf{B}^{\{\{B,R\}\}}_{(\kappa_B,\kappa_B^{\rm top}),t;I_{\{B,R\}}}\big(\varrho_B(u)/\varrho_R(v),1\big)$. So $P_F(\mathbf{m};s,t)$ is the Trailmoment of Definition 19.27 for the single linear letter $x_R\mathbf{E}^r+x_B\mathbf{E}^d$ at the exponent t and at $\mathbf{m}^{\rm tot}=(\kappa_B,\kappa_B^{\rm top})$, with $\phi=\big(K_{\mathcal{B}/R}K_{\mathcal{B}|R}\big)^{-2\delta^d}\big(K_{\mathcal{B}|B}K_{\mathcal{B}/B}\big)^{-2\delta^r}u^{\mathbf{m}|_B-\mathbf{1}}v^{\mathbf{m}|_R-\mathbf{1}}d\omega_B\,d\omega_R$, and the shapes enter the Breta only through the ratio $\varrho_B(u)/\varrho_R(v)$ of its coefficients. Opened by Corollary 4.4, the linear letter has the share $b^d=\sigma^d-\delta^d$ on $x_B\mathbf{E}^d$, and the integrand is that of Theorem 19.13: the free even share is the share of this letter, and the integral over the totals is the even share integrated.

Theorem 19.30 (Closing at the peaks, one reference per coefficient)**.** *In the Trailmoment of Definition 19.27 let every $w_i>0$, and choose constants $\bar L_{i,l}\geq L_i^{(l)}$, one for each coefficient, at ϕ-almost every shape; the* reference letters *are $\bar L_i(x)=\sum_{l=0}^{c_i}x_B^lx_R^{c_i-l}\bar L_{i,l}$. For an array $\mathbf{k}=(k_{i,l})$ with the rows $\mathbf{k}_i=(k_{i,l})_{0\leq l\leq c_i}$ put*

$$\boldsymbol{\beta}(\mathbf{k})=\big(\beta_B(\mathbf{k}),\beta_R(\mathbf{k})\big)=\Big(m_B^{\rm tot}+\sum_{i,l}l\,k_{i,l},\ m_R^{\rm tot}+\sum_{i,l}(c_i-l)\,k_{i,l}\Big),\qquad \mathbf{w}(\mathbf{k})=\big(w_i+|\mathbf{k}_i|\big)_i.$$

Introduce one singleton scale $\mathfrak{v}_i$ per letter, $\mathfrak{V} = \{\mathfrak{v}_1, \dots, \mathfrak{v}_q\}$, take the partition $\mathcal{P}_{\mathrm{tot}} = \{\{B, R\}\} \cup \{\{\mathfrak{v}_i\} : 1 \le i \le q\}$, and let $(\pi^{\mathrm{tot}}, \ell^{\mathrm{tot}})$ be the term arrays of the letter presentation (Proposition 3.6) with the kernel column of shape exponent 0, level $(1, 0_{\mathfrak{V}})$ and coefficient 1, and for every (i, l) with $\bar{L}_{i,l} > 0$ a column of shape exponent $\big((l, c_i - l), \mathbf{e}_i\big)$, level $(0, \mathbf{e}_i)$ and coefficient $\bar{L}_{i,l}$; $1 \oplus \bar{\mathbf{L}}$ lists the coefficients in this order. Then, with the arrays $\mathbf{k}$ supported on these columns,

$$\int_{\Delta_B \times \Delta_R} \int_{\Delta_{\{B,R\}}} x^{\mathbf{m}^{\mathrm{tot}} - \mathbf{1}} \prod_i \widehat{L}_i(x)^{-w_i} \, d\omega(x) \, \phi(du, dv)$$
$$= \sum_{\mathbf{k}} \prod_i \frac{(w_i)_{|\mathbf{k}_i|}}{\mathbf{k}_i!} \; \mathsf{B}^{\mathcal{P}_{\mathrm{tot}}}_{(\boldsymbol{\beta}(\mathbf{k}), \mathbf{w}(\mathbf{k})), \, (1, \mathbf{w}(\mathbf{k})); \, (\pi^{\mathrm{tot}}, \ell^{\mathrm{tot}})}\big(1 \oplus \bar{\mathbf{L}}\big) \int \prod_{i,l} \big(\bar{L}_{i,l} - L_i^{(l)}\big)^{k_{i,l}} \, d\phi,$$

a series of nonnegative terms, both sides finite or infinite together. The Breta coefficient is a number: the kernel integrates its scale to 1, and

$$\mathsf{B}^{\mathcal{P}_{\mathrm{tot}}}_{(\boldsymbol{\beta}(\mathbf{k}), \mathbf{w}(\mathbf{k})), \, (1, \mathbf{w}(\mathbf{k})); \, (\pi^{\mathrm{tot}}, \ell^{\mathrm{tot}})}\big(1 \oplus \bar{\mathbf{L}}\big) = \int_{\Delta_{\{B,R\}}} x^{\boldsymbol{\beta}(\mathbf{k}) - \mathbf{1}} \prod_i \bar{L}_i(x)^{-w_i - |\mathbf{k}_i|} \, d\omega(x).$$

Each moment is a read of ϕ against the one-scale kernels $\mathsf{Z}_{-k_{i,l};(1)}\big(\bar{L}_{i,l} - L_i^{(l)}\big) = \big(\bar{L}_{i,l} - L_i^{(l)}\big)^{k_{i,l}}$.

Corollary 19.31 (Closing at the peak on the totals)**.** *In Theorem 19.30 take the references $\bar{L}_{i,l} = \binom{c_i}{l} \bar{L}_i$ with constants $\bar{L}_i > 0$ such that the deviations $h_{i,l} = \binom{c_i}{l} \bar{L}_i - L_i^{(l)}$ are nonnegative. The reference letter is then the constant $\bar{L}_i (x_B + x_R)^{c_i} = \bar{L}_i$ on the totals, the Breta coefficient is $\prod_i \bar{L}_i^{-w_i - |\mathbf{k}_i|}$ times the Beta corner $\Gamma^{\,2}_{\,1}\!\begin{bmatrix} \beta_B(\mathbf{k}), & \beta_R(\mathbf{k}) \\ \beta_B(\mathbf{k}) + \beta_R(\mathbf{k}) & \end{bmatrix}$, and that Trailmoment is*

$$\sum_{\mathbf{k}} \prod_i \frac{(w_i)_{|\mathbf{k}_i|}}{\mathbf{k}_i!} \, \bar{L}_i^{-w_i - |\mathbf{k}_i|} \; \Gamma^{\,2}_{\,1}\!\begin{bmatrix} \beta_B(\mathbf{k}), & \beta_R(\mathbf{k}) \\ \beta_B(\mathbf{k}) + \beta_R(\mathbf{k}) & \end{bmatrix} \int \prod_{i,l} h_{i,l}^{k_{i,l}} \, d\phi.$$

For linear letters $\widehat{L}_i(x) = x_R L_i^{(0)} + x_B L_i^{(1)}$ with $\bar{L}_i \ge L_i^{(0)}, L_i^{(1)}$, with n_i counting the constant coefficient and n_i' the scale coefficient of the letter i, it is

$$\sum_{\mathbf{n}, \mathbf{n}'} \prod_i \frac{(w_i)_{n_i + n_i'}}{n_i! \, n_i'!} \, \bar{L}_i^{-w_i - n_i - n_i'} \; \Gamma^{\,2}_{\,1}\!\begin{bmatrix} m_B^{\mathrm{tot}} + |\mathbf{n}'|, & m_R^{\mathrm{tot}} + |\mathbf{n}| \\ |\mathbf{m}^{\mathrm{tot}}| + |\mathbf{n}| + |\mathbf{n}'| & \end{bmatrix} \int \prod_i \big(\bar{L}_i - L_i^{(0)}\big)^{n_i} \big(\bar{L}_i - L_i^{(1)}\big)^{n_i'} \, d\phi.$$

If a coefficient is a product $f'(u) f''(v)$ and its reference a product $\bar{f}' \bar{f}''$ of constants $\bar{f}' \ge f'$ and $\bar{f}'' \ge f''$, then $\bar{f}' \bar{f}'' - f' f'' = \bar{f}'(\bar{f}'' - f'') + f''(\bar{f}' - f')$, both terms nonnegative and each a function on the bunch times a function on the room; so when every coefficient, every reference and ϕ are products, every moment is a finite nonnegative combination of products of moments over Δ_B and over Δ_R.

No order of the values is used, only bounds on the coefficients, and the terms are nonnegative. Applied to every letter on the whole simplex with the references $M_i = \max_T \theta_{j,T} / g_i!$, Theorem 15.13 is the draw series (Proposition 20.12); applied on the totals it closes the scale of the bunch alone, and the shapes of the bunch and the room enter only through the moments of the deviations of the coefficients from their references. Across a bunch of width one every coefficient is a letter of a minor on the bunch times a letter of a minor on the room (Theorem 19.20), so with references that are products the moments pair the bunch with the room, as the lattices of Theorem 19.20 do, with nonnegative terms. If every $\widehat{L}_i$ is at least $(1 - \lambda) \bar{L}_i$ on the totals at every shape, with $\lambda < 1$,

the terms of total order $\sum_i |\mathbf{k}_i| = k$ add up to at most $\frac{(|\mathbf{w}|)_k}{k!}\lambda^k$ times the term of order 0; when a coefficient vanishes on a face of a shape simplex the terms need not decay geometrically.

For one table read at $\rho_0 = 1$ the two letters on the totals are linear, and so are their reference letters, one constant for each coefficient. Rescaling the scale by the ratio of the references of the letter K carries its reference letter to a multiple of $x_R + x_B$, and that of Ψ to a multiple of the linear letter whose scale coefficient over its constant coefficient is the reference of the even letter of the level d over that of the level r; the rescaling multiplies the Breta coefficient by a power of the ratio of the references of K. Two letters on the line of the totals have two zeros besides its two endpoints, and four points of a line have one modulus, the ratio of the references of the even letters of the two levels: the Breta coefficients depend on the references only through their scales and this modulus, defined up to its inverse by the naming of the two levels. What one reference for each coefficient adds is that every deviation can vanish at its own peak, at the price of the one modulus in the coefficients. When the modulus is 1 both reference letters are multiples of x_R+x_B, which is 1 on the simplex, and Corollary 19.31 applies. With N tables there are $2N$ letters on the totals and $2N-1$ such moduli.

Corollary 19.32 (The ladder on the totals)**.** *In Theorem 19.28(ii) let every $w_i > 0$, put $w' = \sum_{i\neq i_0} w_i$, and let $\zeta > 0$.*

(i) At shapes where every ratio ξ_{i_0}/ξ_i lies in $(0, 2\zeta)$,

$$\int_{\Delta_{\{B,R\}}} x_B^{\kappa_B-1} x_R^{\kappa_B^{\mathrm{top}}-1} \prod_{i\neq i_0} \Big(x_R + x_B\,\frac{\xi_{i_0}}{\xi_i}\Big)^{-w_i} d\omega(x)$$
$$= \sum_{\mathbf{n}} \prod_{i\neq i_0} \frac{(w_i)_{n_i}}{n_i!} \Big(\zeta - \frac{\xi_{i_0}}{\xi_i}\Big)^{n_i}\ \mathsf{B}^{\{\{B,R\}\}}_{(\kappa_B+|\mathbf{n}|,\kappa_B^{\mathrm{top}}),\, w'+|\mathbf{n}|;\, I_{\{B,R\}}}(\zeta, 1),$$

absolutely: the linear letters are moved to the common ratio ζ, where they merge into one, and the coefficients do not depend on the shapes. At $\zeta = 1$ they are the Beta corners $\Gamma_{\begin{smallmatrix}2\\1\end{smallmatrix}}\left[\begin{smallmatrix}\kappa_B+|\mathbf{n}|,\ \kappa_B^{\mathrm{top}}\\ \kappa_B+\kappa_B^{\mathrm{top}}+|\mathbf{n}|\end{smallmatrix}\right]$. For one linear letter this is the ladder of the Breta in its first coefficient (Theorem 3.5(ii)), $\partial_\zeta \mathsf{B}^{\{\{B,R\}\}}_{(\kappa_B,\kappa_B^{\mathrm{top}}),w;I_{\{B,R\}}}(\zeta,1) = -w\,\mathsf{B}^{\{\{B,R\}\}}_{(\kappa_B+1,\kappa_B^{\mathrm{top}}),w+1;I_{\{B,R\}}}(\zeta,1)$, summed as a Taylor series.

(ii) Let $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ converge and let every ratio ξ_{i_0}/ξ_i lie in $[\zeta_-,\zeta_+] \subset (0,2\zeta)$ on $\Delta_B\times\Delta_R$. Then (i) integrates term by term against ϕ of Theorem 19.28(i) multiplied by $\xi_{i_0}^{\kappa_B}\prod_i (L_i^{(0)})^{-w_i}$ and by the further factor of Theorem 19.28(ii), and the terms of $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ with $|\mathbf{n}| = n$ add up in absolute value to at most $C\frac{(w')_n}{n!}\vartheta^n P_F(\mathbf{m};\mathbf{s},\mathbf{t})$, where $\vartheta = \max(1-\zeta_-/\zeta,\ \zeta_+/\zeta - 1) < 1$ and $C = \mathsf{B}^{\{\{B,R\}\}}_{(\kappa_B,\kappa_B^{\mathrm{top}}),w';I_{\{B,R\}}}(\zeta,1)\big/\mathsf{B}^{\{\{B,R\}\}}_{(\kappa_B,\kappa_B^{\mathrm{top}}),w';I_{\{B,R\}}}(\zeta_+,1)$. If $\zeta \geq \sup \xi_{i_0}/\xi_i$ for every i the terms are nonnegative and no lower bound on the ratios is needed; both sides are then finite or infinite together.

(iii) For one table with i_0 the letter of K, under the hypotheses of (ii) the only other ratio is $\varrho_B(u)/\varrho_R(v)$, and

$$P_F(\mathbf{m};s,t) = \sum_{n\geq 0} \frac{(t)_n}{n!}\,\mathsf{B}^{\{\{B,R\}\}}_{(\kappa_B+n,\kappa_B^{\mathrm{top}}),\,t+n;\,I_{\{B,R\}}}(\zeta,1) \int_{\Delta_B\times\Delta_R} \big(\zeta\mathbf{E}^r - \mathbf{E}^d\big)^n\,(\mathbf{E}^r)^{-t-n}\,\phi(du,dv),$$

with $\mathbf{E}^d$, $\mathbf{E}^r$ and ϕ of Corollary 19.29. With i_0 the letter of Ψ the ratio is $\varrho_R(v)/\varrho_B(u)$, and the same holds with s for t, the moments $\int(\zeta\mathbf{E}^d - \mathbf{E}^r)^n(\mathbf{E}^d)^{-s-n}$ and the measure

$\phi = \big(\Psi_{\mathcal{B}/R}\Psi_{\mathcal{B}|R}\big)^{2\delta^d}\big(\Psi_{\mathcal{B}|B}\Psi_{\mathcal{B}/B}\big)^{2\delta^r} u^{\mathbf{m}|_B-\mathbf{1}}v^{\mathbf{m}|_R-\mathbf{1}}d\omega_B\,d\omega_R$. *So one table closes on the totals with nonnegative terms about any* $\zeta \geq \sup\varrho_B/\inf\varrho_R$ *when no slope is positive, and with* i_0 *the letter of* Ψ *about any point at least* $\sup\varrho_R/\inf\varrho_B$ *when no slope is negative (Lemma 19.15). With* $\zeta = \zeta'\zeta''$, $\zeta' \geq \sup_{\Delta_B}\varrho_B$ *and* $\zeta'' \geq 1/\inf_{\Delta_R}\varrho_R$,

$$\zeta\mathbf{E}^r - \mathbf{E}^d = \zeta'\mathbf{E}_{\mathcal{B}|B}(u)\big(\zeta''\mathbf{E}_{\mathcal{B}/B}(v) - \mathbf{E}_{\mathcal{B}|R}(v)\big) + \mathbf{E}_{\mathcal{B}|R}(v)\big(\zeta'\mathbf{E}_{\mathcal{B}|B}(u) - \mathbf{E}_{\mathcal{B}/R}(u)\big),$$

both terms nonnegative and each a function on the bunch times a function on the room.

(iv) Since $x_R + x_B\xi_{i_0}/\xi_i = (\xi_{i_0}/\xi_i)\big(x_B + x_R\xi_i/\xi_{i_0}\big)$, *the integral of (i) is* $\prod_{i\neq i_0}(\xi_i/\xi_{i_0})^{w_i}$ *times the same integral with* κ_B *and* κ_B^{top} *swapped and every ratio replaced by its inverse. So (i) and (ii) hold in the inverse ratios, the factor* $\prod_{i\neq i_0}(\xi_i/\xi_{i_0})^{w_i}$ *joining* ϕ, *with nonnegative terms about any common point at least* $\sup\xi_i/\xi_{i_0}$: *the ladder closes whenever the ratios are bounded on one side.*

The three closings of the even share read the same linear letters. At a wall the even share closes toward the level whose even letter is the smaller, which needs ϱ_B/ϱ_R on one side of 1 with room (Corollary 19.21(i)); the ladder moves the linear letters to a common ratio, which needs the quotient bounded on one side, and its coefficients are constants of the scale; the peak closing moves each linear letter to a constant reference, which needs the coefficients bounded and asks nothing of their ratio. In all three the terms pair moments of the bunch with moments of the room. With $\varrho_B(u) < \varrho_R(v)$ throughout and $\sup\varrho_B = \inf\varrho_R$, the ladder about $\zeta = 1$ is a series of nonnegative terms whose coefficients are Beta corners, where Proposition 19.23 sums the lattices by scaling the level weights. Where the quotient takes every positive value, of the three only the peak closing applies; the gauge closing applies as well, its terms not separating over the bunch and the room (Proposition 19.24).

19.8 Width zero

Proposition 19.33 (A loop or a coloop on the simplex)**.** *Let a mark* e *be in every table a loop* ($\eta_j = -1$) *or a coloop* ($\eta_j = +1$), *let* F' *be the family of Corollary 15.16 on* $\mathcal{E} - e$, *and put* $\nu_e = \mu_e - \sum_j \eta_j\delta_j$, *so that* $\kappa' = \kappa_{\mathcal{E}} - \nu_e$ *is the imbalance of* F' *at the masses* $\mathbf{m}|_{\mathcal{E}-e}$. *Where* $\nu_e > 0$ *and* $\kappa' > 0$,

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \Gamma_{\!1}^{\,2}\begin{bmatrix}\nu_e,\ \kappa'\\ \kappa_{\mathcal{E}}\end{bmatrix}\ P_{F'}(\mathbf{m}|_{\mathcal{E}-e};\mathbf{s},\mathbf{t}),$$

the mark rescaling every other mark by the common factor $1 - u_e$; *it is the compound formula of Theorem 16.17 at* $S = \{e\}$, *with the walls* $\kappa_{\{e\}} = \nu_e$ *and* $\kappa_{\mathcal{E}\setminus e} = \kappa'$. *Marks* $e_1,\dots,e_k$ *of this kind combine first among themselves and then with the rest,* $\Gamma_{\!1}^{\,k+1}\begin{bmatrix}(\nu_{e_i})_i,\ \kappa'\\ \kappa_{\mathcal{E}}\end{bmatrix} = \Gamma_{\!1}^{\,k}\begin{bmatrix}(\nu_{e_i})_i\\ a\end{bmatrix}\Gamma_{\!1}^{\,2}\begin{bmatrix}a,\ \kappa'\\ \kappa_{\mathcal{E}}\end{bmatrix}$ *with* $a = \sum_i \nu_{e_i}$ *and* κ' *the imbalance once all of them are removed (Theorem 3.12). On the balance wall* $\kappa' = -\nu_e$ *and the period of the compound diverges (Proposition 8.16): the Foreman tree splits molecules first (Definition 14.4).*

The bunch $\{e\}$ has width zero: the room does not see it at all, and the period integrates it out as the Beta corner $\Gamma_{\!1}^{\,2}\begin{bmatrix}\nu_e,\ \kappa'\\ \kappa_{\mathcal{E}}\end{bmatrix}$, whose Gamma $\Gamma(\nu_e)$ is the Gamma $\Gamma(\mu_e - \langle\boldsymbol{\delta}\rangle_e)$ of the port at e (Theorem 15.15).

19.9 Pooling is a move

Theorem 19.34 (Pooling is a move)**.** *Let a bunch B have width one in every table of a family of tables with positive rational weights, the weights of every table factoring across B and R with rational factors, at rational exponents and masses on the balance wall.*

(i) Theorem 19.8 is one change of variables, $(\rho, u, \alpha_R) \mapsto (\rho u, \alpha_R)$, the scale and the shape of B: it is birational over $\mathbb{Q}$ with the inverse $\alpha \mapsto (|\alpha_B|, \alpha_B/|\alpha_B|, \alpha_R)$, bijective on the open domains, and it carries the face of $S \subseteq \mathcal{E}$ to $\{\rho = 0\} \times \{\alpha_{S\cap R} = 0\}$ if $S \supseteq B$ and to $\{u_{S\cap B} = 0\} \times \{\alpha_{S\cap R} = 0\}$ otherwise, with the walls matched by Theorem 19.9: by (i) there when $S \supseteq B$ or $S \subseteq R$, by (ii) there when $S \subseteq B$, and by the gluing of the counts otherwise.

(ii) When the factorizations, with rational factors, give every active letter the one hinge value γ of Theorem 19.10, that theorem is a composite of moves: the change of variables (i); the change $\rho \mapsto \rho\,\gamma(u)$, birational over $\mathbb{Q}$ and positive on the open domain; the product of the datum of the shape with that of the cell family of the room; and the integral of the hinge, the Beta corner of a linear letter (Proposition 15.1 with one coefficient), itself a change of variables and a product with the datum of the list on two marks whose bases are the two singletons, at the exponents $(0, 2\sigma)$. Every integral in the chain converges exactly when $P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$ does (Theorem 19.10).

So the identities of Theorems 19.8 and 19.10 hold between period data, not only between their values: when every active letter has one hinge value the period datum of the family times that of the list on two marks is the product of the data of its two cell families.

In the interior Theorem 19.8 writes the period as an integral over the shape simplex, whose faces carry the walls of Theorem 19.9(ii), of the periods of the pooled families $F_{B\to g}(u)$, whose walls are those of Theorem 19.9(i).

19.10 Cleaning a molecule

Definition 19.35 (Cleaning)**.** A *cleaning* of a list is a sequence of poolings of parallel and series bunches of width one, each in the list left by the previous ones, until at most two marks or no such class remain.

Proposition 19.36 (Poolings of disjoint classes commute)**.** *Let X and Y be disjoint parallel or series bunches of width one of a list. Pooling X keeps Y a class of the same kind and width, with the same restriction to Y and the same contraction of its room, and the two orders of pooling give the same list on $(\mathcal{E} \setminus (X \cup Y)) \sqcup \{g_X, g_Y\}$, the same cell kernels and the same hinge values. A cleaning ends after at most $|\mathcal{E}| - 2$ poolings.*

Proposition 19.37 (Cleaning commutes with maps)**.** *A bijection that carries one table to another (Definition 11.13) maps the parallel and series bunches of the first onto those of the second, with the same widths and, the weights factoring across a bunch and its room and the factorization carried along, the same hinge values. An exchange maps parallel bunches onto series bunches and swaps the hinge values by K and by Ψ, the weight θ'_p of a pattern p of a bunch B becoming that of the pattern $g(B \setminus p)$ of its image. Between lists it maps the cleaning of the first list at the exponents (s, t) onto the cleaning of the second at (t, s).*

Theorem 19.38 (Cleaning has one result)**.** *Let a list be one molecule. Every cleaning of it ends at the same list up to the names of its marks. If that list has more than two marks, every cleaning*

ends with the same marks, each the same set of marks of the original list; a list that ends with two marks may divide its marks between them in more than one way. Pooling the parallel bunches first, then the series bunches, and repeating, is one cleaning, and every other order ends at the same place.

Pooling keeps a molecule a molecule, and two poolings at one list can be continued to one list; so the end of a cleaning does not depend on the order of the poolings. The cleaned list has no parallel or series bunch of width one left, each of its marks gathers a set of marks of the molecule, and the period of the molecule is the integral, over the shape simplices of the pooled bunches against their cell kernels, of the periods of the pooled families of the cleaned list.

Chapter 20

Words of a tree

A period is read back from what the Foreman procedure leaves: the bunches peeled at the nodes of a tree of bunches and the leaves at its bottom. The period of a family is the word of such a tree, an iterated fibre integral of stacked Gammas and of the periods of the leaves; opened at the atoms along a chain, or wherever no table is opened on two childcules, the word is one Gramma on the marks and the letters. The word closes in three ways: by draws, with nonnegative terms at nonnegative exponents; at the centre, through the half-sum and the difference of the two letters of a table; and node by node in one scale, where each side of a node of width one is an interval from the decay of its transform to its reach. Read on one tree, the period shows what each node adds, what the leaves contain, and how the integrations of the simplex are shared out.

20.1 The two letters of a table at once

Proposition 20.1 (The pair ladder is the expansion about the midpoint)**.** *For $a, b > 0$, $s, t > 0$ and $x = \frac{a-b}{a+b} \in (-1, 1)$,*

$$a^{-s} b^{-t} = \Big(\frac{a+b}{2}\Big)^{-s-t} (1+x)^{-s} (1-x)^{-t},$$

and the coefficients of the power series $(1+x)^{-s}(1-x)^{-t}$ are

$$[x^k](1+x)^{-s}(1-x)^{-t} = \sum_{i+i'=k} (-1)^i \frac{(s)_i\,(t)_{i'}}{i!\,i'!} = \frac{(s+t)_k}{k!} \Gamma_{\begin{smallmatrix}1\\2\end{smallmatrix}}\begin{bmatrix} s+t \\ s,\ t \end{bmatrix} \int_0^1 w^{s-1}(1-w)^{t-1}(1-2w)^k\, dw.$$

So $\Gamma_{\begin{smallmatrix}2\\1\end{smallmatrix}}\begin{bmatrix} s,\ t \\ s+t+k \end{bmatrix} [x^k](1+x)^{-s}(1-x)^{-t} = \frac{1}{k!}\int_0^1 w^{s-1}(1-w)^{t-1}(1-2w)^k\, dw$; swapping s and t multiplies the k-th coefficient by $(-1)^k$; and at $s = t$ only even k occur, $[x^{2l}](1-x^2)^{-s} = (s)_l/l!$.

The two letters of a table enter a period as $\Lambda(z)^{-s}\Lambda(-z)^{-t}$. The pair ladder expands such a pair about its midpoint; under one power, the shape of a two-element bunch in the tower decides how much of each letter is taken (Proposition 20.3).

Definition 20.2 (Side shape; half-sum and difference; pattern coefficients)**.** For table j of a family and $w \in [0,1]$ the letter of the *side shape* w is $L_{j,w}(z) = w\Lambda_j(z) + (1-w)\Lambda_j(-z)$; $L_{j,1/2}(z) = \frac{1}{2}\big(\Lambda_j(z) + \Lambda_j(-z)\big)$ is the *half-sum* and $\partial_w L_{j,w}(z) = \Lambda_j(z) - \Lambda_j(-z)$ the *difference* of the two letters of table j. For a bunch B with room R and the Taylor cube $\Lambda_j(z) = \sum_{p \subseteq B} e^{\langle z_B, \chi_p\rangle} \Lambda_{j,(p)}(z_R)$

(Theorem 12.7), $\Lambda_{j,(p)} = 0$ when p is not a pattern of table j, the *pattern coefficients* of the side shape are

$$c_{j,p}(w; z_R) = w\,\Lambda_{j,(p)}(z_R) + (1-w)\,\Lambda^*_{j,(p)}(z_R), \qquad \Lambda^*_{j,(p)}(z_R) = \Lambda_{j,(B\setminus p)}(-z_R),$$

so that $L_{j,w}(z) = \sum_p e^{\langle z_B, \chi_p\rangle} c_{j,p}(w; z_R)$. For one table the index j is omitted.

Proposition 20.3 (The side shape, and what an exchange does to it)**.** *Let a bijection g carry or exchange a family F, with the bijection h of its tables (Definition 11.13). If g carries F, then $L_{h(j),w}(z) = L_{j,w}(g^*z)$; if it exchanges F, then $L_{h(j),w}(z) = L_{j,1-w}(g^*z)$ (Definition 20.2). For $s_j, t_j > 0$, by the tower at the unit configuration on a two-element set J (Theorem 3.2),*

$$\begin{aligned}\Lambda_j(z)^{-s_j}\Lambda_j(-z)^{-t_j} &= \Gamma_{\frac12}\begin{bmatrix} s_j+t_j \\ s_j,\ t_j\end{bmatrix}\, \mathsf{B}^{\{J\}}_{(s_j,t_j),\, s_j+t_j;\, I_J}\big(\Lambda_j(z), \Lambda_j(-z)\big) \\ &= \Gamma_{\frac12}\begin{bmatrix} s_j+t_j \\ s_j,\ t_j\end{bmatrix} \int_0^1 w^{s_j-1}(1-w)^{t_j-1}\, \mathsf{Z}_{s_j+t_j;(1)}\big(L_{j,w}(z)\big)\, dw,\end{aligned}$$

and for one table an exchange together with $w \mapsto 1-w$ keeps $\mathsf{Z}_{s+t;(1)}(L_w(z))$, keeping the factor $w^{s-1}(1-w)^{t-1}$ exactly when $s = t$.

The side shape weighs the basis letter against the cobasis letter, and an exchange of the table turns it over. The half-sum is even in z and the difference odd: $\Lambda(z)\Lambda(-z) = L_{1/2}(z)^2 - \frac14\big(\partial_w L_w(z)\big)^2$.

20.2 The junction in pattern form

Theorem 20.4 (The junction in pattern form)**.** *Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$ be a molecule on n marks with real exponents $s_j, t_j \geq 0$, its masses on the balance wall with every proper wall positive, and let B be a proper bunch with room R and $g \in R$. For a table at a full lean put $w_j = 1$ when $t_j = 0$ and $w_j = 0$ when $s_j = 0$. With the pattern coefficients $c_{j,p}(w; z_R)$ of the side shapes (Definition 20.2),*

$$\begin{aligned}P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \frac{2^{n-1}}{\prod_{j:\, s_j>0}\Gamma(s_j)\prod_{j:\, t_j>0}\Gamma(t_j)} \int \prod_{j:\, s_j, t_j>0} w_j^{s_j-1}(1-w_j)^{t_j-1} \int_{\mathbb{R}^{R-g}} e^{2\langle \boldsymbol{\mu}|_R, z_R\rangle} \\ \times \int \prod_{j\ \mathit{active}} y_j^{s_j+t_j-1}\, \mathsf{G}_{2\boldsymbol{\mu}|_B;(\chi_p)_p}\Big(\Big(\sum_{j\ \mathit{active}} y_j\, c_{j,p}(w_j; z_R)\Big)_p\Big)\, d\mathbf{y}\, dz_{R-g}\Big|_{z_g=0}\, d\mathbf{w},\end{aligned}$$

with $d\mathbf{y} = \prod_j dy_j$ over the active tables, $y_j \in (0,\infty)$, and $d\mathbf{w} = \prod_j dw_j$ over the tables with $s_j, t_j > 0$, $w_j \in [0,1]$; the Gramma on the scales e^{z_B} with one term for each $p \subseteq B$ whose coefficient $\sum_j y_j c_{j,p}(w_j; z_R)$ is not 0. A table at a full lean has no integral over its side shape: at $(s_j, 0)$ its coefficients are $y_j\Lambda_{j,(p)}(z_R)$, at $(0, t_j)$ they are $y_j\Lambda^*_{j,(p)}(z_R)$.

The two letters of every table become one letter, the side shapes are integrated last, and the bunch is integrated on its own orthant against the patterns of all the tables at once: each pattern is one term of one Gramma on the bunch, whose coefficient adds the pattern coefficients of the tables, each at its own scale y_j, and the room sits in the coefficients. A map that keeps the bunch moves the coefficients with the side shapes and the tables.

Proposition 20.5 (What a map keeping the bunch gives the coefficients)**.** *In Theorem 20.4 let a bijection $\tilde{g}$ of $\mathcal{E}$ keep B, with $\tilde{g}_R$ its restriction to the room, and carry or exchange F with the bijection h of its tables. If $\tilde{g}$ carries F, then $c_{h(j),\tilde{g}(p)}(w; z_R) = c_{j,p}(w; \tilde{g}_R^* z_R)$ for every j, p and w; if it exchanges F, then $c_{h(j),\tilde{g}(p)}(1-w; z_R) = c_{j,p}(w; \tilde{g}_R^* z_R)$.*

Proposition 20.6 (Level form of the half-sum)**.** *In Theorem 20.4 the half-sum and the difference of table j have the pattern coefficients $c_{j,p}(\frac{1}{2}; z_R) = \frac{1}{2}\big(\Lambda_{j,(p)} + \Lambda^*_{j,(p)}\big)(z_R)$ and $\partial_w c_{j,p}(w; z_R) = \big(\Lambda_{j,(p)} - \Lambda^*_{j,(p)}\big)(z_R)$.*

(i) For every table, $c_{j,B\setminus p}(\frac{1}{2}; -z_R) = c_{j,p}(\frac{1}{2}; z_R)$ and $\partial_w c_{j,B\setminus p}(w; -z_R) = -\partial_w c_{j,p}(w; z_R)$.

(ii) The half-sum of table j has level form on B (Proposition 14.12), $c_{j,p}(\frac{1}{2}; \cdot)$ depending on $|p|$ alone, exactly when every transposition of two marks of B fixing the rest carries the multiset $\mathcal{B}_j \uplus \{\mathcal{E} \setminus T : T \in \mathcal{B}_j\}$, with its weights, onto itself; if $2r_j \neq n$ this is the condition that every such transposition carries table j (Proposition 14.12).

(iii) If every such transposition carries or exchanges table j, its half-sum has level form and the square of its difference is unchanged by every permutation of B.

20.3 The word of a tree

Definition 20.7 (Tree of bunches)**.** A *tree of bunches* of a family F on $\mathcal{E}$ has *vertices* v, each with marks $M_v \subseteq \mathcal{E}$ and tables on M_v with their exponents, the root having $M_v = \mathcal{E}$ and the active tables of F. A vertex whose tables form one molecule is a *node*. A node v that is not a leaf carries a proper bunch $B_v \subsetneq M_v$; the tables at v have their children at B_v, indexed by the table and the pattern as in the record of the peel (Definition 14.2) and not merged, the *tables made at* v, each carrying the letters its parent carries, its exponent in each letter a positive multiple of the parent's, as at every native split (Definition 12.25). The molecules $R_{v,1}, \dots, R_{v,q_v}$ of the tables made at v on $M_v \setminus B_v$, in a fixed order, are the childcules of v (Definition 14.1), each a node whose tables are the restrictions to it of the tables made at v. The *room* of v is the one childcule when $q_v = 1$; when $q_v \geq 2$ it is a *split vertex*, with the marks $M_v \setminus B_v$ and the tables made at v, whose children are the childcules. The root of a family whose active tables form two or more molecules is likewise a split vertex, whose children are the molecules with the restrictions of its tables. A leaf v has $B_v = M_v$. The *width* of a node is the largest width $c(B_v)$ of its bunch in the tables at v, zero at a leaf. Merging equal children with their exponents added, as the peel does (Definition 14.1), keeps every letter when the exponents are nonnegative, and can cancel a letter when exponents of both signs meet; the tables made at a node are therefore indexed. The tables at a node are thus the children of the tables of F at the patterns shown on the bunches above it, restricted to its marks (Proposition 14.5); with a native gauge they carry as exponents the shares of the native splits at the nodes above (Theorem 12.26). Its descents are the sequences of nodes from the root to a leaf, each a childcule of the one before, as on the Foreman tree (Definition 14.17), which is a tree of bunches (Definition 14.4).

Corollary 20.8 (The tree of a linked molecule is a chain)**.** *Let some active table of a molecule F be connected, as for a molecule of one table. Every tree of bunches of F is then a chain $M_0 \supset M_1 \supset \cdots \supset M_d$ with $M_{k+1} = M_k \setminus B_k$, above one leaf: the tables at M_k are the children of the tables of F at $S_k = B_0 \sqcup \cdots \sqcup B_{k-1}$ (Proposition 14.5), which form one molecule (Lemma 18.14). With a native gauge their exponents are the shares of the native split, and on the Foreman tree the family at M_k is the peel $F_{S_k}(\mathbf{a}^\star, \mathbf{b}^\star)$ (Definition 14.1).*

Corollary 20.9 (A linked molecule)**.** *Let some active table of F be connected, as for a molecule of one table. Every peel then leaves one childcule, so the tree is a chain (Corollary 20.8), there are no twins, and the room of each node is the next node. For every chain that peels a class at each node, every class of a node other than its bunch lies inside one class of the next node, and the leaf is a union of whole classes of every node above it (Theorems 14.20(ii) and 14.22(i)). For the Foreman tree, which is then a chain, at every realization, the centre and every lean, Theorem 14.22(ii) with no twins gives*

$$|B_0| \le |B_1| \le \cdots \le |B_{d-1}| \le |M_d| :$$

the leaf alone has at least as many marks as every bunch.

Corollary 20.10 (The word of a tree)**.** *Let F have real data with $s_j, t_j \ge 0$, a native gauge and its masses on the balance wall, and let the children's weights factor across the childcules at every node of a tree of bunches. Run the port of Theorem 18.13(ii) at every node, on the native splits. A table $\mathcal{B}'$ made at a node, with the exponents $(a_{\mathcal{B}'}, b_{\mathcal{B}'})$, is the direct sum of its restrictions to the childcules there (Proposition 7.9); let $q_{\mathcal{B}'}$ be the number of those childcules, other than leaves, on which its letter is not a monomial. Then*

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \prod_j \frac{1}{\Gamma(s_j)\Gamma(t_j)} \int_{\mathcal{X}} \prod_{\mathcal{B}'} \big(\Gamma(a_{\mathcal{B}'})\Gamma(b_{\mathcal{B}'})\big)^{1-q_{\mathcal{B}'}} \prod_{leaves\ v} P_{F_v}(\mathbf{m}|_{M_v};\mathbf{a}_v,\mathbf{b}_v),$$

the word of the tree*: an iterated fibre integral through the native splits, over the fibre $\mathcal{X}$ cut out by the share sums and by the $|B_v|+q_v-1$ pins of every node v that is not a leaf (Theorem 18.13(ii)), a monomial restriction entering the pins of its node as a load; F_v is the family of the tables at the leaf v with their exponents $(\mathbf{a}_v,\mathbf{b}_v)$, and a letter with exponent zero carries no shares and no Gamma. A table opened on one childcule carries no factor, and when an active table is connected every $q_{\mathcal{B}'}$ is 0 or 1 (Corollary 20.8).*

Theorem 20.11 (Building back up)**.** *In Corollary 20.10 open every leaf by the atom formula on the balance wall (Corollary 18.16), a unit being a monomial, and write the shares (a,b) of one pattern of one table in pair coordinates, $\sigma = \frac{a+b}{2}$ and $\delta = \frac{a-b}{2}$.*

(i) Polycules multiply. *At every node and at every point of its fibre on the wall contour of the native split (Theorem 18.13(iii)), the integral over the shares below the node is the product over its childcules of their words: the polycule of the childcules is evaluated as the product of its molecules, a unit contributing a monomial in the weights.*

(ii) The pins are odd. *If every table has $s_j, t_j > 0$, every pin other than the share sums involves the odd shares alone: the pins $\langle \boldsymbol{\delta} \rangle_e = \mu_e$ of the bunch, the pins of the childcules,*

$$\kappa_{R_i} = \mu_{R_i} - \sum_{j,p} \delta_{j,p}\big(2r_{j,(p)}(R_i) - |R_i|\big) = 0,$$

the sum over the tables made at the node, indexed as in Theorem 18.13 by the table j at the node and the pattern p, and the pins of the atoms. The share sums are $\sum_p \sigma_{j,p} = \sigma_j$ and $\sum_p \delta_{j,p} = \delta_j$, so the fibre is the product of an even fibre, cut by the even sums alone, and an odd fibre.

(iii) One Gramma. *If at every node every table made there is a monomial on all its childcules but at most one, in particular along a chain (Corollary 20.8), the leaf shares are one for each basis $T \in \mathcal{B}_j$ and letter, the pins of the tree are, for a fixed mark g, the pins $\langle \boldsymbol{\delta} \rangle_e = \mu_e$,*

$e \in \mathcal{E}-g$, of Corollary 18.16 after a change of determinant ±1, and the word is the atom formula, one Gramma on the marks and the letters:

$$\prod_{j:\,s_j>0}\Gamma(s_j)\prod_{j:\,t_j>0}\Gamma(t_j)\,P_F(\mathbf{m};\mathbf{s},\mathbf{t})=\mathsf{G}_{(\boldsymbol{\mu}|_{\mathcal{E}-g};\mathbf{s};\mathbf{t});\,t_F^{(g)}}(\boldsymbol{\theta}\oplus\boldsymbol{\theta}),$$

with $t_F^{(g)}$ the configuration t_F of Theorem 8.9 without its unit columns and without the row of g: on the scales $(\mathcal{E}-g)\sqcup\{v_j\}\sqcup\{w_j\}$, the columns $(\frac12\chi_T|_{\mathcal{E}-g};\mathbf{e}_j;0)$ and $(-\frac12\chi_T|_{\mathcal{E}-g};0;\mathbf{e}_j)$, $T\in\mathcal{B}_j$, each with the coefficient $\theta_{j,T}$, a letter with exponent zero omitted: one scale for each mark but g, which carries an odd pin, and one for each letter.

(iv) The even shares close jointly. *In (iii) let every table have $s_j,t_j>0$, and write $c_{j,T}=b_{j,T}-a_{j,T}=-2\delta_{j,T}$. At fixed differences the K-shares of table j close into one scale,*

$$\int_{\sum_T a_{j,T}=s_j}\prod_{T\in\mathcal{B}_j}\Gamma(a_{j,T})\,\Gamma(a_{j,T}+c_{j,T})\,\theta_{j,T}^{-2a_{j,T}}=\int_0^\infty y^{s_j-1}\prod_{T\in\mathcal{B}_j}\mathsf{G}_{c_{j,T};(1,-1)}\big(1,\theta_{j,T}^2y\big)\,dy,$$

and $\prod_j\Gamma(s_j)\Gamma(t_j)P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ is the fibre integral over the differences, with the pins $\sum_T c_{j,T}=t_j-s_j$ and $-\frac12\sum_{j,T}c_{j,T}\chi_T(e)=\mu_e$, $e\in\mathcal{E}-g$, of $\prod_j\prod_T\theta_{j,T}^{-c_{j,T}}$ times these scale integrals; on the wall contour of the native split (Theorem 18.13(iii)) every integral converges absolutely. The fibre of differences has dimension $\sum_j(|\mathcal{B}_j|-1)-(n-1)$. At the centre, every table riding the line, $s_j=t_j$, with the masses $\sigma\mathbf{1}$, the pins are $\sum_{T\in\mathcal{B}_j}c_{j,T}=0$ for every j and $\sum_j M_j^{\mathsf{T}}\mathbf{c}_j=0$, with $\mathbf{c}_j=(c_{j,T})_{T\in\mathcal{B}_j}$ and the incidence matrices $(M_j)_{Te}=\mathbf{1}_T(e)$, and the contour is $\operatorname{Re}\mathbf{c}=0$.

Built back up, the word is the period read from its atoms. At every node the childcules multiply and the pins see only the odd shares; along a chain nothing is opened twice, and the word is the atom formula itself, one Gramma on the marks and the letters whose configuration is that of the interest with the masses' own columns removed. The even shares are free but for their sums, and they close table by table into one scale of Grammas $\mathsf{G}_{\nu;(1,-1)}$, as at the centre of a molecule (Theorem 20.11(iv)) and for the table that is one circuit (Corollary 18.24).

20.4 Closing the tree by draws

Proposition 20.12 (The draw series)**.** *Let $U=(U_Q)_{Q\in\mathcal{P}}$ have independent blocks $U_Q\sim\operatorname{Dir}_{\mathbf{m}|_Q}$ on a partition $\mathcal{P}$ of the marks, and let $P_1,\dots,P_q$ be nonzero polynomials with nonnegative coefficients, P_i homogeneous of degree $g_{i,Q}$ in the variables of each block Q. For an exponent vector $\mathbf{a}$ with block sums $g_{i,Q}$ put $b_{\mathbf{a}}=\prod_Q g_{i,Q}!/\prod_e a_e!$ and $C_i=\max_{\mathbf{a}}\big([u^{\mathbf{a}}]P_i\big)/b_{\mathbf{a}}$. Then $\prod_Q\big(\sum_{e\in Q}u_e\big)^{g_{i,Q}}-P_i/C_i$ has nonnegative coefficients and equals $1-P_i/C_i\in[0,1)$ on the interior of the source, and for $\nu_i\ge0$*

$$\mathbb{E}_{U\sim\bigotimes_Q\operatorname{Dir}_{\mathbf{m}|_Q}}\Big[\prod_i P_i(U)^{-\nu_i}\Big]=\prod_i C_i^{-\nu_i}\sum_{\mathbf{k}\in\mathbb{N}^q}\prod_i\frac{(\nu_i)_{k_i}}{k_i!}\times\mathbb{E}_{U\sim\bigotimes_Q\operatorname{Dir}_{\mathbf{m}|_Q}}\Big[\prod_i\Big(1-\frac{P_i(U)}{C_i}\Big)^{k_i}\Big],$$

every term nonnegative, both sides finite or infinite together. The left side is the Trailmoment of Proposition 5.22,

$$\Big(\mathsf{T}_{\boldsymbol{\nu};I_q}[(P_i)_i]\bigotimes_Q\operatorname{Dir}_{\mathbf{m}|_Q}\Big)\Big(\prod_Q\Delta_Q\Big),$$

and each expectation on the right is a finite nonnegative combination of the moments of Theorem 3.11. For a family $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$ *with* $s_j, t_j \geq 0$*, one block,* $P_{2j-1} = K_j$ *and* $P_{2j} = \Psi_j$ *with the indices* (s_j, t_j)*, the constants are* $C_{2j-1} = \theta_{j,\max}/r_j!$ *and* $C_{2j} = \theta_{j,\max}/(n-r_j)!$*,* $\theta_{j,\max} = \max_T \theta_{j,T}$*; the left side times* $\Gamma_1^n \begin{bmatrix} \mathbf{m} \\ m_{\mathcal{E}} \end{bmatrix}$ *is* $\int_{\Delta_\mathcal{E}} u^{\mathbf{m-1}} \prod_j K_j(u)^{-s_j} \Psi_j(u)^{-t_j}\, d\omega_\mathcal{E}(u)$*, which on the balance wall is* $P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$*; and the expectation of the term* $\mathbf{k} = (k_j, l_j)_j$ *is the chance that, in the urn that draws a mark with probability proportional to its current mass and then adds one to that mass, for* $j = 1, \dots, N$ *in turn* k_j *rounds of* r_j *draws and then* l_j *rounds of* $n - r_j$ *draws all fail for table* j*, a round failing when its marks are not a basis, respectively not a cobasis, of table* j*, and, when they are the basis* T*, respectively the cobasis* $\mathcal{E} \setminus T$*, with probability* $1 - \theta_{j,T}/\theta_{j,\max}$*: a finite nonnegative combination of Dirichlet moments, a finite sum of them for lists. This series is Theorem 15.13(i) with the references* $M_{2j-1} = C_{2j-1}$ *and* $M_{2j} = C_{2j}$*.*

Corollary 20.13 (At $\delta = 0$ and at a full lean the period reads the law of one letter for each table)**.** *Let a family* $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$*, every table active, carry its masses* $\mathbf{m}$ *on the balance wall with every proper wall positive, every table riding the line,* $(s_j, t_j) = (\sigma_j, \sigma_j)$*, or at a full lean,* $(s_j, 0)$ *or* $(0, t_j)$*. Put* $L_j = \mathbf{E}_j = K_j \Psi_j$ *and* $\nu_j = \sigma_j$ *when table* j *rides the line,* $L_j = K_j$ *and* $\nu_j = s_j$ *at* $(s_j, 0)$*, and* $L_j = \Psi_j$ *and* $\nu_j = t_j$ *at* $(0, t_j)$*, and let* $\phi_\mathbf{m}$ *be the joint law of* $(L_1(U), \dots, L_N(U))$ *for* $U \sim \mathrm{Dir}_\mathbf{m}$ *(Proposition 8.12). The kernel* $\prod_j a_j^{-s_j} b_j^{-t_j}$ *of the letters* $a_j = K_j$ *and* $b_j = \Psi_j$ *is the kernel* $\mathsf{Z}_{\boldsymbol{\nu}; I_N}\big((L_j)_j\big)$*, one scale for each table, so*

$$P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \Gamma_1^n \begin{bmatrix} \mathbf{m} \\ m_{\mathcal{E}} \end{bmatrix} \big(\mathsf{T}_{\boldsymbol{\nu}; I_N}[\mathrm{id}]\, \phi_\mathbf{m}\big)\big((0,\infty)^N\big);$$

with one table $\phi_\mathbf{m}$ *is a law on the half-line and the right side is* $\Gamma_1^n \begin{bmatrix} \mathbf{m} \\ m_{\mathcal{E}} \end{bmatrix} (\mathsf{T}_{\nu;(1)}[x]\, \phi_\mathbf{m})((0,\infty))$*, at* $\delta = 0$ *the law* $\mathbf{E}_* \mathrm{Dir}_\mathbf{m}$ *of the even letter* $\mathbf{E}(U) = K(U)\Psi(U)$ *(Theorem 5.9). The law* $\phi_\mathbf{m}$ *is carried by* $\prod_j (0, \max_{\Delta_\mathcal{E}} L_j]$*, it is determined by its moments, and its moments are finite sums of Dirichlet moments (Theorem 3.11).*

Theorem 20.14 (The draw series along a chain)**.** *Let a family* $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$ *have the exponents* $s_j, t_j \geq 0$ *and masses* $\mathbf{m} \in \mathbb{R}^\mathcal{E}_{>0}$*, and let* $M_0 = \mathcal{E} \supset M_1 \supset \cdots \supset M_d$ *be a chain of sets with* $B_i = M_i \setminus M_{i+1}$*,* $i < d$*, and* $S_i = B_0 \sqcup \cdots \sqcup B_{i-1}$*,* $S_0 = \varnothing$*,* $S_{d+1} = \mathcal{E}$*. A round of draws* extends on S *for table* j *when its draws inside* S *are distinct and are* $T \cap S$ *for some basis* T *of table* j*. In this statement write* $\theta_j(S; P)$ *for the largest weight* $\theta_{j,T}$ *over the bases* T *of table* j *with* $T \cap S = P$*, and say that a round that extends on* S_i *and on* S_{i+1}*, with the traces* P_i *and* P_{i+1}*, is* accepted at S_{i+1} *with probability* $\theta_j(S_{i+1}; P_{i+1})/\theta_j(S_i; P_i)$*, independently for each* i*. Let* $\mathfrak{f}_{j,i}(u)$*,* $0 \leq i \leq d$*, be the chance that a round of* r_j *draws from* u *extends on* S_i *and is accepted at* $S_1, \dots, S_i$ *but does not both extend on* S_{i+1} *and get accepted there, and* $\mathfrak{f}^*_{j,i}$ *the same for rounds of* $n - r_j$ *draws and the cobases* $\mathcal{E} \setminus T$ *with the weights* $\theta_{j,T}$*. Then, with* $\theta_{j,\max}$ *the largest weight of table* j*,* $1 - r_j!\, K_j/\theta_{j,\max} = \sum_i \mathfrak{f}_{j,i}$*,* $1 - (n-r_j)!\, \Psi_j/\theta_{j,\max} = \sum_i \mathfrak{f}^*_{j,i}$*, and*

$$\int_{\Delta_\mathcal{E}} u^{\mathbf{m-1}} \prod_j K_j^{-s_j} \Psi_j^{-t_j}\, d\omega_\mathcal{E} = \Gamma_1^n \begin{bmatrix} \mathbf{m} \\ m_{\mathcal{E}} \end{bmatrix} \prod_j \Big(\frac{r_j!}{\theta_{j,\max}}\Big)^{s_j} \Big(\frac{(n-r_j)!}{\theta_{j,\max}}\Big)^{t_j} \times \sum_{\mathbf{k},\mathbf{l}} \prod_j \frac{(s_j)_{|\mathbf{k}_j|}\, (t_j)_{|\mathbf{l}_j|}}{\mathbf{k}_j!\, \mathbf{l}_j!}\ \mathbb{E}_{U \sim \mathrm{Dir}_\mathbf{m}}\Big[\prod_{j,i} \mathfrak{f}_{j,i}(U)^{k_{j,i}}\, \mathfrak{f}^*_{j,i}(U)^{l_{j,i}}\Big],$$

over $\mathbf{k}_j, \mathbf{l}_j \in \mathbb{N}^{d+1}$*, every term a finite nonnegative combination of Dirichlet moments, a finite sum of them for lists, whose rounds are always accepted. The numbers* $\sum_{i' \geq i} k_{j,i'}$ *of failing basis rounds of table* j *that pass* $B_0, \dots, B_{i-1}$ *decrease with* i*: they are nested, as the coordinates of the region* X_N *of a trail are (Definition 5.23). Let a bijection* g *keep each* B_i *and the masses, let* h *be a bijection of the tables, and put* $(g_* u)_{g(e)} = u_e$*. If* g *maps the bases of every table* j *onto those of table* $h(j)$ *with their weights, then* $\mathfrak{f}_{h(j),i}(g_* u) = \mathfrak{f}_{j,i}(u)$ *and* $\mathfrak{f}^*_{h(j),i}(g_* u) = \mathfrak{f}^*_{j,i}(u)$*; if* $T \mapsto \mathcal{E} \setminus g(T)$ *does, then* $\mathfrak{f}^*_{h(j),i}(g_* u) = \mathfrak{f}_{j,i}(u)$ *and* $\mathfrak{f}_{h(j),i}(g_* u) = \mathfrak{f}^*_{j,i}(u)$*, and the array of expectations is unchanged when every* $(\mathbf{k}_j, \mathbf{l}_j)$ *is replaced by* $(\mathbf{l}_{h^{-1}(j)}, \mathbf{k}_{h^{-1}(j)})$*; for one table, where an exchange forces* $2r = n$*, this is the symmetry under* $\mathbf{k} \leftrightarrow \mathbf{l}$*.*

Theorem 20.15 (The draw series along a tree)**.** *Let a molecule* $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_j$ *on* $\mathcal{E}$ *carry* $s_j, t_j \geq 0$ *and masses* $\mathbf{m} \in \mathbb{R}^{\mathcal{E}}_{>0}$*, and take a tree of bunches (Definition 20.7) at every node of which the children's weights factor across the childcules, as they do for lists: for a table* $\mathcal{B}'$ *at a node* v *and a pattern* p *of* $\mathcal{B}'$ *at* B_v*, the restrictions* $\mathcal{B}'_{(p)}|R_{v,i}$ *of the child to the childcules (Proposition 7.9) carry weights whose products are the weights of the child,* $\theta_{(p),X} = \prod_i \theta_{(p),i}(X \cap R_{v,i})$*. Write* $\theta_{\max}(\mathcal{B}')$ *for the largest weight of a table* $\mathcal{B}'$*, and say that a round of draws that is a basis* T *of* $\mathcal{B}'$ *is* accepted *with probability* $\theta_T / \theta_{\max}(\mathcal{B}')$*. A cobasis round of table* j *is a basis round of its dual table, whose children are the duals of the children, with the same weights (Lemma 14.7(ii) with the identity). The* coordinates of the tree *are, at each node* v*, the totals* $x^{(v)} \in \Delta_{\{B_v, R_{v,1}, \dots, R_{v,q_v}\}}$ *of the shape of* M_v *on its blocks and the shape* $u^{(v)} \in \Delta_{B_v}$ *of the bunch; under* $\mathrm{Dir}_{\mathbf{m}}$ *they are independent, with the laws* $\mathrm{Dir}_{(m_{B_v}, m_{R_{v,1}}, \dots, m_{R_{v,q_v}})}$ *and* $\mathrm{Dir}_{\mathbf{m}|_{B_v}}$ *(Theorem 3.12). For a table* $\mathcal{B}'$ *at a node write its chances as functions of the coordinates of the subtree of that node.*

(i) A round passes a node, then each childcule. *For a table* $\mathcal{B}'$ *of rank* r' *at a node* v*, the chance* $\mathfrak{s}_{\mathcal{B}'} = r'! \, K_{\mathcal{B}'} / \theta_{\max}(\mathcal{B}')$ *that* r' *draws from the shape of* M_v *are a basis of* $\mathcal{B}'$ *and are accepted is*

$$\mathfrak{s}_{\mathcal{B}'} = \sum_p \mathfrak{p}_{\mathcal{B}',p} \prod_i \mathfrak{s}_{\mathcal{B}'_{(p)}|R_{v,i}},$$

$$\mathfrak{p}_{\mathcal{B}',p} = \frac{\prod_i \theta_{\max}\big(\mathcal{B}'_{(p)}|R_{v,i}\big)}{\theta_{\max}(\mathcal{B}')} \, \frac{r'!}{\prod_i r'_{p,i}!} \, \big(x^{(v)}_{B_v}\big)^{|p|} \big(u^{(v)}\big)^p \prod_i \big(x^{(v)}_{R_{v,i}}\big)^{r'_{p,i}},$$

over the patterns p *of* $\mathcal{B}'$ *at* B_v*, with* $r'_{p,i}$ *the rank on* $R_{v,i}$ *of the child* $\mathcal{B}'_{(p)}$*:* $\mathfrak{p}_{\mathcal{B}',p}$ *is the chance that the round* passes v *showing* p*, its draws in* B_v *being the marks of* p *and its numbers of draws in the childcules the* $r'_{p,i}$*, and is accepted there, with the probability given by its first factor, which is at most* 1*; and* $\mathfrak{s}_{\mathcal{B}'_{(p)}|R_{v,i}}$ *is the chance that its draws in* $R_{v,i}$ *are a basis of the restriction of the child there and are accepted. At a leaf* $\mathfrak{s}_{\mathcal{B}'} = r'! \, K_{\mathcal{B}'} / \theta_{\max}(\mathcal{B}')$*.*

(ii) A failure is met at one node. *The chance* $1 - \mathfrak{s}_{\mathcal{B}'}$ *that the round fails, by not being a basis or by not being accepted, is* $\sum_w \mathfrak{f}_{\mathcal{B}' \to w}$ *over the nodes and leaves* w *of the subtree of* v*, where* $\mathfrak{f}_{\mathcal{B}' \to v} = 1 - \sum_p \mathfrak{p}_{\mathcal{B}',p}$ *and, for* w *in the subtree of* $R_{v,i}$*,*

$$\mathfrak{f}_{\mathcal{B}' \to w} = \sum_p \mathfrak{p}_{\mathcal{B}',p} \prod_{i' < i} \mathfrak{s}_{\mathcal{B}'_{(p)}|R_{v,i'}} \; \mathfrak{f}_{\mathcal{B}'_{(p)}|R_{v,i} \to w},$$

the chance that the round first fails at w*. Each* $\mathfrak{f}_{\mathcal{B}' \to w}$ *is a finite sum of products, over the blocks of the tree, of polynomials with nonnegative coefficients in one block each.*

(iii) The series. *With* $\mathfrak{f}_{j,w}$ *and* $\mathfrak{f}^*_{j,w}$ *these chances for the basis and the cobasis rounds of table* j *of* F *from the root, and* $\theta_{j,\max}$ *the largest weight of table* j*,*

$$\int_{\Delta_{\mathcal{E}}} u^{\mathbf{m}-\mathbf{1}} \prod_j K_j^{-s_j} \Psi_j^{-t_j}\, d\omega_{\mathcal{E}} = \Gamma_1^n \begin{bmatrix} \mathbf{m} \\ m_{\mathcal{E}} \end{bmatrix} \prod_j \Big(\frac{r_j!}{\theta_{j,\max}}\Big)^{s_j} \Big(\frac{(n-r_j)!}{\theta_{j,\max}}\Big)^{t_j}$$
$$\times \sum_{\mathbf{k},\mathbf{l}} \prod_j \frac{(s_j)_{|\mathbf{k}_j|}\,(t_j)_{|\mathbf{l}_j|}}{\mathbf{k}_j!\,\mathbf{l}_j!}\ \mathbb{E}_{U\sim \mathrm{Dir}_{\mathbf{m}}}\Big[\prod_{j,w} \mathfrak{f}_{j,w}(U)^{k_{j,w}}\, \mathfrak{f}^*_{j,w}(U)^{l_{j,w}}\Big],$$

every term nonnegative, both sides finite or infinite together; on the balance wall the left side is $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$. Each expectation is a finite nonnegative combination of products over the blocks of Dirichlet moments, a finite sum of them for lists: at every node, the node's own moments times the product over its childcules of theirs.

(iv) Nesting along the tree. *The numbers $k_{j,\geq w} = \sum_{w'} k_{j,w'}$, over the w' in the subtree of w, of the basis rounds of table j that first fail in the subtree of w, satisfy $k_{j,\geq w} = k_{j,w} + \sum_{w'} k_{j,\geq w'}$ over the childcules w' of w, and likewise for the cobasis rounds: along every descent they are nested, as the coordinates of the region X_N of a trail are (Definition 5.23). On a chain this is Theorem 20.14.*

At nonnegative exponents every share of the word closes at once. The draw series closes each letter about its largest coefficient on the simplex, and the tree only sorts its failures: a round that fails is charged to the first node at which it stops passing, the chances of passing are monomials in the coordinates of that node, and the coordinates of different nodes are independent. So every term is a nonnegative combination of products, over the blocks of the tree, of Dirichlet moments, and the counts of failures nest along the descents as the coordinates of the region X_N of a trail do.

Corollary 20.16 (What each node of a chain integrates)**.** *Let the tree of a molecule on n marks be a chain $M_0 \supset M_1 \supset \cdots \supset M_d$ with bunches B_k and rooms $R_k = M_{k+1}$. The simplex of the molecule is the product*

$$\Delta_{M_0} \cong \prod_{k=0}^{d-1} \Big(\Delta_{B_k} \times \Delta_{\{B_k,R_k\}}\Big) \times \Delta_{M_d}$$

of the shape of each bunch, the totals of the bunch and its room at each node, and the shape of the leaf, and under $\mathrm{Dir}_{\mathbf{m}}$ these coordinates are independent: they are the coordinates of the tree of Theorem 20.15, which use no weights. The node of B_k has $|B_k|$ coordinates, $|B_k|-1$ of shape and one total, the leaf has $|M_d|-1$, and they add up to $n-1$. When some active table is connected, the Foreman tree, which is then a chain, has, at the centre and at every lean, no node with more coordinates than the leaf has marks (Corollary 20.9).

Proposition 20.17 (Rates at the centre)**.** *Let a family on $n \geq 3$ marks be at the centre, every table with the exponents (σ_j,σ_j), with the masses $\sigma\mathbf{1}$, $\sigma = \sum_j \sigma_j$, and let every active table be connected.*

(i) The walls are $\kappa_S = \sum_j \sigma_j c_j(S)$ (Proposition 8.21(ii)), so $\kappa_S = \kappa_{\mathcal{E}\setminus S}$.

(ii) The rate of the peak closing (Theorem 15.13(ii)) is $\varpi = \sigma/\max_j \max(r_j-1, n-r_j-1)$, the maximum over the active tables, attained at the faces $S = \mathcal{E}-e$, where every active table has $c_j = 1$, $d_j = r_j - 1$ and $d_j^* = n - r_j - 1$.

(iii) Near the vertex of e, with $u_e = 1-x$ and $u_{\mathcal{E}-e} = xv$, $v \in \Delta_{\mathcal{E}-e}$, every active table has

$$K_j(u) = (1-x)\,x^{r_j-1} K_{j,/e}(v) + x^{r_j} K_{j,\setminus e}(v),$$
$$\Psi_j(u) = (1-x)\,x^{n-r_j-1} \Psi_{j,\setminus e}(v) + x^{n-r_j} \Psi_{j,/e}(v);$$

the vertex product *of e in table j is $K_{j,/e}\Psi_{j,\setminus e}$, the product of the letters of the two minors that dominate as $x \to 0$.*

(iv) For two marks e, f and a bijection β with $\beta(e) = f$ that carries or exchanges the family, with the bijection h of its tables, the restriction $\beta : \mathcal{E} - e \to \mathcal{E} - f$ takes the vertex product of e in table j to that of f in table $h(j)$. For one table such a β exists exactly when e and f lie in one class at the centre (Corollary 11.16).

20.5 Devices at the centre

Proposition 20.18 (The half-sum and the difference of a table with $2r = n$)**.** *Let $F = ((\mathcal{B}, \theta); \sigma, \sigma)$, $\sigma > 0$, have $2r = n$ and masses $\mathbf{m}$ on its balance wall. The half-sum $\frac{1}{2}(K + \Psi) = \frac{1}{2}\sum_T \theta_T\big(\alpha^T + \alpha^{\mathcal{E}\setminus T}\big)$ is homogeneous of degree r and unchanged by $T \mapsto \mathcal{E} \setminus T$; the difference $K - \Psi$ vanishes at the table's gauge; in signed coordinates they are $e^{\langle \mathbf{1}, z\rangle} L_{1/2}(z)$ and $e^{\langle \mathbf{1}, z\rangle}\partial_w L_w(z)$ (Definition 20.2). Then $K\Psi = \big(\frac{1}{2}(K + \Psi)\big)^2 - \frac{1}{4}(K - \Psi)^2$ with $|K - \Psi| < K + \Psi$ on the orthant, and by Proposition 20.1*

$$(K\Psi)^{-\sigma} = \sum_{l \geq 0} \frac{(\sigma)_l}{l!\, 4^l}\, (K - \Psi)^{2l} \Big(\frac{K + \Psi}{2}\Big)^{-2\sigma - 2l},$$

a series of nonnegative terms. For a mark e with room $R = \mathcal{E} - e$ write $\frac{1}{2}(K + \Psi) = h_0(\alpha_R) + \alpha_e h_1(\alpha_R)$, so that, by Definition 7.3, $h_0 = \frac{1}{2}(K_{\setminus e} + \Psi_{/e})$, $h_1 = \frac{1}{2}(K_{/e} + \Psi_{\setminus e})$ and $h_1(u) = u^R h_0(u^{-1})$. Expanding $(K - \Psi)^{2l} = \sum_{\mathbf{a}} \big([\alpha^{\mathbf{a}}](K - \Psi)^{2l}\big)\, \alpha^{\mathbf{a}}$ and integrating the mark e of each term as the Beta corner of a linear letter (Proposition 15.1 with one coefficient), with $w_l = 2\sigma + 2l$,

$$P_F(\mathbf{m}; \sigma, \sigma) = \sum_{l \geq 0} \frac{(\sigma)_l}{l!\, 4^l} \sum_{\mathbf{a}} \big([\alpha^{\mathbf{a}}](K - \Psi)^{2l}\big)\, \Gamma_{\substack{2\\1}}\begin{bmatrix} m_e + a_e, & w_l - m_e - a_e \\ & w_l \end{bmatrix} \times \int_{\Delta_R} u^{(\mathbf{m}+\mathbf{a})|_R - \mathbf{1}} h_0(u)^{-(w_l - m_e - a_e)} h_1(u)^{-(m_e + a_e)}\, d\omega_R(u),$$

whenever the terms converge absolutely.

The half-sum is a positive polynomial whose support is closed under complements, but it is not in general the basis polynomial of a table: the bases together with the cobases need not have the exchange property, even for connected tables, so the integrals left over the room are integrals of a positive polynomial against its complement and not periods of a family. When complementation maps the bases onto themselves the difference vanishes and the room is a period.

Corollary 20.19 (Merged Skeleton values)**.** *If $T \mapsto \mathcal{E} \setminus T$ maps the bases of a table $(\mathcal{B}, \theta)$ onto themselves with $\theta_{\mathcal{E}\setminus T} = \theta_T$, then $2r = n$, no mark is a loop or a coloop, $\Psi = K$, $\Psi_{\setminus e} = K_{/e}$ and $\Psi_{/e} = K_{\setminus e}$ for every mark e, and the two Skeleton values of the scale of e coincide at every gauge (Corollary 15.4). For $F = ((\mathcal{B}, \theta); s, t)$ with $s, t \geq 0$, $s + t > 0$, its masses on the balance wall with every proper wall positive, and a mark e, one has $0 < m_e < s + t$ and*

$$P_F(\mathbf{m}; s, t) = \Gamma_{\substack{2\\1}}\begin{bmatrix} m_e, & s + t - m_e \\ & s + t \end{bmatrix}\, P_{\mathcal{B}\setminus e}\big(\mathbf{m}|_{\mathcal{E}-e};\, s + t - m_e,\, m_e\big),$$

the period of the deletion $(\mathcal{B} \setminus e, \theta)$ on $\mathcal{E} - e$ at the exponents $(s + t - m_e, m_e)$, on its balance wall; so $P_F(\mathbf{m}; s, t)$ depends on the exponents only through $s + t$, and at the centre, $s = t = \sigma$ and $\mathbf{m} = \sigma\mathbf{1}$, the identity reads $P_F(\sigma\mathbf{1}; \sigma, \sigma) = \Gamma_{\substack{2\\1}}\begin{bmatrix} \sigma, & \sigma \\ & 2\sigma \end{bmatrix}\, P_{\mathcal{B}\setminus e}(\sigma\mathbf{1}|_{\mathcal{E}-e}; \sigma, \sigma)$.

Theorem 20.20 (The scale integral of one mark)**.** *Let a family $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_j$ carry real exponents $s_j, t_j \geq 0$, its masses on the balance wall with every proper wall positive, and let e be a mark that is neither a loop nor a coloop in any active table, with room $R = \mathcal{E} - e$; write $\Lambda_{j,\backslash e}$ and $\Lambda_{j,/e}$ for the centred polynomials of the deletion and the contraction of table j, so that $\Lambda_j(z) = e^{z_e}\Lambda_{j,/e}(z_R) + e^{-z_e}\Lambda_{j,\backslash e}(z_R)$ (Theorem 12.7).*

(i) At the gauge $(1, e^{2z_R})$ the scale integral of the bunch $\{e\}$ (Theorem 15.3) is

$$\begin{aligned}&\mathrm{Sc}_{\{e\}}\big((1, e^{2z_R}); \mathbf{m}; \mathbf{s}, \mathbf{t}\big)\\ &= e^{-2\sigma\langle \mathbf{1}, z_R\rangle}\int_0^\infty x^{m_e-1}\prod_j \big(\Lambda_{j,\backslash e}(z_R) + x\Lambda_{j,/e}(z_R)\big)^{-s_j}\big(\Lambda_{j,/e}(-z_R) + x\Lambda_{j,\backslash e}(-z_R)\big)^{-t_j}dx,\end{aligned}$$

$\sigma = \sum_j \sigma_j$ the total strength: up to the factor $e^{-2\sigma\langle \mathbf{1}, z_R\rangle}$ it depends only on m_e, the exponents and the functions $\Lambda_{j,\backslash e}$ and $\Lambda_{j,/e}$ on the room, and Corollary 16.6 at the bunch $\{e\}$ reads, for every $g \in R$,

$$P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = 2^{n-2}\int_{\mathbb{R}^{R-g}} e^{2\langle \mathbf{m}|_R, z_R\rangle}\ \mathrm{Sc}_{\{e\}}\big((1, e^{2z_R}); \mathbf{m}; \mathbf{s}, \mathbf{t}\big)\, dz_{R-g}\Big|_{z_g=0}.$$

(ii) At an atom $\Upsilon = ((s_j, t_j)_j; \alpha^\star)$ with its target $\boldsymbol{\tau}$, under $\mathrm{Breta}^\circ(F; \boldsymbol{\tau}; \mathbf{s}, \mathbf{t})$ the law of the log-ratios $(y_{g_k} - y_e)_{k=1}^{n-1}$, read in an order $\mathbf{g}_e$ of the room that writes the potential from e as the one pair of functions of Proposition 10.4, does not depend on e.

(iii) For one table at the centre, $s = t = \sigma$ and $\boldsymbol{\mu} = 0$, with the even statistics $E_{\backslash e}$ and $E_{/e}$ of the deletion and the contraction (Theorem 7.16) and a two-element set J, the functions of z_R understood,

$$\begin{aligned}&\int_0^\infty x^{\sigma-1}\big(\Lambda_{\backslash e} + x\Lambda_{/e}\big)^{-\sigma}\big(\Lambda_{/e}(-\cdot) + x\Lambda_{\backslash e}(-\cdot)\big)^{-\sigma}dx\\ &\qquad = e^{-\frac{\sigma}{2}(E_{\backslash e}+E_{/e})}\,\mathsf{B}^{\{J\}}_{(\sigma,\sigma),\,\sigma;\,I_J}\big(e^{\frac{1}{2}(E_{\backslash e}-E_{/e})},\, e^{\frac{1}{2}(E_{/e}-E_{\backslash e})}\big),\end{aligned}$$

and the Breta is ${}_1^{}\Gamma_2^{}\left[\begin{matrix}\sigma,\ \sigma\\ 2\sigma\end{matrix}\right]$ where the two even statistics agree.

For one table at the centre the scale integral of a mark is the factor $e^{-\frac{\sigma}{2}(E_{\backslash e}+E_{/e})}$ times a Breta that sees the room through one number, the difference of the even statistics of the deletion and the contraction; at an atom the law of the log-ratios read from a mark does not depend on the mark. Proposition 20.21 reads the scale integral of the mark with the exponents in the shape index.

Proposition 20.21 (A mark is the Breta of its children's even letters)**.** *For one table, a mark e that is neither a loop nor a coloop, exponents $s, t > 0$, $0 < m_e < s+t$ and the top wall $\kappa^{\mathrm{top}}_{\{e\}} = s+t-m_e$, integrating $\alpha_e = x$ with the room fixed,*

$$\int_0^\infty x^{m_e-1}K^{-s}\Psi^{-t}\,dx = K_{/e}^{\,t-m_e}\Psi_{\backslash e}^{\,s-m_e}\,{}_2^{}\Gamma_2^{}\left[\begin{matrix}m_e,\ \kappa^{\mathrm{top}}_{\{e\}}\\ s,\ t\end{matrix}\right]\ \mathsf{B}^{\{J\}}_{(s,t),\,\kappa^{\mathrm{top}}_{\{e\}};\,I_J}\big(\mathbf{E}_{\backslash e}, \mathbf{E}_{/e}\big),$$

with $\mathbf{E}_{\backslash e} = K_{\backslash e}\Psi_{\backslash e}$ and $\mathbf{E}_{/e} = K_{/e}\Psi_{/e}$ the even letters of the deletion and the contraction, J a two-element set, and

$$\mathsf{B}^{\{J\}}_{(s,t),\,\kappa;\,I_J}(a, b) = \int_0^1 w^{s-1}(1-w)^{t-1}\,\mathsf{Z}_{\kappa;(1)}\big(wa + (1-w)b\big)\,dw,$$

the shape w of J weighing the deletion against the contraction. At the centre, $s = t = m_e = \sigma$, the prefactor and the stacked Gamma are 1.

The same scale integral is the Breta of Corollary 19.29 for the bunch $\{e\}$, whose levels d and r have the children $\mathcal{B}\setminus e$ and $\mathcal{B}/e$: there the walls $(m_e, \kappa^{\mathrm{top}}_{\{e\}})$ fill the shape index and the exponent t the scale index, here the exponents (s,t) fill the shape index and the top wall the scale index. Both read the scale integral of the mark through the even letters of the two children, the deletion and the contraction.

20.6 The junction under level form

Lemma 20.22 (An even power of $e^{v}-e^{-v}$ on a symmetric two-sided scale)**.** *For $\xi>0$ and $l\in\mathbb{N}$,*

$$\int_{\mathbb{R}} \big(e^{v}-e^{-v}\big)^{2l} e^{-\xi(e^{v}+e^{-v})}\,dv = 4^{l}\big(\tfrac{1}{2}\big)_{l}\,\xi^{-l}\,\mathsf{G}_{l;(1,-1)}(\xi,\xi).$$

Theorem 20.23 (The junction under level form)**.** *Let $F=((\mathcal{B}_j,\theta_j);\sigma_j,\sigma_j)_{j=1}^{N}$, every $\sigma_j>0$, be a molecule on n marks with the masses $\sigma\mathbf{1}$, $\sigma=\sum_j\sigma_j$, let B, $b=|B|$, be a proper bunch with room R such that every transposition of two marks of B fixing the rest carries or exchanges every table, and let $g\in R$. By Proposition 20.6 every half-sum has level form; in this statement write $q_{j,k}(z_R)$ for the common value of $c_{j,p}(\frac{1}{2};z_R)$ over $|p|=k$ and $\mathbf{q}_j=(q_{j,0},\dots,q_{j,b})$, so that $q_{j,b-k}(-z_R)=q_{j,k}(z_R)$ and*

$$L_{j,1/2}(z)=\sum_{k=0}^{b} e^{-\langle\mathbf{1},z_B\rangle}e_k\big(e^{2z_B}\big)\,q_{j,k}(z_R),\qquad e^{-\langle\mathbf{1},z_B\rangle}e_k\big(e^{2z_B}\big)=\sum_{|p|=k}e^{\langle z_B,\chi_p\rangle},$$

the centred polynomial of the list on B whose bases are the k-subsets of B; and for each $\mathbf{l}=(l_j)_j\in\mathbb{N}^N$

$$\prod_j\big(\partial_w L_{j,w}(z)\big)^{2l_j}=e^{-2|\mathbf{l}|\langle\mathbf{1},z_B\rangle}\sum_{|\mathbf{h}|=2|\mathbf{l}|}\prod_{k=0}^{b}e_k\big(e^{2z_B}\big)^{h_k}\,c^{(\mathbf{l})}_{\mathbf{h}}(z_R),$$

with $c^{(\mathbf{l})}_{\mathbf{h}}$ Laurent polynomials in e^{z_R}.

(i) With the Gramma $\mathsf{G}_{0;(\chi_p)_{p\subseteq B}}\big((\upsilon_{|p|})_{p\subseteq B}\big)$, $\boldsymbol{\upsilon}=(\upsilon_0,\dots,\upsilon_b)$, whose coefficients depend on $|p|$ alone and which depends on B through b alone,

$$P_F(\sigma\mathbf{1};\boldsymbol{\sigma},\boldsymbol{\sigma})=2^{n-1}\sum_{\mathbf{l}\in\mathbb{N}^N}\prod_j\frac{(\sigma_j)_{l_j}}{l_j!\,4^{l_j}\,\Gamma(2\sigma_j+2l_j)}\int_{\mathbb{R}^{R-g}}\int_{(0,\infty)^N}\prod_j y_j^{2\sigma_j+2l_j-1}$$
$$\times\sum_{|\mathbf{h}|=2|\mathbf{l}|}c^{(\mathbf{l})}_{\mathbf{h}}(z_R)\Big((-\partial_{\boldsymbol{\upsilon}})^{\mathbf{h}}\,\mathsf{G}_{0;(\chi_p)_p}\big((\upsilon_{|p|})_p\big)\Big)\Big|_{\boldsymbol{\upsilon}=\sum_j y_j\mathbf{q}_j(z_R)}\,d\mathbf{y}\,dz_{R-g}\Big|_{z_g=0},$$

the inner sum being $\int_{\mathbb{R}^B}\prod_j\big(\partial_w L_{j,w}(z)\big)^{2l_j}e^{-\sum_j y_j L_{j,1/2}(z)}\,dz_B\ge 0$, a level with $\sum_j y_j q_{j,k}=0$ absent.

(ii) One mark at a time. *For $e\in B$, $B'=B-e$ and $\boldsymbol{\upsilon}>0$,*

$$\mathsf{G}_{0;(\chi_p)_{p\subseteq B}}\big((\upsilon_{|p|})_p\big)=\int_0^{\infty}\mathsf{G}_{0;(\chi_p)_{p\subseteq B'}}\big((x\,\upsilon_{|p|+1}+x^{-1}\upsilon_{|p|})_p\big)\,\frac{dx}{x},$$

and for $B=\{e\}$ this Gramma is $\mathsf{G}_{0;(1,-1)}(\upsilon_1,\upsilon_0)$.

(iii) The share side. *Let G be the family on B of the lists whose bases are the k-subsets of B, $1 \le k \le b-1$, with the exponents $(a'_k, 0)$, at the masses $\frac{1}{b}\sum_{k=1}^{b-1} k a'_k\, \mathbf{1}_B$ on its balance wall. Where every $\operatorname{Re} a'_k > 0$ its period converges, is unchanged when the exponents of the lists of ranks k and $b-k$ are swapped, and is read on the hyperplane $\langle \mathbf{1}, w\rangle = 0$:*

$$P_G\Big(\tfrac{1}{b}\sum_{k=1}^{b-1} k a'_k\, \mathbf{1}_B; (a'_k)_{k=1}^{b-1}, \mathbf{0}\Big) = 2^{b-1}\sqrt{b}\int_{\langle \mathbf{1}, w\rangle = 0} \prod_{k=1}^{b-1} e_k\big(e^{2w}\big)^{-a'_k}\, d\mathrm{vol}_{b-1}(w).$$

For $\boldsymbol{\upsilon} > 0$ and $\mathbf{h} \in \mathbb{N}^{b+1}$, on a contour with $\operatorname{Re} a_k > h_k$ for every k and with $a'_k = a_k - h_k$,

$$\Big((-\partial_{\boldsymbol{\upsilon}})^{\mathbf{h}}\, \mathsf{G}_{0;(\chi_p)_p}\big((\upsilon_{|p|})_p\big)\Big)(\boldsymbol{\upsilon}) = 2^{1-b}\int_{\sum_{k=0}^{b}(2k-b)(a_k-h_k)=0} \prod_{k=0}^{b} \Gamma(a_k)\, \upsilon_k^{-a_k}\; P_G\Big(\tfrac{1}{b}\sum_{k=1}^{b-1} k a'_k\, \mathbf{1}_B; (a'_k)_{k=1}^{b-1}, \mathbf{0}\Big).$$

(iv) Two marks. *If $B = \{e, f\}$ and the swap of e and f exchanges every table, then with $z_\pm = z_e \pm z_f$, for every j,*

$$L_{j,1/2}(z) = e^{-z_+} c_{j,\varnothing}(\tfrac{1}{2}; z_R) + e^{z_+} c_{j,\varnothing}(\tfrac{1}{2}; -z_R) + \big(e^{z_-} + e^{-z_-}\big) c_{j,\{e\}}(\tfrac{1}{2}; z_R),$$
$$\partial_w L_{j,w}(z) = \big(e^{z_-} - e^{-z_-}\big)\, \partial_w c_{j,\{e\}}(w; z_R),$$

the functions $c_{j,\{e\}}(\frac{1}{2}; \cdot)$ and $\partial_w c_{j,\{e\}}$ are even, and, writing in this statement $C_\varnothing(z_R) = \sum_j y_j c_{j,\varnothing}(\frac{1}{2}; z_R)$ and $C_e(z_R) = \sum_j y_j c_{j,\{e\}}(\frac{1}{2}; z_R)$,

$$P_F(\sigma\mathbf{1}; \boldsymbol{\sigma}, \boldsymbol{\sigma}) = 2^{n-2} \sum_{\mathbf{l}\in\mathbb{N}^N} \big(\tfrac{1}{2}\big)_{|\mathbf{l}|} \prod_j \frac{(\sigma_j)_{l_j}}{l_j!\,\Gamma(2\sigma_j + 2l_j)} \int_{\mathbb{R}^{R-g}} \prod_j \big(\partial_w c_{j,\{e\}}\big)^{2l_j}$$
$$\times \int_{(0,\infty)^N} \prod_j y_j^{2\sigma_j + 2l_j - 1}\, C_e^{-|\mathbf{l}|}\, \mathsf{G}_{0;(1,-1)}\big(C_\varnothing(-z_R),\, C_\varnothing(z_R)\big)$$
$$\times\, \mathsf{G}_{|\mathbf{l}|;(1,-1)}\big(C_e(z_R),\, C_e(z_R)\big)\, d\mathbf{y}\, dz_{R-g}\Big|_{z_g = 0},$$

a series of nonnegative terms.

Under level form the bunch enters only through its levels: one Gramma with one coefficient for each level, which depends on the number of its marks alone and is computed one mark at a time, is differentiated at the level coefficients of the half-sums, added over the tables with their scales, and its share side is a period of the lists of k-subsets of the bunch's own marks. For a pair whose swap exchanges every table the bunch splits along $z_e + z_f$ and $z_e - z_f$ into two Grammas $\mathsf{G}_{\nu;(1,-1)}$.

20.7 The node in one scale

At a bunch of width one the integrand of Theorem 19.13 is, in the even share, the product of two Mellin transforms, one carrying the bunch and one the room. Read back on the half-line, the period is one integral over one scale of two functions, the bunch transform and the room transform, each an integral of a Gramma $\mathsf{G}_{\nu;(1,-1)}$ over its own shape. A closing toward a level is the expansion of one of them in powers of the scale, integrated term by term against the other. The expansion

of a bunch is measured by one number, its reach: every bunch has a reach, no reach lies below the least value of the bunch's ratio, and a node closes on its lattice toward every level at which the growths of its two families multiply to less than one. Each side of a node is an interval, from the decay of its transform to its reach, and, against a room and a bunch bounded below, a node closes on a geometric lattice exactly when the two intervals are disjoint.

Definition 20.24 (Node of width one; its two transforms)**.** A *node of width one*, a node of a tree of bunches (Definition 20.7) whose bunch has width one, is a family $F = ((\mathcal{B}, \theta); s, t)$ with real data, $s, t > 0$, its masses on the balance wall with every proper wall positive, and a bunch B of width one with room R, the weights factoring across them: the setting of Theorem 19.13 for one table. Along the level d its level shares are $(a^d, b^d, a^r, b^r) = (s - \kappa_B + b^d,\ b^d,\ \kappa_B - b^d,\ t - b^d)$, the odd share being fixed at $2\delta^d = s - \kappa_B$; its ratios ϱ_B on Δ_B and ϱ_R on Δ_R are those of Definition 19.2; and σ_*^d is a real value of the even share at which both families converge and the four arguments of its stacked Gamma are positive, so that the line $\operatorname{Re}\sigma^d = \sigma_*^d$ is a contour of Theorem 19.13, with $b_* = \sigma_*^d - \delta^d > 0$ the real part of b^d there. The node carries the nonnegative measures

$$\phi_B(du) = u^{\mathbf{m}|_B - \mathbf{1}} K_{\mathcal{B}/R}^{-(s-\kappa_B)} K_{\mathcal{B}|B}^{-\kappa_B} \Psi_{\mathcal{B}|B}^{-t}\, d\omega_B(u) \quad \text{on } \Delta_B,$$
$$\phi_R(dv) = v^{\mathbf{m}|_R - \mathbf{1}} K_{\mathcal{B}|R}^{-(s-\kappa_B)} K_{\mathcal{B}/B}^{-\kappa_B} \Psi_{\mathcal{B}/B}^{-t}\, d\omega_R(v) \quad \text{on } \Delta_R,$$

the forms of the bunch family and of the room family at the level share $b^d = 0$; Chapter 23 calls ϕ_B the base form of the cell of the bunch $\mathcal{B}_B^+$ at the exponents (s, t). At the share b^d the periods of the two families are

$$P_{F^{\mathrm{bunch}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_B; \mathbf{a}, \mathbf{b}) = \int_{\Delta_B} \varrho_B^{-b^d}\, d\phi_B, \qquad P_{F^{\mathrm{room}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_R; \mathbf{a}, \mathbf{b}) = \int_{\Delta_R} \varrho_R^{b^d}\, d\phi_R,$$

continued meromorphically in b^d by their sector forms (Theorem 8.5, Lemma 8.4): the *continued periods along the level d*. For $y > 0$ the *bunch transform* and the *room transform* are

$$f_B(y) = \int_{\Delta_B} \mathsf{G}_{s-\kappa_B;(1,-1)}\big(1, \varrho_B(u)\, y\big)\, \phi_B(du),$$
$$f_R(y) = \int_{\Delta_R} \big(\varrho_R(v)\, y\big)^{\kappa_B}\, \mathsf{G}_{t-\kappa_B;(1,-1)}\big(1, \varrho_R(v)\, y\big)\, \phi_R(dv),$$

with values in $[0, \infty]$. Swapping B and R gives the *swapped node*, with the bunch R, the room B and the two levels swapped (Theorem 19.13).

The bunch family at the share b^d has the form ϕ_B times $(\mathbf{E}_{\mathcal{B}/R}/\mathbf{E}_{\mathcal{B}|B})^{-b^d} = \varrho_B^{-b^d}$, and the room family the form ϕ_R times $(\mathbf{E}_{\mathcal{B}|R}/\mathbf{E}_{\mathcal{B}/B})^{-b^d} = \varrho_R^{b^d}$: the even share enters through the ratio of the hinge values of each side alone (Lemma 19.15).

Lemma 20.25 (Two letters in one scale)**.** *For linear letters $L_i(\rho) = L_i^{(0)} + \rho L_i^{(1)}$ with positive coefficients and the Skeleton values $\xi_i = L_i^{(0)}/L_i^{(1)}$, $i = 1, 2$, exponents $s, t > 0$ and $0 < \kappa < s + t$,*

$$\int_0^\infty \rho^{\kappa-1} L_1(\rho)^{-s} L_2(\rho)^{-t}\, d\rho$$
$$= \frac{(L_1^{(0)})^{\kappa-s} (L_1^{(1)})^{-\kappa} (L_2^{(0)})^{-t}}{\Gamma(s)\Gamma(t)} \int_0^\infty x^{\kappa-1}\, \mathsf{G}_{s-\kappa;(1,-1)}\Big(1, \frac{\xi_1}{\xi_2}\, x\Big)\, \mathsf{G}_{t-\kappa;(1,-1)}(1, x)\, dx.$$

Theorem 20.26 (The node in one scale)**.** *Let F and B be a node of width one (Definition 20.24).*

(i) The period is one integral over one scale of the two transforms,

$$P_F(\mathbf{m}; s, t) = \frac{1}{\Gamma(s)\Gamma(t)} \int_0^\infty f_B(y)\, f_R(y)\, \frac{dy}{y},$$

the integrand nonnegative.

(ii) With the hinge values of Definition 19.2,

$$f_B(y) = \int_{\Delta_B} u^{\mathbf{m}|_B - \mathbf{1}} K_{\mathcal{B}|B}^{-s} \Psi_{\mathcal{B}|B}^{-t}\, \mathsf{G}_{s-\kappa_B;(1,-1)}\big(\gamma_B^K(u)^{-1},\, y\,\gamma_B^\Psi(u)\big)\, d\omega_B(u) :$$

the bunch meets the room through its two hinge values, as in pooling (Theorem 19.8).

(iii) For real $b^d > 0$ with $a^d > 0$, and for real b^d with $a^r > 0$ and $b^r > 0$, respectively, in $[0, \infty]$,

$$\int_0^\infty y^{b^d - 1} f_B(y)\, dy = \Gamma(b^d)\, \Gamma(a^d) \int_{\Delta_B} \varrho_B^{-b^d}\, d\phi_B,$$
$$\int_0^\infty y^{-b^d - 1} f_R(y)\, dy = \Gamma(a^r)\, \Gamma(b^r) \int_{\Delta_R} \varrho_R^{b^d}\, d\phi_R.$$

Where the integrals over the shapes are finite they are the continued periods of the bunch family and of the room family at the share b^d, with their Gamma pairs, and (i), written through these two integrals in the share b^d, is Theorem 19.13 for one table.

(iv) If no slope on the room is positive, so that $\inf \varrho_R > 0$ (Lemma 19.15), then $\phi_R(\Delta_R) < \infty$, and with $a = \frac{t+\kappa_B}{2} - \frac{1}{4}$

$$f_R(y) \le \sqrt{\pi}\, e^{(t-\kappa_B)^2/4}\, \phi_R(\Delta_R)\, \big(y \inf \varrho_R\big)^a\, e^{-2\sqrt{y \inf \varrho_R}} \qquad \Big(y \ge \frac{\max(1, a^2)}{\inf \varrho_R}\Big) :$$

the room transform decays at the least ratio of the room.

Lemma 20.27 (The bunch transform on the orthant)**.** *For a node of width one and $y > 0$,*

$$f_B(y) = \int_{\mathbb{R}^B_{>0}} x^{\mathbf{m}|_B - \mathbf{1}} K_{\mathcal{B}|B}(x)^{-s} \Psi_{\mathcal{B}|B}(x)^{-t} \exp\Big(- \frac{1}{\gamma_B^K(x)} - y\,\gamma_B^\Psi(x)\Big)\, dx.$$

The bunch transform is a Laplace transform in the hinge value γ_B^Ψ, damped by the hinge value γ_B^K: the room meets the bunch through its two hinge values and nothing else. Its expansion in powers of y is measured by its reach.

Definition 20.28 (Lattice expansion; reach)**.** A function f on $(0, \infty)$ has a *lattice expansion of reach* $x \ge 0$ when there are finitely many reals $\eta_1, \dots, \eta_q$, an integer $J \ge 0$ and coefficients $\beta_{\eta,j}$, for η in $A = \bigcup_i (\eta_i + \mathbb{N})$ and $0 \le j \le J$, such that

$$f(y) = \sum_{\eta \in A} \sum_{j=0}^{J} \beta_{\eta,j}\, y^\eta (-\log y)^j \quad (y > 0), \qquad |\beta_{\eta,j}| \le C(1+\eta)^D\, \frac{x^\eta}{\Gamma(1+\eta)^2} \quad (\eta \in A,\ \eta \ge 0),$$

with constants C and D; the series then converges absolutely at every $y > 0$, and $\sum_{\eta,j} |\beta_{\eta,j}| < \infty$. Its *least exponent* is the least η with some $\beta_{\eta,j} \ne 0$. A function has at most one lattice expansion. The *reach of the bunch* of a node of width one, $\mathrm{reach}(B)$, is the infimum of the x for which the bunch transform has a lattice expansion of reach x, and the *reach of the room*, $\mathrm{reach}(R)$, is the reach of R as the bunch of the swapped node.

Lemma 20.29 (The lattice of one mark)**.** *Let ν be real.*

(i) For $x > 0$, $\mathsf{G}_{\nu;(1,-1)}(1,x)$ is the sum of the residues of $\Gamma(z)\Gamma(z+\nu)x^{-z}$ at the poles of $\Gamma(z)\Gamma(z+\nu)$. Off the integers

$$\mathsf{G}_{\nu;(1,-1)}(1,x) = \sum_{k\geq 0} \frac{(-1)^k}{k!}\Big(\Gamma(\nu-k)\,x^k + \Gamma(-\nu-k)\,x^{\nu+k}\Big);$$

at $\nu = l \in \mathbb{N}$

$$\mathsf{G}_{l;(1,-1)}(1,x) = \sum_{k<l} \frac{(-1)^k}{k!}\Gamma(l-k)\,x^k + (-1)^l \sum_{k\geq l} \frac{x^k}{k!\,(k-l)!}\Big((\log\Gamma)'(1+k) + (\log\Gamma)'(1+k-l) - \log x\Big),$$

and $\mathsf{G}_{-l;(1,-1)}(1,x) = x^{-l}\mathsf{G}_{l;(1,-1)}(1,x)$.

(ii) For $x \geq 1$, $0 < \mathsf{G}_{\nu;(1,-1)}(1,x) \leq \sqrt{\pi}\, e^{\nu^2/4}\, x^{\nu/2-1/4} e^{-2\sqrt{x}}$.

(iii) For $w > 0$, $y \mapsto \mathsf{G}_{\nu;(1,-1)}(1,w^2y)$ has a lattice expansion of reach w^2, with exponents in $\mathbb{N} \cup (\nu+\mathbb{N})$, in $-l+\mathbb{N}$ at $\nu = -l$, and at most one power of $-\log y$.

Lemma 20.30 (Products of lattice expansions)**.** *If f_1 and f_2 have lattice expansions of reaches x_1 and x_2, then $f_1 f_2$ has one of reach $(\sqrt{x_1}+\sqrt{x_2})^2$, whose terms are the products of theirs collected by exponent, and for real a, $y^a f_1$ has one of reach x_1.*

Lemma 20.31 (Closing a lattice expansion against a decaying function)**.** *Let f have a lattice expansion $\sum_{\eta,j} \beta_{\eta,j} y^\eta (-\log y)^j$ of reach x with least exponent η_0, and let g be measurable on $(0,\infty)$ and integrable on its compact subsets, with $\int_0^1 y^{\eta_0-1-\epsilon}|g(y)|\,dy < \infty$ for some $\epsilon > 0$ and $|g(y)| \leq C' y^a e^{-2\sqrt{x'y}}$ for $y \geq y_0$, where $x < x'$. Then*

$$\int_0^\infty f(y)\,g(y)\,\frac{dy}{y} = \sum_{\eta,j} \beta_{\eta,j} \int_0^\infty y^{\eta-1}(-\log y)^j\, g(y)\,dy,$$

every integral on the right and the series converging absolutely, and the terms with $\eta \geq N$ add up in absolute value to at most $C''(1+N)^{D''}(x/x')^N$, with C'' and D'' independent of N.

Lemma 20.32 (Continued cube integrals grow at most exponentially)**.** *Let G and h be analytic on a neighbourhood of $[0,1]^m$ in $\mathbb{C}^m$, with $h > 0$ on $[0,1]^m$, and let a_k, b_k be real with $a_k > 0$ wherever $b_k = 0$. The integral*

$$I(z) = \int_{[0,1]^m} \prod_k q_k^{a_k + b_k z - 1}\, G(q)\, h(q)^{-z}\, dq,$$

convergent where every $a_k + b_k \operatorname{Re} z > 0$, continues meromorphically to $z \in \mathbb{C}$, with poles only in the set $\mathcal{W}$ of the real points at which some $a_k + b_k z$ lies in $-\mathbb{N}$ (Lemma 8.4). For every $\vartheta > 0$ there is M, and then for every $\epsilon > 0$ there are C and D, with

$$|I(z)| \leq C(1+|z|)^D\, M^{|\operatorname{Re} z|}\, e^{\vartheta|\operatorname{Im} z|}$$

at every z at distance at least ϵ from $\mathcal{W}$.

Definition 20.33 (Growth along a level; growth at the integers)**.** For a node of width one, the *growth* $\operatorname{growth}(B)$ of the bunch family along the level d is the infimum of the $M \geq 0$ for which, for every $\epsilon > 0$, there are C, D and $\vartheta < \pi$ with

$$\left|P_{F^{\text{bunch}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_B;\mathbf{a},\mathbf{b})\right| \leq C(1+|b^d|)^D\, M^{-\operatorname{Re} b^d}\, e^{\vartheta|\operatorname{Im} b^d|}$$

for the continued period at the share b^d, at every b^d with $\operatorname{Re} b^d \leq 0$ at distance at least ϵ from the set $\mathcal{W}_B$ of the real points at which a proper wall of the bunch family lies in $-\mathbb{N}$, which holds its poles; the growth $\operatorname{growth}(R)$ of the room family is the same with $P_{F^{\text{room}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_R;\mathbf{a},\mathbf{b})$ and the set $\mathcal{W}_R$ of the room family. Along the level r the growths are those of the swapped node. The *growth at the integers* of the bunch is

$$\operatorname{growth}_{\mathbb{Z}}(B) = \limsup_{k\to\infty} \left|P_{F^{\text{bunch}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_B;\mathbf{a},\mathbf{b})\right|^{1/k},$$

the continued period of the bunch family taken at $b^d = -k$, $k \in \mathbb{N}$.

Theorem 20.34 (A node closes at the growth of its two families)**.** *Let F and B be a node of width one.*

(i) Every bunch has a reach. *The growths are finite;* $\operatorname{growth}(B) \leq \sup \varrho_B$ *and* $\operatorname{growth}(R) \leq 1/\inf \varrho_R$ *when these are finite; and* $\operatorname{reach}(B) \leq \operatorname{growth}(B)$. *The exponents of the lattice expansion of f_B are the η for which $b^d = -\eta$ is a pole of $\Gamma(b^d)\Gamma(a^d)P_{F^{\text{bunch}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_B;\mathbf{a},\mathbf{b})$ to the left of the line $\operatorname{Re} b^d = b_*$, and $\sum_j j!\,\beta_{\eta,j}(b^d+\eta)^{-j-1}$ is its principal part there: the lattice of the bunch is the lattice of its continued period with its Gamma pair, the wall residues joining.*

(ii) Against a room bounded below. *Let no slope on the room be positive, and let* $\operatorname{reach}(B) < \inf \varrho_R$. *Then*

$$P_F(\mathbf{m};s,t) = \frac{1}{\Gamma(s)\Gamma(t)} \sum_{\eta,j} \beta_{\eta,j}\, \partial_{b^d}^j \Big[\Gamma(a^r)\Gamma(b^r)\, P_{F^{\text{room}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_R;\mathbf{a},\mathbf{b})\Big]_{b^d=-\eta},$$

absolutely, every room period in it convergent, and for every $x > \operatorname{reach}(B)$ the terms with $\eta \geq N$ add up in absolute value to at most $C(1+N)^D(x/\inf\varrho_R)^N$. The terms are the residues of the integrand of Theorem 19.13 at its poles toward the level d: the even share closes on the lattice of continued periods of the bunch family at the root rate $\operatorname{reach}(B)/\inf\varrho_R$.

(iii) Both families continued. *Whatever the slopes, if* $\operatorname{growth}(B)\operatorname{growth}(R) < 1$, *then $P_F(\mathbf{m};s,t)$ is the sum of the residues of the integrand*

$$\Gamma_{\!\!\begin{smallmatrix}4\\2\end{smallmatrix}}\!\begin{bmatrix} a^d,\ b^d,\ a^r,\ b^r \\ s,\ t \end{bmatrix} P_{F^{\text{bunch}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_B;\mathbf{a},\mathbf{b})\, P_{F^{\text{room}}(\mathbf{a},\mathbf{b})}(\mathbf{m}|_R;\mathbf{a},\mathbf{b})$$

of Theorem 19.13, continued in b^d, at its poles with $\operatorname{Re} b^d < b_*$; for every $M_B > \operatorname{growth}(B)$ and $M_R > \operatorname{growth}(R)$ the residues at the poles with real part in $(-N-1,-N]$ add up in absolute value to at most $C(1+N)^D(M_BM_R)^N$. The even share closes on the lattices of continued periods of both families, the wall residues of both joining.

(iv) Toward the level r. *Swapping B and R leaves the period and Theorem 19.13 unchanged; the swapped node has the bunch R with the ratio ϱ_R and the room B with the ratio ϱ_B. Applied to it, (i) to (iii) close the even share toward the level r: against a bunch with* $\inf\varrho_B > 0$ *at the root rate* $\operatorname{reach}(R)/\inf\varrho_B$, *and in general at a root rate at most the product of the growths of the two families along the level r.*

A node is therefore closed on its lattice toward the level at which the growths of its two families multiply to less than one, each growth read on its family alone; where neither level has a product below one, the peak closing (Theorem 19.30) closes the node with nonnegative terms and needs no root rate. Against a room bounded below the bunch enters through its reach alone, and the domination is a reach against a decay.

Proposition 20.35 (No reach is below the least ratio)**.** *Let F and B be a node of width one.*

(i) If $\inf \varrho_B > 0$, there are C and a with $f_B(y) \le C y^a e^{-2\sqrt{y \inf \varrho_B}}$ for $y \ge 1$, and for every $x' > \inf \varrho_B$ there is $C_- > 0$ with $f_B(y) \ge C_- e^{-2\sqrt{x' y}}$ for $y \ge 1$: the bunch transform decays at the least ratio of the bunch.

(ii) $\operatorname{reach}(B) \ge \inf \varrho_B$*: no lattice expansion of the bunch transform has a reach below the least ratio.*

(iii) When ϱ_B is bounded, $\operatorname{reach}(B) = \operatorname{growth}(B) = \sup \varrho_B$*: the reach of a bounded bunch is its largest ratio.*

Against a room bounded below, the root rate $\operatorname{reach}(B)/\inf \varrho_R$ of Theorem 20.34(ii) therefore lies between $\inf \varrho_B/\inf \varrho_R$ and $\sup \varrho_B/\inf \varrho_R$. The series bunches take the lower end, and the bounded bunches the upper, which is $\sup(\varrho_B/\varrho_R)$, the root rate of Corollary 19.21(i).

Proposition 20.36 (A series bunch is its marks)**.** *Let the bunch B of a node of width one be a series bunch, θ'_B the weight of its pattern B and θ'_{B-e} that of its pattern $B - e$ (Definition 19.2, Proposition 19.3), and in this statement write $w_e = \theta'_{B-e}/\theta'_B$.*

(i) The bunch transform is the product over the marks of B:

$$\begin{aligned} f_B(y) &= (\theta'_B)^{-s-t} \prod_{e \in B} \mathsf{G}_{m_e - s;(1,-1)}(w_e y,\, w_e) \\ &= (\theta'_B)^{-s-t}\, y^{s-\kappa_B} \prod_{e \in B} w_e^{s-m_e}\, \mathsf{G}_{m_e-s;(1,-1)}\big(1,\, w_e^2 y\big). \end{aligned}$$

(ii) $\varrho_B(u) = \big(\sum_e w_e/u_e\big)\big(\sum_e w_e u_e\big) \ge \big(\sum_e w_e\big)^2$, with equality exactly at the point of equal coordinates of Δ_B, and ϱ_B is unbounded: whatever the weights, the least ratio of a series bunch is taken at the point of equal coordinates of its shape.

(iii) f_B has the lattice expansion of reach $\big(\sum_e w_e\big)^2 = \inf \varrho_B$ that is the product of the lattices of its marks, so $\operatorname{reach}(B) = \inf \varrho_B$*. With $\boldsymbol{\nu} = \mathbf{m}|_B - s\mathbf{1}_B$ and no ν_e an integer, its exponents lie in the lattices $-\nu_S + \mathbb{N}$, $S \subseteq B$: $S = \varnothing$ and $S = B$ are the lattices of the Gamma pair, and for every other S the lattice is where the wall of the bunch family at $B \setminus S$, continued, meets $-\mathbb{N}$. Finally $f_B(y) \le C\, y^a\, e^{-2(\sum_e w_e)\sqrt{y}}$ for $y \ge \max_e w_e^{-2}$, with constants C and a.*

Proposition 20.37 (A bunch in series is the product of its parts)**.** *Let the bunch of a node of width one be $B = B_1 \sqcup \cdots \sqcup B_q$, and on each B_i let $\mathcal{X}_i$ and $\mathcal{Y}_i$ be tables, $\mathcal{Y}_i$ of rank one less than $\mathcal{X}_i$, with the hinge values $\gamma_i^K = K_{\mathcal{X}_i}/K_{\mathcal{Y}_i}$ and $\gamma_i^\Psi = \Psi_{\mathcal{Y}_i}/\Psi_{\mathcal{X}_i}$ and the ratio $\varrho_i = \mathbf{E}_{\mathcal{Y}_i}/\mathbf{E}_{\mathcal{X}_i}$, such that for constants $C, C' > 0$*

$$K_{\mathcal{B}|B} = C \prod_i K_{\mathcal{X}_i}, \qquad \Psi_{\mathcal{B}|B} = C' \prod_i \Psi_{\mathcal{X}_i}, \qquad \frac{1}{\gamma_B^K} = \sum_i \frac{1}{\gamma_i^K}, \qquad \gamma_B^\Psi = \sum_i \gamma_i^\Psi :$$

B is the series connection *of the parts B_i. A series bunch is the series connection of its marks, with $K_{\mathcal{X}_e} = \alpha_e$, $\Psi_{\mathcal{X}_e} = 1$, $K_{\mathcal{Y}_e} = w_e$, $\Psi_{\mathcal{Y}_e} = w_e \alpha_e$ and $\varrho_e = w_e^2$ (Proposition 20.36).*

(i) $f_B = C^{-s}C'^{-t}\prod_i f_i^\circ$, *with the* orthant transforms *of the parts*

$$f_i^\circ(y) = \int_{\mathbb{R}_{>0}^{B_i}} x^{\mathbf{m}|_{B_i}-\mathbf{1}} K_{\mathcal{X}_i}(x)^{-s}\Psi_{\mathcal{X}_i}(x)^{-t}\exp\Big(-\frac{1}{\gamma_i^K(x)} - y\,\gamma_i^\Psi(x)\Big)\,dx;$$

and $\sqrt{\inf\varrho_B} = \sum_i \sqrt{\inf\varrho_i}$.

(ii) If every f_i° *has a lattice expansion of reach* x_i, *then* f_B *has one of reach* $\big(\sum_i\sqrt{x_i}\big)^2$.

(iii) Let every part be a single mark, or have a bounded ratio and a finite measure $u^{\mathbf{m}|_{B_i}-\mathbf{1}}K_{\mathcal{X}_i}^{-s}\Psi_{\mathcal{X}_i}^{-t}(\gamma_i^\Psi)^{-a_i}\,d\omega_{B_i}$ *on* Δ_{B_i}, *where* $a_i = m_{B_i} - s\,r_i - t\,(|B_i| - r_i)$ *with* r_i *the rank of* $\mathcal{X}_i$; *and let no sum of the* a_i *over a nonempty set of parts be an integer. Then* f_i° *has the reach* $\sup\varrho_i$, *and* $\operatorname{reach}(B) = \big(\sum_i\sqrt{\sup\varrho_i}\big)^2$: *in a series connection the square roots of the reaches add.*

Lemma 20.38 (The point of equal coordinates is stationary)**.** *Let* $\mathcal{X}$ *be a table on a set* S, *with any weights. At every point* u *of* $(0,\infty)^S$ *with equal coordinates,* $u_e\,\partial_{u_e}\log\mathbf{E}_\mathcal{X}(u) = 1$ *for every* $e \in S$. *So a ratio of even letters of tables on* S *is stationary at the point of equal coordinates of* Δ_S: ϱ_B *on* Δ_B, ϱ_R *on* Δ_R, *and* ϱ_B/ϱ_R *at the pair of these points.*

Theorem 20.39 (The two intervals of a node)**.** *For a node of width one, the bunch transform of the swapped node is* $y^{-t}f_R(y)$, *so that* $\inf\varrho_B$ *and* $\inf\varrho_R$ *are the decays of the two transforms, and* $\operatorname{reach}(B)$ *and* $\operatorname{reach}(R)$ *their reaches (Proposition 20.35(i), Lemma 20.30).*

(i) No transform reaches less far than it decays: $\inf\varrho_B \le \operatorname{reach}(B)$ *and* $\inf\varrho_R \le \operatorname{reach}(R)$.

(ii) Toward the level d. *Let no slope on the room be positive, so that* $\inf\varrho_R > 0$, *and index the terms of the lattice of Theorem 20.34(ii) by* (η, j). *Their root rate is* $\operatorname{reach}(B)/\inf\varrho_R$: *for every* $x > \operatorname{reach}(B)$ *they are at most* $C(1+\eta)^D(x/\inf\varrho_R)^\eta$ *in modulus, and for every* $\epsilon > 0$ *infinitely many of them exceed* $\big(\operatorname{reach}(B)/\inf\varrho_R - \epsilon\big)^\eta$. *So the lattice converges absolutely when* $\operatorname{reach}(B) < \inf\varrho_R$, *and its terms do not tend to zero when* $\operatorname{reach}(B) > \inf\varrho_R$.

(iii) Toward the level r. *Let no slope on the bunch be negative, so that* $\inf\varrho_B > 0$. *The terms of the lattice of continued periods toward the level* r *have the root rate* $\operatorname{reach}(R)/\inf\varrho_B$ *in the same sense: the lattice converges absolutely when* $\operatorname{reach}(R) < \inf\varrho_B$, *and its terms do not tend to zero when* $\operatorname{reach}(R) > \inf\varrho_B$.

(iv) One level at most. $\operatorname{reach}(B) < \inf\varrho_R$ *and* $\operatorname{reach}(R) < \inf\varrho_B$ *never hold together. Under both hypotheses of (ii) and (iii) the node therefore closes on a geometrically convergent lattice exactly when the intervals* $[\inf\varrho_B, \operatorname{reach}(B)]$ *of the bunch and* $[\inf\varrho_R, \operatorname{reach}(R)]$ *of the room are disjoint, toward the level of the lower one, at the ratio of the upper end of the lower interval to the lower end of the upper. When each interval extends beyond the lower end of the other, neither lattice converges, and the share closes at its peaks (Theorem 19.30); when they touch, the root rate is one and domination decides nothing.*

Each side of a node is read by two numbers of its own transform, its decay and the reach of its expansion, and no expansion reaches less far than its transform decays. A series bunch has both at its least ratio, and its interval is the point $(\sum_e w_e)^2$ (Proposition 20.36); a bounded bunch spreads over its whole range $[\inf\varrho_B, \sup\varrho_B]$ (Proposition 20.35(iii)); in a series connection of marks and bounded parts the square roots of the reaches add (Proposition 20.37(iii)). When the bunch and the room are both series bunches the two intervals are points: the node closes toward the level of the smaller point at the ratio of the two points, its terms toward the other level grow at the inverse ratio, and where the points meet domination decides nothing. Where a far side is unbounded, the

level toward it can still close with both families continued, at a root rate at most the product of their growths (Theorem 20.34(iii)). By Lemma 20.38 the value of ϱ_B/ϱ_R at the points of equal coordinates of Δ_B and Δ_R is a stationary value of the node's ratio, but the root rate is read at the extremes of the two transforms. The reach of a bunch that is neither bounded nor built from parallel and series bunches is read on the law of its ratio (Section 20.8).

Theorem 20.40 (A series connection closes at its reach)**.** *(i) Let the bunch B of a node of width one be the series connection of parts $B_1, \dots, B_q$ (Proposition 20.37), every orthant transform f_i° having a lattice expansion of reach x_i, and let no slope on the room be positive. If $\left(\sum_i \sqrt{x_i}\right)^2 < \inf \varrho_R$, the even share closes toward the level d on the lattice of continued periods of the bunch family (Theorem 20.34(ii)): for every $x > \left(\sum_i \sqrt{x_i}\right)^2$ its terms with $\eta \geq N$ add up in absolute value to at most a constant times $(1+N)^D (x/\inf \varrho_R)^N$, and its coefficients $\beta_{\eta,j}$ are those of $C^{-s}C'^{-t}\prod_i f_i^\circ$, finite sums of products, over the parts, of the coefficients of their lattice expansions. Under the hypotheses of Proposition 20.37(iii) the root rate of the terms is $\left(\sum_i \sqrt{\sup \varrho_i}\right)^2 / \inf \varrho_R$ (Theorem 20.39(ii)). For a series bunch, the series connection of its marks with w_e as in Proposition 20.36 and $x_e = w_e^2$, the root rate is $\inf \varrho_B / \inf \varrho_R = \left(\sum_e w_e\right)^2 / \inf \varrho_R$ and the coefficients are those of $(\theta'_B)^{-s-t} y^{s-\kappa_B} \prod_e w_e^{s-m_e} \mathsf{G}_{m_e-s;(1,-1)}(1, w_e^2 y)$: finite sums of products, over the marks of B, of the coefficients of Lemma 20.29, Laurent coefficients of the Gamma pairs $\Gamma(z)\Gamma(z+m_e-s)$.*

(ii) Let B be the series connection of parts $B_1, \dots, B_q$ in the dual table at the exponents (t, s) (Proposition 8.15), its orthant transforms there having lattice expansions of reaches x_i^*, and let no slope on the room be negative. If $\left(\sum_i \sqrt{x_i^*}\right)^2 \sup \varrho_R < 1$, the even share closes toward the level r on the lattice of continued periods of the bunch family, at a root rate at most $\left(\sum_i \sqrt{x_i^*}\right)^2 \sup \varrho_R$. A parallel bunch B is a series bunch of the dual table (Proposition 19.37), with $w_e = \theta'_{\{e\}}/\theta'_\varnothing$, $\theta'_\varnothing$ and $\theta'_{\{e\}}$ the weights of its patterns $\varnothing$ and $\{e\}$; then $x_e^* = w_e^2$ and $\sup \varrho_B = \left(\sum_e w_e\right)^{-2}$, taken at the point of equal coordinates of Δ_B, so the share closes when $\sup \varrho_R < \sup \varrho_B$, at the root rate $\sup \varrho_R / \sup \varrho_B$.

No order of the values is asked: the room's ratio need only be bounded on the side away from the closing, and the bunch's ratio may be unbounded, its walls falling toward the level closed on. When the bunch and the room are both series bunches, the root rate $\inf \varrho_B / \inf \varrho_R$ is read at the points of equal coordinates of both shapes. When the extreme ratio of the room sits at a vertex of its shape simplex the root rate is not read at the points of equal coordinates, which are only stationary.

Theorem 20.41 (Products of Grammas $\mathsf{G}_{\nu;(1,-1)}$ close on nested lattices)**.** *For a finite set S, numbers $w_e > 0$ and real indices ν_e, put $w_S = \sum_{e\in S} w_e$ and $\nu_S^- = \sum_{e\in S} \min(0, \nu_e)$, and in this statement write, for $\operatorname{Re} z > -\nu_S^-$,*

$$\mathcal{M}_S(z) = \int_0^\infty y^{z-1} \prod_{e\in S} \mathsf{G}_{\nu_e;(1,-1)}\big(1, w_e^2 y\big)\, dy.$$

(i) $\mathcal{M}_{\{e\}}(z) = w_e^{-2z}\, \Gamma(z)\Gamma(z+\nu_e)$, and for two marks with $w_e = w_f = w$

$$\mathcal{M}_{\{e,f\}}(z) = w^{-2z}\, {}_4\Gamma_1\left[\begin{matrix} z,\ z+\nu_e,\ z+\nu_f,\ z+\nu_e+\nu_f \\ 2z+\nu_e+\nu_f \end{matrix}\right].$$

(ii) For $S = S_1 \sqcup S_2$ with $w_{S_1} < w_{S_2}$, let $\prod_{e\in S_1} \mathsf{G}_{\nu_e;(1,-1)}(1, w_e^2 y) = \sum \beta_{\eta,j} y^\eta (-\log y)^j$ be the product of the lattices of the marks of S_1 (Lemmas 20.29 and 20.30). For $\operatorname{Re} z > -\nu_S^-$ and $i \in \mathbb{N}$,

$$(-\partial_z)^i \mathcal{M}_S(z) = \sum_{\eta,j} \beta_{\eta,j}\, (-\partial_z)^{i+j} \mathcal{M}_{S_2}(z+\eta),$$

every $z+\eta$ in the domain of $\mathcal{M}_{S_2}$, absolutely, the terms with $\eta \geq N$ adding up in absolute value to at most $C(1+N)^D (w_{S_1}/w_{S_2})^{2N}$.

(iii) Removing at each step a mark e of least w_e, until one mark is left or two with equal w_e, writes $\mathcal{M}_S(z)$ and its derivatives as nested lattice sums of products of Laurent coefficients of Gamma pairs at the points of the lattices, ending at (i): at most $|S|-1$ nested lattices, summed from the inside out, the one that removes e from S' converging absolutely at every point of the lattices above it, at the root rate $\big(w_e/(w_{S'} - w_e)\big)^2$, its constant depending on that point.

Corollary 20.42 (A table that is one circuit is a nested lattice of Gamma data)**.** *In Corollary 18.24 the integral over y is the integral of Theorem 20.41 with $S = \mathcal{E}$, $w_e = \theta_e$ and the indices $\nu_e = m_e - s$, taken at $z = s$, and $s > -\sum_e \min(0, \nu_e)$. So the period of every table that is one circuit, at all exponents $s, t > 0$, all masses of Corollary 18.24 and all weights, is a nested lattice sum of products of Laurent coefficients of Gamma pairs, with at most $n-1$ nested lattices, each converging absolutely at every point of the lattices above it and summed from the inside out. With unit weights, removing one mark at a time, the root rates are $(n-1)^{-2}, (n-2)^{-2}, \dots, \frac{1}{4}$, and the last two marks give four Gammas over one; splitting the marks into a lighter part S_1 and a heavier part S_2 converges at the root rate $(\theta_{S_1}/\theta_{S_2})^2$. At integer data with unit weights every coefficient is a rational combination of products of values $(\log\Gamma)^{(i)}(k)$, $i, k \geq 1$, which are Trailmoments of the counting input (Propositions 5.13 and 5.14).*

20.8 The reach read on the law

The reach of a bunch is defined by the expansion of its transform (Definition 20.28) and is bounded below by the least ratio and above by the growth of the continued family (Proposition 20.35, Theorem 20.34). Read on one measure on the half-line, the law of the ratio under the base form, the reach is the point beyond which the law has a density equal to its own wall series (Definition 20.43), the series whose terms are the poles of the continued family; every point at which the law fails to be analytic therefore bounds the reach from below, and the least ratio and the largest ratio of a bounded bunch are such points. From above the reach is bounded by the ceiling of a continuation (Definition 20.47): in each sector the falling variables are carried around zero on circles, as far as the sector letters allow, and the largest modulus of the ratio met there bounds the reach. From below it is bounded by the growth of the continued family at the integers; a continuation whose largest values sit at simple tops that do not cancel has that growth as its ceiling, so that the reach is at least the modulus of a stationary value of the ratio on a flat face, and equal to it when the ceilings come down to it.

Definition 20.43 (The law of a bunch; wall series)**.** The *law* of the bunch of a node of width one is the image $(\varrho_B)_*\phi_B$ of its base form under its ratio, a measure on $(0,\infty)$ (Definition 5.4). The continued period of the bunch family at the share b^d is $\int_0^\infty x^{-b^d}\, d\big((\varrho_B)_*\phi_B\big)(x)$ wherever the integral converges, which is for $\operatorname{Re} b^d$ in an open interval containing b_*, the *domain interval* of the law, the walls being affine in b^d and the conditions of Theorem 8.7 strict. A function g on (x_0,∞),

$x_0 \geq 0$, is a *wall series of radius* x_0 when there are finitely many reals η_i, an integer $J \geq 0$ and coefficients $a_{\eta,j}$, for $\eta \in A = \bigcup_i (\eta_i + \mathbb{N})$ and $0 \leq j \leq J$, with $\sum_{\eta,j} |a_{\eta,j}| x'^{-\eta} < \infty$ for every $x' > x_0$, such that

$$g(x) = \sum_{\eta,j} a_{\eta,j}\, x^{-\eta-1} (\log x)^j \qquad (x > x_0).$$

The series then converges absolutely and locally uniformly on $\{x \in \mathbb{C} : \ |x| > x_0, \ |\arg x| < \pi\}$, so a wall series is real-analytic.

Theorem 20.44 (The reach is read on the law)**.** *Let F and B be a node of width one.*

(i) On $(\mathrm{reach}(B), \infty)$ *the law* $(\varrho_B)_* \phi_B$ *has a density, and the density is a wall series of radius* $\mathrm{reach}(B)$*. Its terms are the poles of the continued period of the bunch family to the left of the domain interval: a pole* $b^d = -\eta$ *with the principal part* $\sum_j j!\, a_{\eta,j} (b^d + \eta)^{-j-1}$ *gives the terms* $a_{\eta,j} x^{-\eta-1} (\log x)^j$*, and there are no others.*

(ii) If on some (x_0, ∞) *the law has a density that is a wall series of radius* x_0*, then* $\mathrm{reach}(B) \leq x_0$*.*

(iii) So the reach is the least $x_0 \geq 0$ *for which the law has on* (x_0, ∞) *a density that is a wall series of radius* x_0*. In particular* $\mathrm{reach}(B) \geq x_1$ *at every* $x_1 > 0$ *near which* $(\varrho_B)_* \phi_B$ *has no real-analytic density: at the least ratio when it is positive, and at the largest ratio of a bounded bunch.*

So no reach lies below a point where the law of its ratio is singular, and Proposition 20.35(ii), with the lower half of (iii), is the case of the two ends of the law. The law of a family at a node is likewise its own wall series beyond its growth, so that $\mathrm{reach}(B) \leq \mathrm{growth}(B)$ of Theorem 20.34(i) is an equality (Corollary 32.11); along a direction of the shares the law reads the reach of a piece of any width (Theorem 32.10). From above the reach is bounded by the ceilings of continuations.

Lemma 20.45 (Finite parts on a keyhole)**.** *Let $0 < r \leq 1$, $r' > r$, a real, and let G be holomorphic on $U \times \mathbb{C}$ for an open U containing $\{|q| \leq r'\} \cup [r, 1]$. Then $I(z) = \int_0^1 q^{a+z-1} G(q, z)\, dq$, defined for $\mathrm{Re}\, z > -a$, continues meromorphically to $\mathbb{C}$ with poles only where $a + z \in -\mathbb{N}$, and*

$$I(z) = \sum_{l \geq 0} g_l(z)\, \frac{r^{a+z+l}}{a+z+l} + \int_r^1 q^{a+z-1} G(q, z)\, dq, \qquad g_l(z) = \frac{1}{2\pi i} \oint_{|\zeta| = r'} \zeta^{-l-1} G(\zeta, z)\, d\zeta.$$

Where $|a + z + l| \geq \epsilon$ for every $l \in \mathbb{N}$,

$$|I(z)| \leq \frac{r'}{\epsilon (r' - r)}\, r^{a + \mathrm{Re}\, z} \max_{|\zeta| = r'} |G(\zeta, z)| + \int_r^1 q^{a + \mathrm{Re}\, z - 1} |G(q, z)|\, dq.$$

If $0 < q_0 \leq 1$ and U contains the closed disc D with diameter $[-q_0, 1]$, then off the points with $a + z \in \mathbb{Z}$

$$I(z) = \frac{1}{e^{2\pi i (a+z)} - 1} \oint_{\partial D} q^{a+z-1} G(q, z)\, dq,$$

the circle run once counterclockwise from 1, with q^{a+z-1} continued along it from its positive value at 1.

Definition 20.46 (Falling and base variables; keyholes)**.** For a node of width one and an order π of its bunch B let $q = (q_k)_k$ be its sector coordinates and U_k its tails, and let $k_{\mathcal{B}|B,\pi}$, $\psi_{\mathcal{B}|B,\pi}$, $k_{\mathcal{B}/R,\pi}$, $\psi_{\mathcal{B}/R,\pi}$ be the sector letters of the two tables of the bunch family (Theorem 8.5(ii)). Along the

level d the wall of the bunch family at U_k is $\kappa_k + \mathrm{sl}_k\, b^d$ at the share b^d, with its *slope* $\mathrm{sl}_k \in \{-1, 0, 1\}$ (Lemma 19.15). On the sector of π the base form is

$$\phi_\pi = \prod_k q_k^{\kappa_k - 1}\, k_{\mathcal{B}/R,\pi}^{-(s-\kappa_B)}\, k_{\mathcal{B}|B,\pi}^{-\kappa_B}\, \psi_{\mathcal{B}|B,\pi}^{-t}\, dq,$$

and the ratio is

$$\varrho_\pi = \frac{k_{\mathcal{B}/R,\pi}\, \psi_{\mathcal{B}/R,\pi}}{k_{\mathcal{B}|B,\pi}\, \psi_{\mathcal{B}|B,\pi}} \prod_k q_k^{-\mathrm{sl}_k},$$

continued to the complex points of the coordinates at which the sector letters do not vanish; so the continued period of the bunch family at the share b^d is $\sum_\pi \int_{[0,1]^{|B|-1}} \varrho_\pi^{-b^d}\, \phi_\pi$. The q_k with $\mathrm{sl}_k = 1$ are the *falling variables* of π, whose walls fall as $\mathrm{Re}\, b^d$ decreases, and the others its *base variables*, *flat* when $\mathrm{sl}_k = 0$ and *rising* when $\mathrm{sl}_k = -1$. Where some flat variables vanish the sector reaches a *flat face* of the shape, on which every wall crossed has slope 0 and ϱ_π has the finite limit given by the leading parts of the letters; where some falling variable vanishes it reaches a *falling face*. For $0 < r \le b \le 1$ the *keyhole* and its *outline* are $Y_r[0,b] = \{q \in \mathbb{C} : |q| \le r\} \cup [r,b]$ and $\mathcal{O}_r[0,b] = \{|q| = r\} \cup [r,b]$, with $Y_r = Y_r[0,1]$ and $\mathcal{O}_r = \mathcal{O}_r[0,1]$.

Definition 20.47 (Keyhole continuations; ceiling)**.** A *keyhole continuation* of the bunch family of a node of width one assigns to every order π of B finitely many closed boxes Ω with disjoint interiors covering the cube of its base variables, and to every such box and falling variable q_k a radius $r_{\pi,\Omega,k} \in (0,1]$, such that none of the four sector letters vanishes on the set $Y = \Omega \times \prod_k Y_{r_{\pi,\Omega,k}}$, the product over the falling variables. The boxes may also divide the sides of the falling variables: they then cover the whole cube of the order, a box being the product of its part in the base variables and of its sides in the falling variables, with radii of its own; a falling variable with the side $[0, b_k]$ carries a radius $r \le b_k$ and the sets $Y_r[0,b_k]$ and $\mathcal{O}_r[0,b_k]$, and one with the side $[a_k, b_k]$, $a_k > 0$, is kept real, its sets Y and $\mathcal{O}$ being $[a_k, b_k]$. A box, divided or not, is written Ω with its radii and its sets Y and $\mathcal{O} = \Omega \times \prod_k \mathcal{O}_{r_{\pi,\Omega,k}}$, where Ω stands for its part in the variables without keyholes and the products run over the falling variables with keyholes. The *ceiling* $H_\mathcal{O}$ of the continuation is the largest value of $|\varrho_\pi|$ on the sets $\mathcal{O}$ of its boxes, an order without falling variables contributing the largest value of ϱ_π on its cube.

The sector letters are positive on the closed cube, with positive constant terms (Theorem 8.5(ii)), so small radii give keyhole continuations, and every bunch has one of finite ceiling. Whether a letter vanishes on a keyhole is decided on its outline and at one point.

Lemma 20.48 (Zeros on a keyhole are decided on its outline and at one point)**.** *Let Ω be a connected set, J a finite set, $0 < r_j \le b_j \le 1$ for $j \in J$, and L a continuous function on $\Omega \times \mathbb{C}^J$, a polynomial in $q = (q_j)_{j \in J}$. If L has no zero on $\Omega \times \prod_j \mathcal{O}_{r_j}[0,b_j]$, and for some $v_0 \in \Omega$ and each j the polynomial in q_j obtained from $L(v_0, \cdot)$ by putting $q_k = r_k$ for $k \ne j$ has no zero in the disc $|q_j| < r_j$, then L has no zero on $\Omega \times \prod_j Y_{r_j}[0,b_j]$.*

So a box and its radii keep a letter from vanishing on the set Y of the box when the letter has no zero on its set $\mathcal{O}$, where the ceiling is read, and, at one point of Ω with the other falling coordinates at their radii, none in the disc of each keyhole; the falling variables kept real count among the coordinates of Ω.

Theorem 20.49 (No reach exceeds the ceiling)**.** *For a node of width one, the reach of its bunch is at most the ceiling of every keyhole continuation:* $\inf \varrho_B \le \mathrm{reach}(B) \le H_\mathcal{O}$ *for the ceiling $H_\mathcal{O}$ of each. When ϱ_B is bounded, every keyhole continuation has the ceiling* $\sup \varrho_B$*, and* $\mathrm{reach}(B) = \sup \varrho_B$.

The letters of the contraction enter the keyhole continuations because the family is continued at points off the integers, where $\varrho_\pi^{-b^d}$ branches at their zeros; at the integers $-k$, $k \in \mathbb{N}$, when $s - \kappa_B$ is zero or a negative integer, only the letters of the restriction $\mathcal{B}|B$ matter. When a zero of a letter of the contraction is met by the keyholes that would bring $|\varrho_\pi|$ down, the ceiling can exceed the reach. From below, the reach is read at the integers, where $\psi_{\mathcal{B}/R,\pi}$ does not enter, nor $k_{\mathcal{B}/R,\pi}$ when $s - \kappa_B$ is an integer, and a continuation whose largest values sit at simple tops that do not cancel cannot be lowered.

Definition 20.50 (Integer keyhole continuations; simple tops)**.** For a node of width one let $\nu = s - \kappa_B$. An *integer keyhole continuation* is defined as in Definition 20.47 with only $k_{\mathcal{B}|B,\pi}$ and $\psi_{\mathcal{B}|B,\pi}$, and $k_{\mathcal{B}/R,\pi}$ when ν is not an integer, required not to vanish on the sets Y of its boxes; its ceiling is defined in the same way. For an order π and a box Ω write J for its falling variables with keyholes and r_j for their radii, and let C_j be the circle $|q_j| = r_j$ run once counterclockwise from r_j. The *keyhole contour* of the continuation is the formal sum over the orders and their boxes of

$$\Omega \times \prod_{j \in J} \Big(\frac{C_j}{e^{2\pi i \kappa_j} - 1} + [r_j, 1] \Big),$$

the segment being $[r_j, b_j]$ on a divided side $[0, b_j]$, a falling variable kept real on $[a_j, b_j]$ entering with that segment, and an order without falling variables contributing its cube; on the keyhole contour of π it carries the form ϕ_π, the powers continued along the circles from their positive values at r_j. A *top* is a point of the keyhole contour at which $|\varrho_\pi|$ equals the ceiling. A top p is *simple* when it lies on no face of its box other than faces $q_j = 0$ of flat variables, its falling coordinates lie on the circles away from r_j or inside the segments, and, with $\mathbf{x}$ the coordinates that vanish at p and $\mathbf{y}$ real coordinates of the keyhole contour for the others, vanishing at p (the angle on a circle),

$$\log \frac{\varrho_\pi}{\varrho_\pi(p)} = -\langle \boldsymbol{\lambda}, \mathbf{x} \rangle - \tfrac{1}{2}\, \mathbf{y}^{\mathsf{T}} \mathbf{Q}\, \mathbf{y} + O\big(|\mathbf{x}|^2 + |\mathbf{x}|\,|\mathbf{y}| + |\mathbf{y}|^3\big)$$

on the keyhole contour near p, with $\operatorname{Re} \lambda_j > 0$ for every j and $\operatorname{Re} \mathbf{Q}$ positive definite. The *exponent* of p is $\operatorname{ex}(p) = \sum_j \kappa_j + \frac{1}{2} \dim \mathbf{y}$, the sum over the coordinates $\mathbf{x}$, and its *coefficient* is

$$A(p) = \phi_p \prod_j \Gamma(\kappa_j)\, \lambda_j^{-\kappa_j}\, (2\pi)^{\dim \mathbf{y}/2} (\det \mathbf{Q})^{-1/2},$$

ϕ_p the value at p of the density of ϕ_π with the coefficient $1/(e^{2\pi i \kappa} - 1)$ of each circle of the keyhole contour through p, κ the wall of its falling variable, against $\prod_j x_j^{\kappa_j - 1}\, d\mathbf{x}\, d\mathbf{y}$, the powers and the root continued from real $\boldsymbol{\lambda}$ and real $\mathbf{Q}$ along segments.

The coordinates $\mathbf{x}$ belong to flat variables, whose walls κ_j are positive, so the Gammas are finite.

Theorem 20.51 (A simple top is the growth at the integers)**.** *For a node of width one let the walls κ_j of the falling variables of every order be off the integers, and let* $\operatorname{growth}_{\mathbb{Z}}(B)$ *be the growth at the integers (Definition 20.33).*

(i) For every integer keyhole continuation and every integer $k \geq \max(0, s - \kappa_B)$, the continued period at $b^d = -k$ is the integral of $\varrho_\pi^k \phi_\pi$ over its keyhole contour. So its modulus is at most $C H_{\mathcal{O}}^k$, $H_{\mathcal{O}}$ the ceiling, and $\operatorname{growth}_{\mathbb{Z}}(B) \leq H_{\mathcal{O}}$.

(ii) $\operatorname{reach}(B) \geq \operatorname{growth}_{\mathbb{Z}}(B)$.

(iii) Let an integer keyhole continuation of ceiling $H_{\mathcal{O}}$ have finitely many tops, all simple, let ex_0 *be the least of their exponents, and for* $|\zeta| = 1$ *let* A_ζ *be the sum of the coefficients* $A(p)$ *of the tops with* $\mathrm{ex}(p) = \mathrm{ex}_0$ *and* $\varrho_\pi(p) = H_{\mathcal{O}}\zeta$*. Each* $A(p)$ *is nonzero, and each top is a stationary point of the restriction of* ϱ_π *to the flat face* $\mathbf{x} = 0$*, the sector itself when there are no coordinates* $\mathbf{x}$*. If some* $A_\zeta \neq 0$*, then* $\mathrm{growth}_{\mathbb{Z}}(B) = H_{\mathcal{O}} \leq \mathrm{reach}(B)$*: the reach is at least the modulus of a stationary value of the ratio on a flat face.*

(iv) If moreover there are keyhole continuations with ceilings arbitrarily close to $H_{\mathcal{O}}$*, then* $\mathrm{reach}(B) = H_{\mathcal{O}}$*. In particular, if a keyhole continuation, with all four letters kept from vanishing, has finitely many tops, all simple, and some* $A_\zeta \neq 0$*, the reach is its ceiling.*

So $\mathrm{growth}_{\mathbb{Z}}(B) \leq \mathrm{reach}(B)$ always, with equality to the ceiling whenever the tops of an integer keyhole continuation are finitely many, all simple, and do not cancel, and the keyhole continuations come down to it: the reach is then the modulus of a stationary value of the ratio on a flat face, the one at which the best continuation is pinned. The stationary point need not be a positive point of the face.

The upper end needs the letters of the contraction only where they meet the falling faces. Elsewhere a zero of $k_{\mathcal{B}/R,\pi}$ or $\psi_{\mathcal{B}/R,\pi}$ is a zero of ϱ_π, and the law is read near infinity on the fibres $\varrho_\pi = x$ with $|x|$ large, which never pass through it.

Lemma 20.52 (A falling variable takes each large value once)**.** *Let* g *be meromorphic on a neighbourhood of the closed disc* $|q| \leq r$*, with a simple pole at* 0 *as its only pole there, and* $|g| \leq M$ *on the circle* $|q| = r$*. Then* g *takes every value* x *with* $|x| > M$ *exactly once in the disc, with* $g' \neq 0$ *there, and maps the open set* $\{|q| < r : \ |g(q)| > M\} \cup \{0\}$ *biholomorphically onto* $\{|x| > M\} \cup \{\infty\}$*.*

Lemma 20.53 (A wall series continued is a wall series)**.** *If the sum of a wall series of radius* x_0 *continues analytically along every path in* $\{|x| > x_1\}$*, with* $x_1 < x_0$*, then the series is a wall series of radius* x_1*.*

Definition 20.54 (Fibre continuations; stationary bound)**.** A *fibre continuation* is defined as in Definition 20.47, divided sides allowed, with only $k_{\mathcal{B}|B,\pi}$ and $\psi_{\mathcal{B}|B,\pi}$ required not to vanish on the sets Y of its boxes, and $k_{\mathcal{B}/R,\pi}$ and $\psi_{\mathcal{B}/R,\pi}$ only at their points with a falling coordinate 0; its ceiling $H_{\mathcal{O}}$ is defined in the same way. Its *stationary bound* S is the supremum of $|\varrho_\pi|$ over the points of these sets with no falling coordinate 0 at which at least two falling coordinates lie inside their discs, $|q_j| < r_j$, and the derivatives of ϱ_π in all the falling coordinates inside their discs vanish; $S = 0$ when there is no such point.

With one falling coordinate inside its disc and the others on their outlines, ϱ_π is in that coordinate as in Lemma 20.52, with the bound $H_{\mathcal{O}}$ on the circle, or identically 0 when a rising base coordinate is 0; so it has no stationary point there with $|\varrho_\pi| > H_{\mathcal{O}}$, and the stationary bound concerns two or more falling coordinates at once.

Theorem 20.55 (The contraction enters only on the falling faces)**.** *For a node of width one and every fibre continuation, of ceiling* $H_{\mathcal{O}}$ *and stationary bound* S*,* $\mathrm{reach}(B) \leq \max(H_{\mathcal{O}}, S)$*. So, under the hypotheses of Theorem 20.51, if a fibre continuation that is also an integer keyhole continuation has* $S \leq H_{\mathcal{O}}$ *and finitely many tops, all simple, with some* $A_\zeta \neq 0$*, then* $\mathrm{reach}(B) = \mathrm{growth}_{\mathbb{Z}}(B) = H_{\mathcal{O}}$*: the reach is read at the integers.*

The letters of the contraction, which Theorem 20.49 keeps from vanishing on whole keyholes, matter for the upper bound only on the falling faces, where the coefficient of the pole of the ratio vanishes, and through the stationary points of the ratio in two or more falling variables. The two bounds from above work box by box, so they can share one continuation.

Theorem 20.56 (Keyhole boxes and fibre boxes mix)**.** *Let a continuation assign to every order π of the bunch B of a node of width one boxes and radii as in Definition 20.47, the sides of the falling variables divided or not, each box either a* keyhole box*, on whose sets Y none of the four sector letters vanishes, or a* fibre box*, on whose sets Y the conditions of Definition 20.54 hold. Let $H_{\mathcal{O}}$ be its ceiling and S the stationary bound of Definition 20.54 taken over its fibre boxes alone. Then* $\operatorname{reach}(B) \leq \max(H_{\mathcal{O}}, S)$.

Corollary 20.57 (One falling variable needs only the restriction)**.** *In an order with at most one falling variable, a box on whose sets Y the letters of the restriction $\mathcal{B}|B$ do not vanish is a fibre box, and it adds nothing to the stationary bound. So in a continuation of Theorem 20.56 such boxes need only the letters of the restriction, and the reach is at most* $\max(H_{\mathcal{O}}, S)$ *with S taken over the fibre boxes of the orders with two or more falling variables.*

So the stationary bound enters only where a letter of the contraction vanishes inside the keyholes of a sector with two or more falling variables. The zeros of the contraction on the falling faces can still keep every such bound above the reach.

These theorems bound the right end of each interval $[\inf \varrho_B, \operatorname{reach}(B)]$ of Theorem 20.39 from both sides. The reach need not be read on the positive shape: the ratio is real at the real points of a flat face whatever their signs, and a keyhole of a falling variable crosses the negative axis nearer to 0 than every pole of the ratio on it, so a simple top can sit at a point with a negative coordinate.

20.9 One tree

Read on one tree, the period of a point, built back up, is the periods of the leaves multiplied by the share kernels of the nodes and integrated over the free shares; its $n-1$ integrations are shared out among the bunches and the leaves; at integer data the share kernels bring the Trailmoments of the counting input order by order; and where the free shares close on integer points the period is the sum of the residues along the lattice of the tree.

Definition 20.58 (Share kernels, contents, integration count)**.** Let a molecule of lists with a native gauge be read on a tree of bunches, its Foreman tree or another, with the port of the balance wall run at every node on the native splits (Corollary 20.10). The share kernels of the tree (Corollary 4.4) are what the ports place on the shares: one stacked Gamma $\Gamma_{\substack{k\\1}}\begin{bmatrix}\mathbf{a}\\ a\end{bmatrix}$ for each letter opened at a node, k the number of its patterns, $\mathbf{a}$ its shares and a its exponent, which in Corollary 20.10 leave the factors $\big(\Gamma(a_{\mathcal{B}'})\Gamma(b_{\mathcal{B}'})\big)^{1-q_{\mathcal{B}'}}$ and $\prod_j \Gamma(s_j)^{-1}\Gamma(t_j)^{-1}$; each is balanced (Definition 1.2), its shares adding to its exponent on the fibre. The *free shares* are coordinates of the fibre of the word. Let $\mathcal{Z}$ be the $\mathbb{Q}$-algebra generated by the Trailmoments $(\mathsf{T}_{k;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$, $k \geq 2$, of the counting input; it maps into the content $\mathcal{C}^{(1)}$ of Chapter 45, the algebra of trails of lattice inputs, which also holds the sums along the lattices of paired words (Chapters 43 and 45). The *content* $\mathcal{C}_M$ of a childcule M of a node, a leaf in particular, is the $\mathcal{Z}$-module spanned by the values, at the integer exponents and masses at which it converges, of the period of a family on M whose tables are those of M, and of its derivatives in the exponents and masses along the balance wall; the content of the molecule is the same with its own tables. The content $\mathcal{C}_B$ of the bunch B of a node with room R is the same for the families on B whose tables, each with both letters, are the minors $\mathcal{B}'|B$ and $\mathcal{B}'/R$ of the tables $\mathcal{B}'$ at the node: those of the face of B (Theorem 16.25), at width one those of the bunch family (Theorem 19.13). The content $\mathcal{C}_R$ of the room is the same for the families on R whose tables are the $\mathcal{B}'|R$ and $\mathcal{B}'/B$.

The *integration count* of an integral as written is the number of its integrations, assigned to the written expression by these rules. The period of a family on k marks has the integration count $k-1$, its simplex. A trail $(\mathsf{T}_{\mathbf{a};I_d}[y]\,\mathbb{I}_{(b+\mathbb{Z})^d})(\{b<y_1<\cdots<y_d\})$ of a lattice input with integer indices, $b>-1$ (Definition 5.23), has the integration count $a_1+\cdots+a_d$, its total index; the counting trails are the case $b=0$. A Gamma has the integration count one, $\Gamma(a)=\int_0^\infty x^{a-1}e^{-x}\,dx$ being one integration, so a stacked Gamma with k Gammas above and l below has the integration count $k-l$. A derivative in an exponent or a mass adds one, the logarithm of a letter or of a mark. A product has the sum of the integration counts of its factors, and a fibre integral of dimension D (Definition 4.1) the integration count of its integrand less D, each share integrated inverting one Mellin transform. A real number has *integration count at most* w when it is a rational combination of values, at rational data with unit weights, of integrals of integration count at most w.

The openings keep the integration count. The power $(X_1+\cdots+X_k)^{-s}$ is the share integral of $\Gamma_{\substack{k\\1}}\begin{bmatrix}\mathbf{a}\\ s\end{bmatrix}\prod_i X_i^{-a_i}$, of integration count $(k-1)-(k-1)=0$ (Corollary 4.4), and e^{-y} is the integral of $\Gamma(b)y^{-b}$ over one share, of integration count $1-1=0$. A Beta corner $\Gamma_{\substack{2\\1}}\begin{bmatrix}a,\ b\\ a+b\end{bmatrix}$ has the integration count one, as the period of the list on two marks whose bases are the two singletons; the stacked Gamma $\Gamma_{\substack{|B|\\1}}\begin{bmatrix}\mathbf{m}\\ m_B\end{bmatrix}$ of the shape integral has the integration count $|B|-1$, its simplex (Theorem 3.9); the interest $J_F=\Gamma(\kappa_{\mathcal{E}})P_F$ has the integration count n, its orthant (Theorem 8.7). The atom formula of a family on n marks (Corollary 18.16) has the integration count $\sum(|\mathcal{B}_j|-1)$ of its stacked Gammas, over the active letters, less its dimension $\sum(|\mathcal{B}_j|-1)-(n-1)$: $n-1$, the integration count of the period. Taking the residue at a pole of one Gamma removes that Gamma and adds one pin (Theorem 4.5), so every term of a closing has the integration count of the integral closed.

Theorem 20.59 (One tree suffices)**.** *Let F be a molecule of lists on n marks with real exponents $s_j,t_j\geq 0$ and masses $\mathbf{m}$ on the balance wall, with $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ convergent, and let its Foreman tree be read at its exponent pairs, at the centre or at a lean (Proposition 16.19, Theorem 14.6). Run the port of the balance wall at every node on the native splits of the point, as in Corollary 20.10. Parts (i), (ii), (iv) and (v) hold as well for every tree of bunches in place of the Foreman tree.*

(i) The word starts at the leaves. *$P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ is the word of the tree (Corollary 20.10): the periods of the leaves, each read at its shares and each entering once on its descent, multiplied by the share kernels and integrated over the free shares. At a node the words of the childcules multiply, and along a chain, its leaf opened by the atom formula, the word is one Gramma on the marks and the letters (Theorem 20.11).*

(ii) The integrations are counted. *The word has the integration count $n-1$, that of the period, and at rational data $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ has integration count at most $n-1$. At a node with bunch B and q childcules the integrations of the simplex are the $|B|+q-1$ pins of the node, $|B|-1$ for the shape of the bunch and q for the totals of the bunch and of the childcules, $q+1$ numbers that add to one; in a leaf L they are the $|L|-1$ integrations of its period.*

(iii) The leaf bounds the bunches. *Along every descent of the Foreman tree, at the centre and at every lean, the copies of every bunch have at most as many marks as the copies of the leaf (Theorem 14.22). When some active list is connected, as for a molecule of one list, the tree is a chain and $|B_0|\leq\cdots\leq|B_{d-1}|\leq|L|$ (Corollary 20.9): the shape of every bunch has at most as many integrations as the leaf, and its node adds one, the total of the bunch against its room.*

(iv) At integer data the share kernels bring $\mathcal{Z}$. *Let the exponents and masses be integers and let x be a point of the fibre at which every share is an integer. The pins and the share sums have integer coefficients, so the directions of the fibre have a rational basis; write the fibre near x as $x + V\mathbf{v}$ with V rational. Near x the share kernels are*

$$c \prod_i \ell_i(\mathbf{v})^{-\epsilon_i} \exp h(\mathbf{v}),$$

with c rational, $\ell_i(\mathbf{v})$ the deviation from its value at x of each argument of the share kernels that is a nonpositive integer at x, ϵ_i equal to 1 for a Gamma above and to -1 for one below, and h a power series without constant term whose part of degree k has its coefficients in $\mathbb{Q} + \mathbb{Q}\,(\mathsf{T}_{k;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$ for $k \geq 2$ and in $\mathbb{Q}$ for $k = 1$: the terms of order k of the share kernels carry total index at most k. Where the periods of the leaves converge at x, every residue of the word at x, taken in turn along rational directions spanning the fibre, is therefore a finite $\mathcal{Z}$-combination of products, over the leaves, of elements of their contents.

(v) Summed along the tree. *A free share closed on the poles of the share kernels, where they alone have poles on the way and the closing converges, writes the word as a sum over a lattice of terms of its own integration count, each a fibre integral with one more pin (Theorem 4.5); where every free share closes so, on points at which every share is an integer and the periods of the leaves converge, the period at integer data is the sum along that lattice of the residues of (iv), finite $\mathcal{Z}$-combinations of products of the contents of the leaves. Across a bunch of width one, grouping its patterns by level puts the period of the bunch family in the word in place of the bunch (Theorem 19.13); for one table the even share then closes on its lattice whenever $\sup \varrho_B < \inf \varrho_R$ or $\inf \varrho_B > \sup \varrho_R$, and at integer data its residues are finite $\mathcal{Z}$-combinations of products of an element of $\mathcal{C}_B$ and one of $\mathcal{C}_R$ (Corollary 19.21).*

Whatever the order of the even letters, with $s, t > 0$, the even share of a node of width one closes on the lattices of continued periods of the bunch family and the room family toward a level at which their growths multiply to less than one (Theorem 20.34); a series bunch closes toward the level d against every room with $\inf \varrho_R > \inf \varrho_B$, and a series connection against every room with $\sqrt{\inf \varrho_R}$ above the sum of the square roots of the reaches of its parts, the room's ratio bounded only on the side away from the closing (Theorem 20.40); and against a room bounded below and a bunch bounded below the node closes on a geometric lattice exactly when the intervals of the bunch and of the room are disjoint, at its peaks otherwise (Theorem 20.39). Off the integers the level shares of several tables close in the same way across bunches of width one whose values stand in one order, node after node down a tree of splits of width one (Theorem 19.20, Corollary 19.22). At nonnegative exponents the period is in every case the sum, along the draws nested on the descents of the tree, of products over its blocks of Dirichlet moments (Theorem 20.15).

The pins need not be unimodular, so a closing can reach points at which some share is not an integer, even at integer data. When the active tables link all the marks the pins reach every integer point of their target (Proposition 18.17), and the fibre has integral coordinates through an integer point; the shares that a closing leaves after pinning the others at the poles of their Gammas are solved from a square block of the pins, whose determinant can exceed 1 in modulus: for the list $\binom{[4]}{2}$ at the data $(\mathbf{1}; 1, 1)$ (Exercise 51.3), the fibre has points at which every share off such a block is an integer and some share is $\frac{1}{2}$. There the share kernels have rational arguments, and their expansion runs in heads and Trailmoments of the lattice inputs of those arguments (Proposition 5.13); that is why (iv) and (v) speak of integer points. Where a node has no free share its sum has one term. For a list whose bunch has width one, at a full lean, $(s, 0)$ or $(0, t)$, the level shares are pinned and the

period is a Beta corner times the periods of the bunch family and the room family (Corollary 19.14); at rational data this is an identity of period data (Theorem 19.34), at integer data the Beta corner is rational, and with the room a leaf the period is a rational multiple of a product of an element of $\mathcal{C}_B$ and one of the content of the leaf. When the two hinge values of a bunch of width one agree the shape and the room separate at every pair of exponents (Proposition 19.12), and at the wall of a set, with the weights factoring on its bottom levels, the residue of the period is the product of the periods of its two faces (Theorem 16.25).

The integration count of a period bounds that of its value, and the theorem is stated for lists because the weights of a table can carry integrations of their own, which the integration count of a period leaves out. With unit weights and rational data nothing is carried in. On an atom the tree is the atom and the theorem says no more than its own content; its atom formula is a word of the same kind whose leaves are single marks, and the argument of (iv) puts each of its residues at integer points in $\mathcal{Z}$. The lattice can make what no bunch or leaf shows: a tree whose bunches and leaves have their contents in $\mathcal{Z}$ can sum, along the lattice of one free share, to a Trailmoment of a lattice input with a frequency (Definition 5.4) that none of them carries. The finite form of the theorem, the period in the $\mathcal{Z}$-algebra generated by the contents of the bunches and the leaves, holds where the shares are pinned at an integer point; where they are free the tree gives the sum along its lattice. For a word of one free share made of Gammas alone, as the atom formula leaves it at integer data, that sum lies in the content of Definition 45.1 when the word is paired (Propositions 43.2 and 45.3), and otherwise it is a combination of Trailmoments of live inputs (Theorem 43.1).

Theorem 20.59 is the Foreman procedure read, step by step, as a statement about numbers. *Split first*: a compound is split into its polycule before any molecule is asked whether it answers yes, and at every node the polycule of the childcules is evaluated as the product of its molecules (Theorem 20.11(i)). *Read at the table's gauge, then ask*: each molecule is read at its table's gauge, native for the masses it uses and inherited by its children (Proposition 12.27), whether it answers yes is read at the centre (Theorem 11.8), and a realization that is not atomic is peeled. *Peel small*: the peel is taken at a class with the fewest marks, it splits a class only across twin childcules, each part inside one class (Theorem 14.20), so the leaf with its copies holds whole classes of every node above it and is at least as large as every bunch with its copies (Theorem 14.22). *The share kernels reapply*: what a node adds is its port, stacked Gammas of the shares of its bunch and the pins of its shape and its totals; near integer data a balanced stacked Gamma brings $\mathcal{Z}$ order by order in total index, and in the draw series each node contributes its own Dirichlet moments to every product over the blocks. *One tree*: every tree of bunches computes the same period and shares out the same $n-1$ integrations, and the Foreman tree is one in which the copies of no bunch have more marks than the copies of the leaf, and when some active list is connected no bunch has more marks than the leaf. *Pinned shares*: where the shares of a node are pinned, as for one list at a full lean across a bunch of width one, the node contributes an identity of period data (Theorem 19.34).

Chapter 34 lifts the statements of this section from periods to motivic periods: at integer data the left factors of the coaction of the motivic period of a family are read along every tree of bunches, the Foreman tree among them, through the steps attached to its vertices (Theorem 34.13); at its nodes, at any width, through the joint spectrum of the bunch (Theorem 34.16); and where the shares of a node are pinned the identities of period data above are identities of motivic periods (Theorem 34.17, Corollary 34.18).

Part V

Construction and composition

Chapter 21

Gluing and what crosses it

Every table read at a bunch is the gluing of what its bunch and its room carry (Proposition 12.5), and at a bunch of width one the gluing is along one mark, the hinge (Theorem 19.4). Gluing is an operation with its own calculus. A table is built from cells, tables with one marked hinge, substituted into the marks of a core; the bases, the weights, the multivectors, the letters and the walls of the result are read off the cells and the core; the blocks of Theorem 21.5 and the series connections of Section 20.7 are the cells and cores of the simplest kinds; two cell families glued along their hinges have hinge walls that add to 2σ on the balance wall; and every connected table whose weights factor at its bunches of width one, every list and every determinantal table among them, is a tree of such substitutions whose nodes are prime tables and series and parallel nodes. Cells with several hinges splice in pairs along any graph of pairs, closed paths included, and stay tables, their channels composing multilinearly. What a room receives from its bunch, at any width, for any family and any multivector, is the joint law of finitely many bunch letters: as many as the ranks of the level weights, which for a multivector are bounded by the squares of its interface ranks and for a determinantal table by $\binom{c(B)}{i}^2$ at the level $d(B)+i$, whatever the numbers of marks; for a determinantal table the bunch crosses its gluing as one positive definite matrix of size $c(B)$, whose determinant at width one is the hinge value γ_B^K, and one scalar.

21.1 Gluing along a mark

Definition 21.1 (Cells, cores, substitution)**.** A *cell* is a table $\mathcal{A}$ on $B \sqcup \{g\}$ in which the mark g, its *hinge*, is neither a loop nor a coloop; it may carry two systems of positive weights on its bases, θ^K for its letter $K_{\mathcal{A}}$ and θ^Ψ for its letter $\Psi_{\mathcal{A}}$ (Definition 8.1), and it is *plain* when they agree, as for one table. Its *hinge minors* are the deletion $\mathcal{A} \setminus g$ and the contraction $\mathcal{A}/g$, tables on B of ranks $r_{\mathcal{A}}$ and $r_{\mathcal{A}} - 1$ with the inherited weights (Definition 7.3), so that

$$K_{\mathcal{A}} = K_{\mathcal{A}\setminus g} + \alpha_g K_{\mathcal{A}/g}, \qquad \Psi_{\mathcal{A}} = \alpha_g \Psi_{\mathcal{A}\setminus g} + \Psi_{\mathcal{A}/g};$$

its hinge values and its ratio, as for a bunch of width one (Definition 19.2), are

$$\gamma_{\mathcal{A}}^K = \frac{K_{\mathcal{A}\setminus g}}{K_{\mathcal{A}/g}}, \qquad \gamma_{\mathcal{A}}^\Psi = \frac{\Psi_{\mathcal{A}/g}}{\Psi_{\mathcal{A}\setminus g}}, \qquad \varrho_{\mathcal{A}} = \frac{\gamma_{\mathcal{A}}^\Psi}{\gamma_{\mathcal{A}}^K} = \frac{\mathbf{E}_{\mathcal{A}/g}}{\mathbf{E}_{\mathcal{A}\setminus g}},$$

functions of α_B homogeneous of the degrees 1, 1 and 0. The cell of a bunch $\mathcal{B}_B^+$ of Theorem 19.4 is a cell, with the hinge minors $\mathcal{B}|B$ and $\mathcal{B}/R$, the hinge values γ_B^K, γ_B^Ψ and the ratio ϱ_B of Definition 19.2. A *core* is a table $\mathcal{H}$ on marks $h_1, \dots, h_q$, none of them a loop or a coloop, plain or

with two systems of weights as a cell. For cells $\mathcal{A}_i$ on $B_i \sqcup \{g_i\}$, the B_i disjoint, the *substitution* $\mathcal{H}\langle \mathcal{A}_1, \dots, \mathcal{A}_q\rangle$ is the family of sets $\bigsqcup_i X_i \subseteq \bigsqcup_i B_i$ for which some basis T of $\mathcal{H}$ has $X_i \in \mathcal{A}_i \setminus g_i$ when $h_i \in T$ and $X_i \in \mathcal{A}_i/g_i$ when $h_i \notin T$, with the weight, in each letter,

$$\theta_{\sqcup_i X_i} = \theta^{\mathcal{H}}_T \prod_{h_i \in T} \theta^{\mathcal{A}_i}_{X_i} \prod_{h_i \notin T} \theta^{\mathcal{A}_i}_{X_i + g_i},$$

every θ read as the weight θ^K of the letter K throughout, or as θ^Ψ throughout; T is determined by the sizes, $h_i \in T$ exactly when $|X_i| = r_{\mathcal{A}_i}$. A mark h is *left in place* by the cell $\binom{\{h,g\}}{1}$, the list on $\{h, g\}$ with the bases $\{h\}$ and $\{g\}$, whose hinge minors have the single bases $\{h\}$ and $\varnothing$ and whose hinge values are both α_h. A plain cell is a *dual pair* when its contraction $\mathcal{A}/g$ is the dual table of its deletion $\mathcal{A} \setminus g$, weights included: the bases of $\mathcal{A}/g$ are the $B \setminus X$, X a basis of $\mathcal{A} \setminus g$, with $\theta^{\mathcal{A}}_{(B\setminus X)+g} = \theta^{\mathcal{A}}_X$; a mark left in place is one. One cell $\mathcal{A}$ at one mark h of $\mathcal{H}$, the other marks left in place, is the *gluing of $\mathcal{A}$ and $\mathcal{H}$ along h*: the gluing (Definition 12.4) of the communicatroid of B whose children are $\theta^{\mathcal{A}}_X$ times $\mathcal{H}/h$ at the bases X of $\mathcal{A} \setminus g$ and $\theta^{\mathcal{A}}_{X+g}$ times $\mathcal{H} \setminus h$ at the bases X of $\mathcal{A}/g$. A family is *substituted* table by table, $(\mathcal{B}_j, \theta_j) = \mathcal{H}_j\langle \mathcal{A}_{1j}, \dots, \mathcal{A}_{qj}\rangle$, the cells of all tables at the mark h_i sharing the marks $B_i \sqcup \{g_i\}$; its masses are on $\mathcal{E} = \bigsqcup_i B_i$.

Lemma 21.2 (Gluing along a mark gives a table)**.** *Let $\mathcal{A}$ be a cell on $B \sqcup \{g\}$ and $\mathcal{A}'$ a cell on $R \sqcup \{g'\}$. The sets $X \sqcup Y$ with $X \in \mathcal{A} \setminus g$ and $Y \in \mathcal{A}'/g'$, or $X \in \mathcal{A}/g$ and $Y \in \mathcal{A}' \setminus g'$, are the bases of a table on $B \sqcup R$ of rank $r_{\mathcal{A}} + r_{\mathcal{A}'} - 1$, in which B is a bunch of width one whose cell of the bunch and cell of the room (Theorem 19.4) are $\mathcal{A}$ and $\mathcal{A}'$, the hinges read as the one mark g.*

Proposition 21.3 (Substitution)**.** *(i) $\mathcal{H}\langle \mathcal{A}_1, \dots, \mathcal{A}_q\rangle$ is a table of rank $r_{\mathcal{H}} + \sum_i (r_{\mathcal{A}_i} - 1)$; it is the gluing of the cells to $\mathcal{H}$ along its marks one at a time, in any order; each B_i is a bunch of it of width one whose cell of the bunch is $\mathcal{A}_i$, its weights factoring across B_i and its room.*

(ii) Substituting into a mark of a cell is substituting the substituted cell: for a mark x of B_1 and a cell $\mathcal{A}'$ at x,

$$\big(\mathcal{H}\langle \mathcal{A}_1, \dots, \mathcal{A}_q\rangle\big)\langle \mathcal{A}' \text{ at } x\rangle = \mathcal{H}\big\langle \mathcal{A}_1\langle \mathcal{A}' \text{ at } x\rangle, \mathcal{A}_2, \dots, \mathcal{A}_q\big\rangle.$$

(iii) Conversely, a table with a bunch B of width one, the weights factoring across B and R, is the gluing of its cell of the bunch $\mathcal{B}^+_B$ and its cell of the room $\mathcal{B}^+_R$ along g (Theorem 19.4): every gluing along a mark is that decomposition read backwards, and every such decomposition is a gluing.

(iv) If $\mathcal{H}\langle \mathcal{A}_1, \dots, \mathcal{A}_q\rangle$ is connected, so are $\mathcal{H}$ and every cell. A connected table with a bunch B of width one, $|B|, |R| \geq 2$, the weights factoring across B and R, is the gluing along a mark of two connected tables on fewer marks.

Theorem 21.4 (The letters of a substitution)**.** *Let K and Ψ be the letters of $\mathcal{H}\langle \mathcal{A}_1, \dots, \mathcal{A}_q\rangle$, each with its own weights, and read the hinge minors and the hinge values of each cell on its own marks. Then*

$$K(\alpha) = \prod_i K_{\mathcal{A}_i/g_i}(\alpha_{B_i})\ K_{\mathcal{H}}\big(\gamma^K_{\mathcal{A}_1}(\alpha_{B_1}), \dots, \gamma^K_{\mathcal{A}_q}(\alpha_{B_q})\big),$$
$$\Psi(\alpha) = \prod_i \Psi_{\mathcal{A}_i\setminus g_i}(\alpha_{B_i})\ \Psi_{\mathcal{H}}\big(\gamma^\Psi_{\mathcal{A}_1}(\alpha_{B_1}), \dots, \gamma^\Psi_{\mathcal{A}_q}(\alpha_{B_q})\big).$$

For one cell, the other marks left in place, this is Theorem 19.4.

The core reads each of its cells as one mark, at the hinge value of the cell by the letter: in K the mark h_i stands at $\gamma^K_{\mathcal{A}_i}$ and in Ψ at $\gamma^\Psi_{\mathcal{A}_i}$, and what is left over is a product of one letter of a hinge minor of every cell. Nothing in the core sees more of a cell than its two hinge values.

A family can be generated rather than found: seed tables assembled under a set of bijections give atoms (Proposition 11.6), and a mark that is neither a loop nor a coloop, replaced by a block of new marks, gives a bunch of width one, which the room reads as the mark it replaced.

Theorem 21.5 (Replacement of marks by blocks)**.** *Let $(\mathcal{B},\theta)$ be a table of rank r on $\mathcal{E}=\mathcal{E}_1\sqcup\mathcal{E}_2$, and replace every mark h by a* block *X_h of $q_h\geq 1$ new marks, by the* first rule *at the marks of $\mathcal{E}_1$ and by the* complementary rule*, the first rule read on the dual table, at those of $\mathcal{E}_2$: a basis T gives the sets that contain one mark of X_h for each $h\in T\cap\mathcal{E}_1$, none for $h\in\mathcal{E}_1\setminus T$, all of X_h for $h\in T\cap\mathcal{E}_2$ and all of X_h but one for $h\in\mathcal{E}_2\setminus T$, each with the weight of T. They are the bases of a table on $\bigsqcup_h X_h$ of rank $r+\sum_{h\in\mathcal{E}_2}(q_h-1)$; a block of one mark leaves its mark in place, and when no mark is a loop or a coloop the table is the substitution into $(\mathcal{B},\theta)$ of the* parallel blocks $\binom{X_h\sqcup\{g_h\}}{1}$ *at $\mathcal{E}_1$ and the* series blocks $\binom{X_h\sqcup\{g_h\}}{q_h}$ *at $\mathcal{E}_2$ (Definition 21.1). Its Foreman polynomials are, each e_k read on the marks of its block,*

$$K'=\prod_{h\in\mathcal{E}_2} e_{q_h-1}\cdot K\Big(\big(e_1\big)_{h\in\mathcal{E}_1},\big(\tfrac{e_{q_h}}{e_{q_h-1}}\big)_{h\in\mathcal{E}_2}\Big),\qquad \Psi'=\prod_{h\in\mathcal{E}_1} e_{q_h-1}\cdot\Psi\Big(\big(\tfrac{e_{q_h}}{e_{q_h-1}}\big)_{h\in\mathcal{E}_1},\big(e_1\big)_{h\in\mathcal{E}_2}\Big);$$

for one block $X=\{x_1,\dots,x_q\}$ at the mark h, the other marks left in place, the first rule gives $K'=K_{\setminus h}+e_1(\alpha_X)\,K_{/h}$ and $\Psi'=e_q(\alpha_X)\,\Psi_{\setminus h}+e_{q-1}(\alpha_X)\,\Psi_{/h}$, and the complementary rule gives $K'=e_q(\alpha_X)\,K_{/h}+e_{q-1}(\alpha_X)\,K_{\setminus h}$ and $\Psi'=\Psi_{/h}+e_1(\alpha_X)\,\Psi_{\setminus h}$ (Definition 7.3). In scale and shape, $\alpha_X=\rho u$ with $u\in\Delta_X$: $e_1(\alpha_X)=\rho$, $e_q(\alpha_X)=\rho^q e_q(u)$, $e_{q-1}(\alpha_X)=\rho^{q-1}e_{q-1}(u)$, and $\alpha_X^{\mathbf{m}|_X-\mathbf{1}}d\alpha_X=\rho^{m_X-1}d\rho\;u^{\mathbf{m}|_X-\mathbf{1}}d\omega_X(u)$ (Lemma 2.7).

Theorem 21.6 (Counts, walls and atoms under replacement)**.** *Let $(\mathcal{B},\theta)$ be a table of rank r on $\mathcal{E}$, $n=|\mathcal{E}|$, and replace every mark h by a block X_h of $q_h\geq 1$ new marks as in Theorem 21.5, by the first rule at the marks of $\mathcal{E}_1$ and by the complementary rule at those of $\mathcal{E}_2$, $\mathcal{E}=\mathcal{E}_1\sqcup\mathcal{E}_2$.*

(i) The marks become $\sum_h q_h$; the rank becomes $r+\sum_{h\in\mathcal{E}_2}(q_h-1)$; the total weight becomes

$$\sum_{T\in\mathcal{B}}\theta_T\prod_{h\in T\cap\mathcal{E}_1}q_h\prod_{h\in\mathcal{E}_2\setminus T}q_h=\prod_{h\in\mathcal{E}_2}q_h\cdot K\Big((q_h)_{h\in\mathcal{E}_1},(q_h^{-1})_{h\in\mathcal{E}_2}\Big),$$

which is $K((q_h)_h)$ under the first rule alone and $\Psi((q_h)_h)$ under the complementary rule alone.

(ii) For a set Y of new marks let $\lceil Y\rceil=\{h:\ X_h\cap Y\neq\varnothing\}$ and $\lfloor Y\rfloor=\{h:\ X_h\subseteq Y\}$, and let r', d', $d^{*\prime}$, c' be the counts of the new table (Definition 7.12). Then

$$d'(Y)=\sum_{h\in\mathcal{E}_2}\max\big(|X_h\cap Y|-1,0\big)+d\big((\lfloor Y\rfloor\cap\mathcal{E}_1)\sqcup(\lceil Y\rceil\cap\mathcal{E}_2)\big),$$
$$d^{*\prime}(Y)=\sum_{h\in\mathcal{E}_1}\max\big(|X_h\cap Y|-1,0\big)+d^*\big((\lceil Y\rceil\cap\mathcal{E}_1)\sqcup(\lfloor Y\rfloor\cap\mathcal{E}_2)\big),$$

and $c'(Y)=|Y|-d'(Y)-d^{*\prime}(Y)$. Under the first rule alone $r'(Y)=r(\lceil Y\rceil)$, $d'(Y)=r-r(\mathcal{E}\setminus\lfloor Y\rfloor)$ and $c'(Y)=r(\lceil Y\rceil)+r(\mathcal{E}\setminus\lfloor Y\rfloor)-r$; under the complementary rule alone $c'(Y)=|\lceil Y\rceil|-|\lfloor Y\rfloor|+r(\mathcal{E}\setminus\lceil Y\rceil)+r(\lfloor Y\rfloor)-r$. If $Y=\bigcup_{h\in S}X_h$, then $c'(Y)=c(S)$; when the seed table is connected on at least two marks, a proper nonempty part of one block has width one.

(iii) Let a family of seed tables with positive exponent pairs be connected on at least two marks and carried to itself by a set H of bijections as in Proposition 11.6, and replace every mark by a block of the same q marks, all by the first rule or all by the complementary rule. Then the bijections of H lift to the blocks, the permutations inside a block carry every replaced table to itself, the replaced family is connected, and for every q its realization at the table's gauge is an atom.

The shape of a block is integrated by Theorem 19.8, and its scale is the mark of the seed. A block X_h of Theorem 21.5 with $q_h \geq 2$ whose mark is neither a loop nor a coloop of the seed is a parallel bunch of width one under the first rule and a series bunch of width one under the complementary rule (Definition 19.1).

Corollary 21.7 (Blocks and closures)**.** *(i) The series block on a set B of ℓ marks (Theorem 21.5) is the cell $\binom{B\sqcup\{g\}}{\ell}$, whose hinge minors have $K_{\backslash g} = e_\ell(\alpha_B)$, $K_{/g} = e_{\ell-1}(\alpha_B)$, $\Psi_{\backslash g} = 1$ and $\Psi_{/g} = e_1(\alpha_B)$; the parallel block is the cell $\binom{B\sqcup\{g\}}{1}$, with $K_{\backslash g} = e_1(\alpha_B)$, $K_{/g} = 1$, $\Psi_{\backslash g} = e_{\ell-1}(\alpha_B)$ and $\Psi_{/g} = e_\ell(\alpha_B)$. Series blocks at the marks h_i, $i \in S$, of a core $\mathcal{H}$ and parallel blocks at the others replace the marks of $\mathcal{H}$ by blocks as in Theorem 21.5, the series blocks by its complementary rule and the parallel blocks by its first rule, and give the letters of that theorem, each e_k read on the marks of its block: a series block is seen by Ψ through its total and by K through the hinge value $e_\ell/e_{\ell-1} = \big(\sum_x \alpha_x^{-1}\big)^{-1}$, a parallel block the other way round.*

(ii) The series closure *of cells $\mathcal{A}_1, \dots, \mathcal{A}_q$ is the substitution $\binom{\{h_1,\dots,h_q\}}{q-1}\langle \mathcal{A}_1, \dots, \mathcal{A}_q\rangle$ into the core of unit weights; its letters are*

$$K = \prod_i K_{\mathcal{A}_i\backslash g_i} \cdot \sum_i \frac{K_{\mathcal{A}_i/g_i}}{K_{\mathcal{A}_i\backslash g_i}}, \qquad \Psi = \prod_i \Psi_{\mathcal{A}_i\backslash g_i} \cdot \sum_i \frac{\Psi_{\mathcal{A}_i/g_i}}{\Psi_{\mathcal{A}_i\backslash g_i}},$$

so that the bunch $B_1 \sqcup \cdots \sqcup B_{q-1}$ is the series connection of the parts B_i with the tables $\mathcal{A}_i \setminus g_i$ and $\mathcal{A}_i/g_i$ (Proposition 20.37, with $C = C' = 1$). The parallel closure $\binom{\{h_1,\dots,h_q\}}{1}\langle \mathcal{A}_1, \dots, \mathcal{A}_q\rangle$ *has the letters $K = \prod_i K_{\mathcal{A}_i/g_i} \cdot \sum_i K_{\mathcal{A}_i\backslash g_i}/K_{\mathcal{A}_i/g_i}$ and $\Psi = \prod_i \Psi_{\mathcal{A}_i/g_i} \cdot \sum_i \Psi_{\mathcal{A}_i\backslash g_i}/\Psi_{\mathcal{A}_i/g_i}$; it is the dual of the series closure of the dual cells.*

(iii) The gluing of two cells along their hinges is $\binom{\{h_1,h_2\}}{1}\langle \mathcal{A}_1, \mathcal{A}_2\rangle$, with the letters $K = K_{\mathcal{A}_1\backslash g_1} K_{\mathcal{A}_2/g_2} + K_{\mathcal{A}_1/g_1} K_{\mathcal{A}_2\backslash g_2}$ and $\Psi = \Psi_{\mathcal{A}_1/g_1}\Psi_{\mathcal{A}_2\backslash g_2} + \Psi_{\mathcal{A}_1\backslash g_1}\Psi_{\mathcal{A}_2/g_2}$.

Proposition 21.8 (Dual pairs)**.** *Let $\mathcal{A}$ be a plain cell on $B \sqcup \{g\}$ of rank $r_\mathcal{A}$ that is a dual pair (Definition 21.1), and put $k = K_{\mathcal{A}\backslash g}$ and $\psi = \Psi_{\mathcal{A}\backslash g}$.*

(i) A plain cell is a dual pair exactly when its bases are closed under complement with equal weights; then $|B| = 2r_\mathcal{A} - 1$, so that k has the degree $r_\mathcal{A}$ and ψ the degree $r_\mathcal{A} - 1$.

(ii) $K_{\mathcal{A}/g} = \psi$ and $\Psi_{\mathcal{A}/g} = k$; the two hinge values agree, $\gamma_\mathcal{A}^K = \gamma_\mathcal{A}^\Psi = k/\psi$, and $\varrho_\mathcal{A} = 1$.

(iii) Let $\mathcal{H}\langle \mathcal{A}_1, \dots, \mathcal{A}_q\rangle$ be a substitution of dual pairs into a plain core $\mathcal{H}$, of rank $r_\mathcal{H}$, with k_i and ψ_i as above and $\pi = \psi_1 \cdots \psi_q$; a mark left in place is a dual pair with $k_i = \alpha_h$ and $\psi_i = 1$. Then, as identities of polynomials, with $\pi k_i/\psi_i = k_i \prod_{l\neq i} \psi_l$ and K, Ψ the letters of the substitution,

$$K_\mathcal{H}\big((\pi k_i/\psi_i)_i\big) = \pi^{\,r_\mathcal{H}-1} K, \qquad \Psi_\mathcal{H}\big((\pi k_i/\psi_i)_i\big) = \pi^{\,q-r_\mathcal{H}-1}\Psi.$$

Proposition 21.9 (The multivector of a substitution)**.** *Let $\mathcal{H}$ and the cells carry multivectors $\boldsymbol{\omega}_{\mathcal{H}}$ and $\boldsymbol{\omega}_i$ (Definition 7.20), the hinge first in the order of the marks of each cell, and order the marks of the substitution by putting B_i, in its order in $\mathcal{A}_i$, in the place of h_i in the order of $\mathcal{H}$. Then*

$$\boldsymbol{\omega}\Big(\bigsqcup_i X_i\Big) = \boldsymbol{\omega}_{\mathcal{H}}(T) \prod_{h_i \in T} \boldsymbol{\omega}_i(X_i) \prod_{h_i \notin T} \boldsymbol{\omega}_i(g_i + X_i)$$

is a multivector of $\mathcal{H}\langle \mathcal{A}_1, \dots, \mathcal{A}_q\rangle$; it is multilinear in $(\boldsymbol{\omega}_{\mathcal{H}}, \boldsymbol{\omega}_1, \dots, \boldsymbol{\omega}_q)$, a substitution of decomposable multivectors is decomposable, and

$$\mathrm{rk}(\boldsymbol{\omega}) \le \mathrm{rk}(\boldsymbol{\omega}_{\mathcal{H}}) \prod_i \mathrm{rk}(\boldsymbol{\omega}_i).$$

A substitution of determinantal tables is determinantal.

Theorem 21.10 (The walls of a substitution)**.** *For $S = \bigsqcup_i S_i$, $S_i \subseteq B_i$, let $D(S)$ be the set of the marks h_i of the core with $d_{\mathcal{A}_i}(S_i + g_i) > d_{\mathcal{A}_i}(S_i)$ and $D^*(S)$ that of the h_i with $d^*_{\mathcal{A}_i}(S_i + g_i) > d^*_{\mathcal{A}_i}(S_i)$, the two differences being 0 or 1. The counts of the substitution are*

$$d(S) = \sum_i d_{\mathcal{A}_i}(S_i) + d_{\mathcal{H}}\big(D(S)\big), \qquad d^*(S) = \sum_i d^*_{\mathcal{A}_i}(S_i) + d^*_{\mathcal{H}}\big(D^*(S)\big),$$

and for a substituted family, with $D_j(S)$ and $D^*_j(S)$ read in table j, its walls are

$$\kappa_S = \sum_i \Big(m_{S_i} - \sum_j \big(s_j d_{\mathcal{A}_{ij}}(S_i) + t_j d^*_{\mathcal{A}_{ij}}(S_i)\big)\Big) - \sum_j \Big(s_j d_{\mathcal{H}_j}\big(D_j(S)\big) + t_j d^*_{\mathcal{H}_j}\big(D^*_j(S)\big)\Big).$$

At $S = B_i$, $D(S) = D^*(S) = \{h_i\}$ and the wall is $\kappa_{B_i} = m_{B_i} - \sum_j \big(s_j(r_{\mathcal{A}_{ij}} - 1) + t_j(|B_i| - r_{\mathcal{A}_{ij}})\big)$, the mass that pooling gives the hinge of B_i (Theorem 19.8).

Corollary 21.11 (The width of the marks left in place)**.** *Let a substitution have the core $\mathcal{H}$ on $L \sqcup H'$, the marks of L left in place and cells with at least two marks at the marks of H'. Every $S \subseteq L$ has the width it has in the core, and*

$$c(S) = c_{\mathcal{H}}(S) \le |L \setminus S| + |H'|.$$

So a bunch of width c that is all the marks left in place needs at least c other cells, and every width occurs: in $\binom{B \sqcup \{h_1, \dots, h_c\}}{c}$ with $|B| = c$, the marks of B left in place, B has the width c, whatever the cells at $h_1, \dots, h_c$.

Lemma 21.12 (Two-sums of cells; hinge walls)**.** *Let $\mathcal{A}$ be a cell on $B \sqcup \{g\}$ and $\mathcal{A}'$ a cell on $R \sqcup \{g\}$ with the one hinge g, $B \cap R = \varnothing$, and let $\mathcal{A} \oplus_g \mathcal{A}'$ be their gluing along the hinge, $\binom{\{h_1, h_2\}}{1}\langle \mathcal{A}, \mathcal{A}'\rangle$ (Corollary 21.7(iii)), each basis carrying in each letter the product of the weights of the two bases of $\mathcal{A}$ and $\mathcal{A}'$ it is made of: a table on $B \sqcup R$ of rank $r_{\mathcal{A}} + r_{\mathcal{A}'} - 1$, plain when $\mathcal{A}$ and $\mathcal{A}'$ are, in which B is a bunch of width one with the cell of the bunch $\mathcal{A}$ and the cell of the room $\mathcal{A}'$ (Lemma 21.2); every table with a bunch of width one, the weights factoring across it, is the two-sum of its two cells (Proposition 21.3(iii)). Let the cell families $F_B = ((\mathcal{A}_j, \theta^{\mathcal{A}_j}); s_j, t_j)_{j=1}^N$ on $B \sqcup \{g\}$ and $F_R = ((\mathcal{A}'_j, \theta^{\mathcal{A}'_j}); s_j, t_j)_{j=1}^N$ on $R \sqcup \{g\}$ be glued table by table into the family $F = ((\mathcal{A}_j \oplus_g \mathcal{A}'_j); s_j, t_j)_j$ on $B \sqcup R$, with masses $\mathbf{m}$. The walls of F at B and at R are the hinge walls of the two cell families, for one table those of the two cells, $\kappa_{\mathcal{A}}$ and $\kappa_{\mathcal{A}'}$,*

$$\kappa_{F_B} = m_B - \sum_j \big(s_j(r_{\mathcal{A}_j} - 1) + t_j(|B| - r_{\mathcal{A}_j})\big), \qquad \kappa_{F_R} = m_R - \sum_j \big(s_j(r_{\mathcal{A}'_j} - 1) + t_j(|R| - r_{\mathcal{A}'_j})\big),$$

and $\kappa_{F_B} + \kappa_{F_R} = 2\sigma + \kappa_{\mathcal{E}}$, σ the total strength and $\kappa_{\mathcal{E}}$ the imbalance of F (Definition 8.1): on the balance wall the two hinge walls add to $2\sigma = \sum_j (s_j + t_j)$, and the mass $2\sigma - \kappa_{F_B}$ on g puts the cell family F_B itself on its balance wall.

Each letter of a two-sum is a letter of a hinge minor of one cell times the letter of the other cell read at one hinge value of the first (Theorem 21.4): K sees $\mathcal{A}$ through $\gamma_{\mathcal{A}}^{K}$ and Ψ through $\gamma_{\mathcal{A}}^{\Psi}$. The hinge wall of a cell is a number of the cell alone, its masses and its exponents, and balance makes the two hinge walls of a two-sum complementary; the period of a two-sum is read through them in Theorem 23.9.

21.2 Splicing hinges in pairs

A cell has one hinge. Gluing along several marks at once, or around a closed path of cells, needs cells with several hinges and a splicing of hinges in pairs. The splicing stays inside tables because the levels of a bunch are tables (Proposition 12.17); one pair joining two cells is the gluing of Lemma 21.2.

Definition 21.13 (Cells with several hinges; channels)**.** A *cell with the hinges* G is a table $\mathcal{A}$ on $B \sqcup G$ with two systems of positive weights θ^K, θ^Ψ on its bases; $n_{\mathcal{A}} = |B|$ is its number of marks other than its hinges. Its *channels* are the letters of the children of the bunch G (Definition 12.1): for a pattern $p \in \mathrm{pat}(G)$, the basis polynomial $K_{\mathcal{A},(p)}$ of the child at p with the weights θ^K and its cobasis polynomial $\Psi_{\mathcal{A},(p)}$ with the weights θ^Ψ, polynomials on B, so that by the Taylor cube (Theorem 12.7)

$$K_{\mathcal{A}} = \sum_{p \in \mathrm{pat}(G)} \alpha_G^p \, K_{\mathcal{A},(p)}(\alpha_B), \qquad \Psi_{\mathcal{A}} = \sum_{p \in \mathrm{pat}(G)} \alpha_G^{G \setminus p} \, \Psi_{\mathcal{A},(p)}(\alpha_B) :$$

p is the set of hinges a basis occupies, in both letters. A channel has positive coefficients on its support and the degree

$$\deg K_{\mathcal{A},(p)} = r_{\mathcal{A}} - |p|, \qquad \deg \Psi_{\mathcal{A},(p)} = n_{\mathcal{A}} - r_{\mathcal{A}} + |p|.$$

The *channel vector* $\mathrm{ch}(\mathcal{A})$ lists the channels by their *tags*, the pairs of a letter and a set $p \subseteq G$, $2^{|G|+1}$ of them; a tag whose set is not a pattern is an absent channel, counted as zero. A cell of Definition 21.1 is the case of one hinge g that is neither a loop nor a coloop, with $K_{\mathcal{A},(\varnothing)} = K_{\mathcal{A}\setminus g}$, $K_{\mathcal{A},(\{g\})} = K_{\mathcal{A}/g}$, $\Psi_{\mathcal{A},(\varnothing)} = \Psi_{\mathcal{A}\setminus g}$ and $\Psi_{\mathcal{A},(\{g\})} = \Psi_{\mathcal{A}/g}$. *Splicing* a pair $\{a, b\}$ of hinges keeps the bases that occupy exactly one of them and forgets the pair; on either letter it is

$$L \longmapsto (\partial_{\alpha_a} + \partial_{\alpha_b}) L \big|_{\alpha_a = \alpha_b = 0}.$$

Cells are spliced along pairs of their hinges by splicing the pairs in their direct sum (Proposition 7.9).

Theorem 21.14 (Splicing hinges in pairs)**.** *(i) Splicing a pair $\{a, b\}$ of hinges of a cell $\mathcal{A}$ at which some basis occupies exactly one of a, b gives a cell on $B \sqcup (G \setminus \{a, b\})$ of rank $r_{\mathcal{A}} - 1$: its bases are the sets $T \setminus \{a, b\}$ with $|T \cap \{a, b\}| = 1$, each carrying in each letter the sum of the weights of the bases T that give it.*

(ii) Let a direct sum of cells carry a set of disjoint pairs of hinges, forming any graph on the cells: closed paths, a pair inside one cell and several pairs between two cells are allowed. If

some choice of one basis in each cell occupies exactly one hinge of every pair, splicing the pairs one at a time, in any order, gives one cell; its rank is the sum of the ranks less the number of pairs, its bases are the unions of the unpaired parts of such choices, and its weight in each letter at a basis is the sum, over the choices that give it, of the products of the weights chosen. Plain cells give a plain cell.

(iii) Under the hypothesis of (ii), let the cells be $\mathcal{A}_1, \dots, \mathcal{A}_m$ with the hinges $G_1, \dots, G_m$, and in this statement let G' be the set of the hinges that lie in no pair, k the number of pairs and, for $p \subseteq G'$, let J run over the sets of paired hinges that contain exactly one hinge of every pair. The spliced cell $\mathcal{A}$ has the channels

$$K_{\mathcal{A},(p)} = \sum_J \prod_{i=1}^{m} K_{\mathcal{A}_i,((p \sqcup J)\cap G_i)}, \qquad \Psi_{\mathcal{A},(p)} = \sum_J \prod_{i=1}^{m} \Psi_{\mathcal{A}_i,((p \sqcup J)\cap G_i)},$$

absent channels counting as zero; it has $\sum_i n_{\mathcal{A}_i}$ marks besides its hinges G' and the rank $\sum_i r_{\mathcal{A}_i} - k$, and every product on the right has the degree of the channel on the left. The map $\big(\mathrm{ch}(\mathcal{A}_1), \dots, \mathrm{ch}(\mathcal{A}_m)\big) \mapsto \mathrm{ch}(\mathcal{A})$ is multilinear. For two cells $\mathcal{A}_1$ and $\mathcal{A}_2$ spliced along k pairs, each pair named once, so that the paired hinges of either cell form one set I of k names and the other hinges form G_1' and G_2', it is the bilinear map

$$K_{\mathcal{A}_{12},(p_1 \sqcup p_2)} = \sum_{I' \subseteq I} K_{\mathcal{A}_1,(p_1 \sqcup I')}\, K_{\mathcal{A}_2,(p_2 \sqcup (I \setminus I'))},$$
$$\Psi_{\mathcal{A}_{12},(p_1 \sqcup p_2)} = \sum_{I' \subseteq I} \Psi_{\mathcal{A}_1,(p_1 \sqcup I')}\, \Psi_{\mathcal{A}_2,(p_2 \sqcup (I \setminus I'))},$$

$p_1 \subseteq G_1'$, $p_2 \subseteq G_2'$; with $k = 1$ and no other hinges it is Corollary 21.7(iii).

Chapter 27 turns the bilinearity of Theorem 21.14(iii) into finite moment vectors and transfer matrices.

21.3 What crosses a gluing

Definition 21.15 (Level weights, level factorizations, interface)**.** Let $(\mathcal{B}, \theta)$ be a table of rank r with a bunch B, of any width, and room R. For a level k, $d(B) \le k \le r(B)$, the *level weights* are the matrix $\Theta_B^{(k)} = (\theta_{p \sqcup X})_{p,X}$ indexed by the k-sets $p \subseteq B$ and the $(r-k)$-sets $X \subseteq R$, with $\theta_{p \sqcup X} = 0$ when $p \sqcup X$ is not a basis. A *level factorization* writes every level letter (Definition 12.16) as a sum of products over a finite set C_k,

$$K_B^{(k)}(\alpha) = \sum_{c \in C_k} V_{k,c}(\alpha_B)\, L_{k,c}(\alpha_R),$$

each $V_{k,c}$ a real linear combination of the monomials α_B^p, $|p| = k$, and each $L_{k,c}$ a real linear combination of the monomials α_R^X, $|X| = r - k$: equivalently, a writing of $\Theta_B^{(k)}$ as a sum of $|C_k|$ products of a column and a row, so that $|C_k| \ge \operatorname{rank} \Theta_B^{(k)}$, with equality for some factorization. The $V_{k,c}$ are the *bunch letters* and the $L_{k,c}$ the *room letters*. With $V_{k,c}^*(\alpha_B) = \alpha_B^B V_{k,c}(\alpha_B^{-1})$ and $L_{k,c}^*(\alpha_R) = \alpha_R^R L_{k,c}(\alpha_R^{-1})$ the same factorization writes the colevel letter of the colevel $|B| - k$,

$$\Psi_B^{(|B|-k)}(\alpha) = \sum_{c \in C_k} V_{k,c}^*(\alpha_B)\, L_{k,c}^*(\alpha_R) :$$

each level is one function read twice (Proposition 7.2). The *stations* of B are the maximal sets of patterns whose children are positive multiples of one another, each with a fixed representative, the *child of the station*; every station lies in one level. The *children factorization* lets c run over the stations of level k, with $V_{k,c} = \sum_{p\in c} w_p\, \alpha_B^p$ for the child at p equal to w_p times the child of the station, and $L_{k,c}$ the basis polynomial of the child of the station: all its terms are nonnegative. The *interface dimension* of B is $\sum_k \operatorname{rank} \Theta_B^{(k)}$; for a family it is summed over the tables.

Along the scale of B, $\alpha_B = \rho u$ with $u \in \Delta_B$ (Lemma 2.7), $V_{k,c}(\rho u) = \rho^k V_{k,c}(u)$ and $V^*_{k,c}(\rho u) = \rho^{|B|-k} V^*_{k,c}(u)$; since $|B| - r(B) = d^*(B)$,

$$K(\rho u, \alpha_R) = \rho^{d(B)} \sum_k \rho^{k-d(B)} \sum_c V_{k,c}(u)\, L_{k,c}(\alpha_R),$$
$$\Psi(\rho u, \alpha_R) = \rho^{d^*(B)} \sum_k \rho^{r(B)-k} \sum_c V^*_{k,c}(u)\, L^*_{k,c}(\alpha_R),$$

each letter counted from its own bottom level, both powers running over $\rho^0, \dots, \rho^{c(B)}$.

Theorem 21.16 (What crosses a gluing)**.** *Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$ be a family on $\mathcal{E}$ with real data and masses $\mathbf{m}$ on its balance wall, B a bunch with room R, and fix a level factorization of every table, with the bunch letters $V_{j,k,c}$, the room letters $L_{j,k,c}$ and the starred letters $V^*_{j,k,c}$, $L^*_{j,k,c}$. Let $\mathbf{V}(u) = \big(V_{j,k,c}(u), V^*_{j,k,c}(u)\big)_{j,k,c}$ be the* letter vector *of $u \in \Delta_B$. Then, in $[0,\infty]$,*

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \int_{\Delta_R} v^{\mathbf{m}|_R - \mathbf{1}} \int_{\Delta_B} u^{\mathbf{m}|_B - \mathbf{1}} \int_0^\infty \rho^{\kappa_B - 1} \prod_j \Big(\sum_{k,c} \rho^{k-d_j(B)} V_{j,k,c}(u)\, L_{j,k,c}(v) \Big)^{-s_j} \times \Big(\sum_{k,c} \rho^{r_j(B)-k} V^*_{j,k,c}(u)\, L^*_{j,k,c}(v) \Big)^{-t_j} d\rho\, d\omega_B(u)\, d\omega_R(v),$$

κ_B the wall of B, and the integrand, apart from the measure $u^{\mathbf{m}|_B-\mathbf{1}} d\omega_B(u)$, depends on u only through $\mathbf{V}(u)$. So the period sees the bunch only through its wall κ_B, its widths $c_j(B)$ and the image $\mathbf{V}_*\big(u^{\mathbf{m}|_B-\mathbf{1}} d\omega_B(u)\big)$, the joint law of its bunch letters, unnormalized: two families that agree on the room, with the same room letters, and whose bunches have equal walls, widths and laws of their letter vectors, have equal periods, whatever the numbers of marks of the bunches; the bunches are interchangeable in every room. The same holds for the interest $J_F(\mathbf{m};\mathbf{s},\mathbf{t})$ at any real masses, with $\alpha_R \in \mathbb{R}^R_{>0}$ in place of $v \in \Delta_R$ and the factor $e^{-\rho - |\alpha_R|}$ in the integrand.

At width one with factoring weights the children factorization has one set at each level, and the letter vector is $(K_{\mathcal{B}/R}, K_{\mathcal{B}|B}; \Psi_{\mathcal{B}|B}, \Psi_{\mathcal{B}/R})$, each letter from its bottom level: Theorem 19.8, which keeps the scale as the hinge g, keeps of it the cell kernel (Definition 22.2) and the two hinge values γ_B^K, γ_B^Ψ. The theorem holds whatever the weights; what the weights decide is how many bunch letters there are.

Theorem 21.17 (Multivectors bound what crosses)**.** *Let the table carry a multivector $\boldsymbol{\omega}$ of any tensor rank (Definition 7.20), the marks of B ordered before those of R, so that $\boldsymbol{\omega}_{p\sqcup X}$ is the coefficient of $\mathbf{e}_p \wedge \mathbf{e}_X$, $\mathbf{e}_p$ the wedge of the unit vectors of the marks of p in their order. At the level k let the* interface rank $\operatorname{ir}_k(\boldsymbol{\omega})$ *of $\boldsymbol{\omega}$ at B be the rank of the matrix $(\boldsymbol{\omega}_{p\sqcup X})_{p,X}$, and write $\boldsymbol{\omega}_{p\sqcup X} = \sum_{i=1}^{\operatorname{ir}_k(\boldsymbol{\omega})} f_i(p)\, f'_i(X)$.*

(i) $\operatorname{rank}\Theta_B^{(k)} \le \operatorname{ir}_k(\boldsymbol{\omega})^2$, *and* $\operatorname{rank}\Theta_B^{(k)} \le \frac12 \operatorname{ir}_k(\boldsymbol{\omega})\big(\operatorname{ir}_k(\boldsymbol{\omega})+1\big)$ *when* $\boldsymbol{\omega}$ *is real. With the positive semidefinite Hermitian matrices*

$$\mathbf{C}_k(\alpha_B) = \sum_p \alpha_B^p\, f(p) f(p)^*, \qquad \mathbf{C}'_k(\alpha_R) = \sum_X \alpha_R^X\, f'(X) f'(X)^*,$$

with $f(p) = \big(f_i(p)\big)_i$ *and* $f'(X) = \big(f'_i(X)\big)_i$, *the level letter is* $K_B^{(k)}(\alpha) = \operatorname{tr}\big(\mathbf{C}_k(\alpha_B)\,\overline{\mathbf{C}'_k(\alpha_R)}\big)$, *and the real and imaginary parts of the entries of* $\mathbf{C}_k(\alpha_B)$ *are the bunch letters of a real level factorization with at most* $\operatorname{ir}_k(\boldsymbol{\omega})^2$ *terms.*

(ii) If $\boldsymbol{\omega} = \sum_{l=1}^{\operatorname{rk}(\boldsymbol{\omega})} \boldsymbol{\omega}^{(l)}$ *with slices* $A^{(l)}$, *let the* width of the slice c_l *be the dimension of the intersection of the column spaces of the columns* $A_B^{(l)}$ *of* B *and* $A_R^{(l)}$ *of* R, *and its* floor $d_l = r - \dim\big($*column space of* $A_R^{(l)}\big)$, *which at tensor rank one are* $c(B)$ *and* $d(B)$. *Then* $\operatorname{ir}_k(\boldsymbol{\omega}) \le \sum_l \binom{c_l}{k-d_l}$.

(iii) So $\operatorname{rank}\Theta_B^{(k)} \le \big(\sum_l \binom{c_l}{k-d_l}\big)^2$, *and the interface dimension of* B *is at most* $\sum_k \big(\sum_l \binom{c_l}{k-d_l}\big)^2$, *a bound in the widths and floors of the slices alone, whatever the numbers of marks of* B *and* R; *for a real multivector each square may be replaced by* $\frac12 i_k(i_k+1)$, $i_k = \sum_l \binom{c_l}{k-d_l}$. *For a determinantal table, of tensor rank one with* $c_1 = c(B)$ *and* $d_1 = d(B)$, $\operatorname{ir}_k(\boldsymbol{\omega}) \le \binom{c(B)}{k-d(B)}$, $\operatorname{rank}\Theta_B^{(k)} \le \binom{c(B)}{k-d(B)}^2$ *and the interface dimension is at most* $\binom{2c(B)}{c(B)}$; *at width one each level has one bunch letter, as Theorem 12.19 says.*

Theorem 21.18 (The interface of a determinantal table)**.** *Let a table be determinantal over* $\mathbb{F}$ *with slice* A, $\theta_T = |\det A_T|^2$, *and let* B *have width* $c(B) = w$, *the minors* $\mathcal{B}|B$ *and* $\mathcal{B}/R$ *on* B *and* $\mathcal{B}|R$ *and* $\mathcal{B}/B$ *on* R *carrying the factoring weights of Theorem 12.19. There are Hermitian* $w \times w$ *matrices* $\mathbf{S}_B(\alpha_B)$ *and* $\mathbf{S}_R(\alpha_R)$, *positive definite on the open orthant, each entry a rational function homogeneous of degree one, with*

$$K(\alpha) = K_{\mathcal{B}/R}(\alpha_B)\, K_{\mathcal{B}/B}(\alpha_R)\, \det\big(\mathbf{S}_B(\alpha_B) + \mathbf{S}_R(\alpha_R)\big), \qquad \det \mathbf{S}_B = \frac{K_{\mathcal{B}|B}}{K_{\mathcal{B}/R}}, \qquad \det \mathbf{S}_R = \frac{K_{\mathcal{B}|R}}{K_{\mathcal{B}/B}},$$

and $\Psi(\alpha) = \alpha^{\mathcal{E}} K(\alpha^{-1})$. *Along the scale of* B, $K(\rho\alpha_B, \alpha_R) = \rho^{d(B)} K_{\mathcal{B}/R}(\alpha_B) K_{\mathcal{B}/B}(\alpha_R) \det\big(\rho\,\mathbf{S}_B + \mathbf{S}_R\big)$, *so the Skeleton values of* B *(Definition 12.10) are the eigenvalues of* $\mathbf{S}_B^{-1/2}\mathbf{S}_R\mathbf{S}_B^{-1/2}$, *real and positive. At width one* $\mathbf{S}_B = \gamma_B^K$, *the hinge value by* K *(Definition 19.2). So a bunch of width* w *of a determinantal table crosses its gluing as one positive definite* $w \times w$ *matrix and one scalar, and the same read at* α^{-1} *for* Ψ.

For a determinantal table a bunch B is thus read by its room through one positive definite matrix, $\binom{c(B)+1}{2}$ real entries when it is symmetric and $c(B)^2$ real parameters when it is Hermitian, and one scalar for each letter, and the bunch letters of Theorem 21.17 are the compound determinants of that matrix. For a multivector of tensor rank $\operatorname{rk}(\boldsymbol{\omega})$ the level letters carry the entries of the matrices $\mathbf{C}_k$ of Theorem 21.17(i), whose size is fixed by the interface ranks. In every case Theorem 21.16 says what crosses, and Theorems 21.17 and 21.18 say how much.

Chapter 22

Periods of constructions

A construction (Definition 33.1) hands its period a structure: the period of a substitution is read from the core and the cells, for any family. The core reads each cell through the joint law of its hinge values, which is pooling done at every cell at once; opened on the core's own shares, the cells ride on the core's fibre, each entering through the period of its own family at the exponents the shares assign it; and where every active letter reads a cell alike, the cell's share is pinned; where the active letters read every cell by one hinge value, as at a full lean of one table, the period factors through the core. Chains of cells are the powers of one operator, and the letters of any chain of bunches, and their integer joint moments, are products of finite matrices. A bunch of any width opens on one share per term of its level factorization; in level form, one term per level, one table at a full lean keeps $c(B) - 1$ free shares. The same periods are read through the laws of the cell families, one measure on $(0,\infty)^{2N-1}$ for each (Chapter 23), and through the periods at the full leans of the nodes (Chapters 25 and 26).

22.1 The core reads its cells

Definition 22.1 (Twists)**.** A *twist* of a family F on $\mathcal{E}$ assigns to every table j two vectors $\mathbf{x}_j^K, \mathbf{x}_j^\Psi \in (0,\infty)^{\mathcal{E}}$. The *twisted family* $F[\mathbf{x}]$, $\mathbf{x} = (\mathbf{x}_j^K, \mathbf{x}_j^\Psi)_j$, has the bases and the exponents of F, the basis weights $\theta^K_{j,T}(\mathbf{x}_j^K)^T$ and the cobasis weights $\theta^\Psi_{j,T}(\mathbf{x}_j^\Psi)^{\mathcal{E}\setminus T}$: its letters are $K_j(\mathbf{x}_j^K \circ \alpha)$ and $\Psi_j(\mathbf{x}_j^\Psi \circ \alpha)$, with $\mathbf{x} \circ \alpha = (x_e \alpha_e)_e$. A twist *at a mark* g has all its coordinates 1 off g and is written by its values $\mathbf{x} = (x_j^K, x_j^\Psi)_j$ at g; then $F[\mathbf{x}@g]$ multiplies, in table j, the weights in K_j of the bases through g by x_j^K and the weights in Ψ_j of the bases avoiding g by x_j^Ψ. A twist of one table $\mathcal{H}$ in its cobasis letter alone, $\mathbf{x}^K = \mathbf{1}$, is written $\mathcal{H}[\mathbf{x}]$ with $\mathbf{x} = \mathbf{x}^\Psi$: $K_{\mathcal{H}[\mathbf{x}]} = K_{\mathcal{H}}$ and $\Psi_{\mathcal{H}[\mathbf{x}]}(\alpha) = \Psi_{\mathcal{H}}(\mathbf{x} \circ \alpha)$. On the balance wall the period obeys the *torus relation*: for every twist $\mathbf{x}$, every $\boldsymbol{\lambda} \in (0,\infty)^{\mathcal{E}}$ and all constants $c_j, c_j^* > 0$,

$$P_{F[(c_j \boldsymbol{\lambda} \circ \mathbf{x}_j^K,\ c_j^* \boldsymbol{\lambda} \circ \mathbf{x}_j^\Psi)_j]}(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \boldsymbol{\lambda}^{-\mathbf{m}} \prod_j c_j^{-r_j s_j}\, c_j^{*\,-r_j^* t_j}\, P_{F[\mathbf{x}]}(\mathbf{m}; \mathbf{s}, \mathbf{t}),$$

both sides converging together, in $[0,\infty]$ for real data; at the scalar $\boldsymbol{\lambda} = \mu\mathbf{1}$ with $c_j = c_j^* = \mu^{-1}$ the twist is unchanged and the factor is 1, by balance. So a twist at a mark g, $\boldsymbol{\lambda}$ equal to 1 off g, has $P_{F[\lambda \mathbf{x}@g]}(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \lambda^{-m_g} P_{F[\mathbf{x}@g]}(\mathbf{m}; \mathbf{s}, \mathbf{t})$ and is read with $x_1^K = 1$, a point of $(0,\infty)^{2N-1}$; for one table it is one number, $x = x_1^\Psi$, and only the cobasis letter moves. A twist of every mark of one letter by one factor multiplies the period by that factor to the power $-r_j s_j$ or $-r_j^* t_j$; for one table in its cobasis letter, $P_{\mathcal{H}[\mu\mathbf{x}]}(\mathbf{m}; s, t) = \mu^{-r^* t} P_{\mathcal{H}[\mathbf{x}]}(\mathbf{m}; s, t)$.

Definition 22.2 (Cell kernels; the core family read at a shape)**.** Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$ be a substituted family (Definition 21.1), table j being $\mathcal{H}_j\langle \mathcal{A}_{1j}, \dots, \mathcal{A}_{qj}\rangle$ with the cells $\mathcal{A}_{ij}$ on $B_i \sqcup \{g_i\}$. The *cell kernel* of B_i is the measure

$$u^{\mathbf{m}|_{B_i}-\mathbf{1}} \prod_j K_{\mathcal{A}_{ij}/g_i}(u)^{-s_j} \Psi_{\mathcal{A}_{ij}\setminus g_i}(u)^{-t_j}\, d\omega_{B_i}(u) \qquad \text{on } \Delta_{B_i}.$$

The *core family* is $F_{\mathcal{H}} = ((\mathcal{H}_j, \theta^{\mathcal{H}_j}); s_j, t_j)_j$ on the marks $h_1, \dots, h_q$. For $u = (u_i)_i \in \prod_i \Delta_{B_i}$ the *core family read at* u is its twist $F_{\mathcal{H}}[\boldsymbol{\gamma}(u)]$ (Definition 22.1) by the hinge values, $\boldsymbol{\gamma}(u)$ putting $\gamma^K_{\mathcal{A}_{ij}}(u_i)$ in K_j and $\gamma^\Psi_{\mathcal{A}_{ij}}(u_i)$ in Ψ_j at the mark h_i: table j has the basis weights $\theta_T^{\mathcal{H}_j} \prod_{h_i \in T} \gamma^K_{\mathcal{A}_{ij}}(u_i)$ and the cobasis weights $\theta_T^{\mathcal{H}_j} \prod_{h_i \notin T} \gamma^\Psi_{\mathcal{A}_{ij}}(u_i)$, and the letters $K_{\mathcal{H}_j}\big((\gamma^K_{\mathcal{A}_{ij}}(u_i)\,\alpha_{h_i})_i\big)$ and $\Psi_{\mathcal{H}_j}\big((\gamma^\Psi_{\mathcal{A}_{ij}}(u_i)\,\alpha_{h_i})_i\big)$.

Theorem 22.3 (The core reads its cells)**.** *For a substituted family F the core family read at u has the imbalance of F, and*

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \int_{\prod_i \Delta_{B_i}} \prod_i \Big(u_i^{\mathbf{m}|_{B_i}-\mathbf{1}} \prod_j K_{\mathcal{A}_{ij}/g_i}(u_i)^{-s_j} \Psi_{\mathcal{A}_{ij}\setminus g_i}(u_i)^{-t_j}\, d\omega_{B_i}(u_i)\Big) \\ \times P_{F_{\mathcal{H}}[\boldsymbol{\gamma}(u)]}\big((\kappa_{B_1}, \dots, \kappa_{B_q});\mathbf{s},\mathbf{t}\big),$$

both sides converging together; the same holds with J for P, and on the balance wall. So the period of a substitution depends on each cell only through its wall κ_{B_i} and the joint law, under its cell kernel, of its hinge values $\big(\gamma^K_{\mathcal{A}_{ij}}, \gamma^\Psi_{\mathcal{A}_{ij}}\big)_j$: two cells with equal walls and equal laws are interchangeable in every core. For one cell this is Theorem 19.8.

Pooling, done at every cell at once, leaves the core: each cell is integrated over its shape with its kernel and collapses to one mark of the core, which keeps the mass κ_{B_i} and is read through the cell's hinge values as weights. The cells meet only in the core.

Theorem 22.4 (The cells ride on the core's fibre)**.** *Let F be a substituted family with complex data, every exponent* 0 *or of positive real part. Open $K_{\mathcal{H}_j}$ with one share $a_{j,T}$ and $\Psi_{\mathcal{H}_j}$ with one share $b_{j,T}$ per basis T of $\mathcal{H}_j$ (in this statement $|\mathcal{H}_j|$ is the number of bases of $\mathcal{H}_j$), $\sum_T a_{j,T} = s_j$ and $\sum_T b_{j,T} = t_j$, a letter with exponent zero opened by nothing, and let the* loads *of the mark h_i be $a_j(h_i) = \sum_{T \ni h_i} a_{j,T}$ and $b_j(h_i) = \sum_{T \not\ni h_i} b_{j,T}$. The* load family $F_i(\mathbf{a},\mathbf{b})$ *is the family on B_i with, for every j, the table $\mathcal{A}_{ij} \setminus g_i$ at the exponents $\big(a_j(h_i),\, t_j - b_j(h_i)\big)$ and the table $\mathcal{A}_{ij}/g_i$ at $\big(s_j - a_j(h_i),\, b_j(h_i)\big)$; its imbalance is $\kappa_{B_i} - \sum_j \big(a_j(h_i) + b_j(h_i)\big)$. In this statement write $\mathbf{s}^{(i)} = \big((a_j(h_i))_j, (s_j - a_j(h_i))_j\big)$ and $\mathbf{t}^{(i)} = \big((t_j - b_j(h_i))_j, (b_j(h_i))_j\big)$ for its exponents, the tables $\mathcal{A}_{ij} \setminus g_i$ listed first. On every contour of positive real parts of the shares at which all load families converge absolutely,*

$$J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \int_{|\mathbf{a}_j|=s_j,\ |\mathbf{b}_j|=t_j} \prod_j \Gamma_{|\mathcal{H}_j|}\begin{bmatrix}\mathbf{a}_j \\ s_j\end{bmatrix} \Gamma_{|\mathcal{H}_j|}\begin{bmatrix}\mathbf{b}_j \\ t_j\end{bmatrix} \prod_{j,T} \big(\theta_T^{\mathcal{H}_j}\big)^{-a_{j,T}-b_{j,T}} \\ \times \prod_i J_{F_i(\mathbf{a},\mathbf{b})}\big(\mathbf{m}|_{B_i};\mathbf{s}^{(i)},\mathbf{t}^{(i)}\big),$$

with $J_{F_i(\mathbf{a},\mathbf{b})}\big(\mathbf{m}|_{B_i};\mathbf{s}^{(i)},\mathbf{t}^{(i)}\big) = \Gamma\big(\kappa_{B_i} - \sum_j (a_j(h_i) + b_j(h_i))\big) P_{F_i(\mathbf{a},\mathbf{b})}\big(\mathbf{m}|_{B_i};\mathbf{s}^{(i)},\mathbf{t}^{(i)}\big)$. The integrand without the periods of the load families is that of the interest $J_{F_{\mathcal{H}}}\big((\kappa_{B_i})_i;\mathbf{s},\mathbf{t}\big)$ of the core family (Definition 22.2) opened with one share per basis (Corollary 4.4).

The cells ride on the core's share space: the core's letters are opened over its bases, every K-share of a basis loads the marks it occupies and every Ψ-share the marks it leaves out, and each cell enters through the period of its own two hinge minors at the exponents that the loads of its mark assign them.

22.2 Pinned cells

Theorem 22.5 (A cell read alike is pinned)**.** *Let F be a substituted family at every cell of which every active letter reads alike: for every i there are a function γ_i on Δ_{B_i} and constants $c_{ij}, c^*_{ij} > 0$ with $\gamma^K_{\mathcal{A}_{ij}} = c_{ij}\gamma_i$ whenever $s_j \neq 0$ and $\gamma^\Psi_{\mathcal{A}_{ij}} = c^*_{ij}\gamma_i$ whenever $t_j \neq 0$, and $c_{ij} = 1$ when $s_j = 0$, $c^*_{ij} = 1$ when $t_j = 0$. Let $F_\mathcal{H}[\mathbf{c}]$ be the core family twisted by these constants at the marks h_i, c_{ij} in K_j and c^*_{ij} in Ψ_j (Definitions 22.1 and 22.2). Then on the balance wall*

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = P_{F_\mathcal{H}[\mathbf{c}]}\big((\kappa_{B_i})_i;\mathbf{s},\mathbf{t}\big)\prod_i \int_{\Delta_{B_i}} \gamma_i^{-\kappa_{B_i}}\, u^{\mathbf{m}|_{B_i}-\mathbf{1}} \prod_j K^{-s_j}_{\mathcal{A}_{ij}/g_i}\Psi^{-t_j}_{\mathcal{A}_{ij}\setminus g_i}\, d\omega_{B_i}(u),$$

the core at the walls of the cells times the pinned shape integrals *of the cells. In general the free shares at the cell i are one fewer than the distinct hinge values of B_i by the active letters, as at a bunch of width one (Theorem 19.13).*

Corollary 22.6 (Read by one hinge value, the period factors through the core)**.** *Let F be a substituted family with real data on its balance wall (Definition 21.1), table j being $\mathcal{H}_j\langle\mathcal{A}_{1j},\dots,\mathcal{A}_{qj}\rangle$, at every cell of which the active letters read the cell by one hinge value: for every i there is a function γ_i on Δ_{B_i} with $\gamma^K_{\mathcal{A}_{ij}} = \gamma_i$ whenever $s_j \neq 0$ and $\gamma^\Psi_{\mathcal{A}_{ij}} = \gamma_i$ whenever $t_j \neq 0$, as at a mark left in place, whose two hinge values are both α_h. Let σ be the total strength (Definition 8.1) and $F_i = ((\mathcal{A}_{ij}, \theta^{\mathcal{A}_{ij}}); s_j, t_j)_j$ the cell family of the cells at B_i, on $B_i \sqcup \{g_i\}$. Then, in $[0,\infty]$,*

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = P_{F_\mathcal{H}}\big((\kappa_{B_i})_i;\mathbf{s},\mathbf{t}\big)\prod_i \int_{\Delta_{B_i}} \gamma_i^{-\kappa_{B_i}}\, u^{\mathbf{m}|_{B_i}-\mathbf{1}} \prod_j K^{-s_j}_{\mathcal{A}_{ij}/g_i}\Psi^{-t_j}_{\mathcal{A}_{ij}\setminus g_i}\, d\omega_{B_i}(u),$$

and at a cell with $0 < \kappa_{B_i} < 2\sigma$ the family F_i at the masses $(\mathbf{m}|_{B_i}, 2\sigma - \kappa_{B_i})$ is on its balance wall and its pinned shape integral is $P_{F_i}\big((\mathbf{m}|_{B_i}, 2\sigma-\kappa_{B_i});\mathbf{s},\mathbf{t}\big)/\Gamma_1^2\begin{bmatrix}\kappa_{B_i}, & 2\sigma-\kappa_{B_i}\\ & 2\sigma\end{bmatrix}$. If F has every proper wall positive, then $0 < \kappa_{B_i} < 2\sigma$ for every cell, and

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t})\prod_i \Gamma_1^2\begin{bmatrix}\kappa_{B_i}, & 2\sigma-\kappa_{B_i}\\ & 2\sigma\end{bmatrix} = P_{F_\mathcal{H}}\big((\kappa_{B_i})_i;\mathbf{s},\mathbf{t}\big)\prod_i P_{F_i}\big((\mathbf{m}|_{B_i}, 2\sigma-\kappa_{B_i});\mathbf{s},\mathbf{t}\big),$$

every factor on its balance wall with every proper wall positive, the hinge g_i at the mass $2\sigma - \kappa_{B_i}$ and the mark h_i of the core family at κ_{B_i}. For one cell this is Theorem 19.10, and the first display is the shape-integral form of Proposition 19.12.

Corollary 22.7 (The pinned shape integral is the period of a load family)**.** *In Corollary 22.6, let the loads a_{ij}, b_{ij} of the cell i be real, with $a_{ij} = 0$ when $s_j = 0$, $b_{ij} = 0$ when $t_j = 0$ and $\sum_j (a_{ij} + b_{ij}) = \kappa_{B_i}$. The load family $F_i(\mathbf{a},\mathbf{b})$ of Theorem 22.4 at the loads $a_j(h_i) = a_{ij}$ and $b_j(h_i) = b_{ij}$, with the tables $\mathcal{A}_{ij} \setminus g_i$ at $(a_{ij}, t_j - b_{ij})$ and $\mathcal{A}_{ij}/g_i$ at $(s_j - a_{ij}, b_{ij})$ and the masses $\mathbf{m}|_{B_i}$, has the imbalance zero, and its form does not depend on the loads: in $[0,\infty]$ its period is the pinned shape integral of the cell,*

$$P_{F_i(\mathbf{a},\mathbf{b})}\big(\mathbf{m}|_{B_i};\mathbf{s}^{(i)},\mathbf{t}^{(i)}\big) = \int_{\Delta_{B_i}} \gamma_i^{-\kappa_{B_i}}\, u^{\mathbf{m}|_{B_i}-\mathbf{1}} \prod_j K^{-s_j}_{\mathcal{A}_{ij}/g_i}\Psi^{-t_j}_{\mathcal{A}_{ij}\setminus g_i}\, d\omega_{B_i}(u),$$

and $P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = P_{F_{\mathcal{H}}}\big((\kappa_{B_i})_i;\mathbf{s},\mathbf{t}\big)\prod_i P_{F_i(\mathbf{a},\mathbf{b})}\big(\mathbf{m}|_{B_i};\mathbf{s}^{(i)},\mathbf{t}^{(i)}\big)$*. If every proper wall of* F *is positive and* $s_j, t_j \geq 0$*, there are such loads with* $0 \leq a_{ij} \leq s_j$ *and* $0 \leq b_{ij} \leq t_j$*, integers when the data are; the load family then has nonnegative exponents, and every proper wall of it is positive when* P_F *is finite.*

22.3 Chains and transfer

Theorem 22.8 (A chain is the power of one operator)**.** *Let* $F = ((\mathcal{A}_j,\theta_j);s_j,t_j)_{j=1}^N$ *be a family on* $\mathcal{E}$ *with two marks* $g_{\text{in}} \neq g_{\text{out}}$*, each neither a loop nor a coloop in every table, real exponents, masses on the balance wall with* $m_{g_{\text{in}}} + m_{g_{\text{out}}} = \sum_j (s_j + t_j)$*, and let* $F^{\triangleright k}$ *be* k *copies of* F *glued table by table along marks,* $g_{\text{out}}^{(i)}$ *with* $g_{\text{in}}^{(i+1)}$ *(Lemma 21.12). For* $\mathbf{x} = (x_j^K, x_j^\Psi)_j \in (0,\infty)^{2N}$ *let* $F^{\triangleright k}[\mathbf{x}@g_{\text{in}}^{(1)}]$ *be* $F^{\triangleright k}$ *twisted at* $g_{\text{in}}^{(1)}$ *(Definition 22.1), and in this statement write* $P_k(\mathbf{x})$ *for its period at the masses of the copies and* $\mathcal{A}_j^{\mathbf{x}}$ *for table* j *of* $F[\mathbf{x}@g_{\text{in}}]$*, read as a cell with the hinge* g_{out}*. With* $B = \mathcal{E}\setminus\{g_{\text{out}}\}$ *define on nonnegative functions* H *of the twist*

$$(\mathcal{Q}H)(\mathbf{x}) = \int_{\Delta_B} H\Big(\big(\gamma^K_{\mathcal{A}_j^{\mathbf{x}}}(u),\gamma^\Psi_{\mathcal{A}_j^{\mathbf{x}}}(u)\big)_j\Big)\, u^{\mathbf{m}|_B - \mathbf{1}} \prod_j K_{\mathcal{A}_j^{\mathbf{x}}/g_{\text{out}}}(u)^{-s_j}\,\Psi_{\mathcal{A}_j^{\mathbf{x}}\setminus g_{\text{out}}}(u)^{-t_j}\, d\omega_B(u),$$

$$P_0(\mathbf{x}) = \int_0^1 v^{m_{g_{\text{in}}}-1}(1-v)^{m_{g_{\text{out}}}-1}\prod_j \big(1-v+x_j^K v\big)^{-s_j}\big(1-v+x_j^\Psi v\big)^{-t_j}\, dv.$$

Then $P_k = \mathcal{Q}P_{k-1}$*, and in* $[0,\infty]$

$$P_{F^{\triangleright k}}(\mathbf{m};\mathbf{s},\mathbf{t}) = (\mathcal{Q}^k P_0)(\mathbf{1}).$$

The operator acts on functions of the $2N$ *twists, of which one is removed by the scale of the hinge. Where the twist is pinned, the active letters reading the cell by one hinge value,* $\gamma^K_{\mathcal{A}_j}$ *for* $s_j \neq 0$ *and* $\gamma^\Psi_{\mathcal{A}_j}$ *for* $t_j \neq 0$ *all equal, as at a full lean of one table, every* P_k *is a multiple of one power of the twist along the diagonal* $\mathbf{x} = \lambda\mathbf{1}$*,* $\mathcal{Q}$ *multiplies it by* $P_F(\mathbf{m};\mathbf{s},\mathbf{t})/\Gamma_{\begin{smallmatrix}2\\1\end{smallmatrix}}\begin{bmatrix} m_{g_{\text{in}}}, & m_{g_{\text{out}}} \\ m_{g_{\text{in}}}+m_{g_{\text{out}}} & \end{bmatrix}$*, and*

$$P_{F^{\triangleright k}}(\mathbf{m};\mathbf{s},\mathbf{t}) = \frac{P_F(\mathbf{m};\mathbf{s},\mathbf{t})^k}{\Gamma_{\begin{smallmatrix}2\\1\end{smallmatrix}}\begin{bmatrix} m_{g_{\text{in}}}, & m_{g_{\text{out}}} \\ m_{g_{\text{in}}}+m_{g_{\text{out}}} & \end{bmatrix}^{k-1}}.$$

Hinge values that are only proportional, with constants other than one, still pin each cell (Theorem 22.5) but carry the twist off the diagonal.

A chain is pooled one copy at a time: the first copy, read as the cell of its bunch, collapses to its hinge and twists the next copy by its hinge values, so the period of the chain is one operator on functions of the twist applied once per copy, and the two-mark table left at the end supplies the starting function. Where the hinge values pin the twist the operator is a multiplication, and the chain costs a power.

Theorem 22.9 (Letters by transfer)**.** *Let* $(\mathcal{B},\theta)$ *be a table with any weights and* $\varnothing = S_0 \subset S_1 \subset \cdots \subset S_L = \mathcal{E}$ *a chain of bunches, with the steps* $B_{l-1} = S_l \setminus S_{l-1}$*. Group the patterns of each* S_l *into its stations (Definition 21.15), the children being tables on* $\mathcal{E}\setminus S_l$ *and the child at* p *being* w_p *times the child of its station* c*. For a station* c *of* S_{l-1} *and a station* c' *of* S_l *let*

$$\mathbf{M}_l^K(c,c') = \sum_{p'} w(c,p')\,\alpha^{p'}_{B_{l-1}}, \qquad \mathbf{M}_l^\Psi(c,c') = \sum_{p'} w(c,p')\,\alpha^{B_{l-1}\setminus p'}_{B_{l-1}},$$

the sums over the patterns p' of B_{l-1} in the child of the station c whose child is $w(c,p')$ times the child of the station c'. Then, with $\mathbf{e}$ the unit vector of the station of the empty pattern of S_0 and $\boldsymbol{\theta}_\varnothing$ the vector of the weights of the one basis $\varnothing$ of the children of the stations of S_L,

$$K = \mathbf{e}^{\mathsf{T}}\mathbf{M}_1^K\mathbf{M}_2^K\cdots\mathbf{M}_L^K\,\boldsymbol{\theta}_\varnothing, \qquad \Psi = \mathbf{e}^{\mathsf{T}}\mathbf{M}_1^\Psi\cdots\mathbf{M}_L^\Psi\,\boldsymbol{\theta}_\varnothing.$$

The number of states at S_l is the number of its stations, at least the interface dimension of S_l (Definition 21.15), and the states can be reduced to that many linearly independent ones; at a bunch S_l of width one with factoring weights it is two. For a table carrying a multivector $\boldsymbol{\omega}$ of any tensor rank (Definition 7.20), with the widths c_i and the floors d_i of its slices at S_l (Theorem 21.17(ii)), the interface dimension of S_l is at most $\sum_k\big(\sum_i\binom{c_i}{k-d_i}\big)^2$, each square q^2 replaced by $\frac{1}{2}q(q+1)$ when $\boldsymbol{\omega}$ is real; for a determinantal table it is at most $\binom{2c(S_l)}{c(S_l)}$ (Theorem 21.17).

Theorem 22.10 (Integer joint moments by fixed matrices)**.** *Let the letters of a family $F = ((\mathcal{B}_j,\theta_j);s_j,t_j)_{j=1}^N$ be products of matrix functions of the variables of the steps $B_0,\dots,B_{L-1}$ of one chain of bunches, $K_j = \mathbf{e}_j^{\mathsf{T}}\mathbf{M}_{j,0}^K(\alpha_{B_0})\cdots\mathbf{M}_{j,L-1}^K(\alpha_{B_{L-1}})\boldsymbol{\theta}_{j,\varnothing}$ and $\Psi_j = \mathbf{e}_j^{\mathsf{T}}\mathbf{M}_{j,0}^\Psi(\alpha_{B_0})\cdots\mathbf{M}_{j,L-1}^\Psi(\alpha_{B_{L-1}})\boldsymbol{\theta}_{j,\varnothing}$ with constant vectors $\mathbf{e}_j$ and $\boldsymbol{\theta}_{j,\varnothing}$, as Theorem 22.9 gives for every table along any chain of bunches; and let the steps carry independent positive measures $\phi_0,\dots,\phi_{L-1}$ with the required moments finite. For integers $a_j,b_j\ge 0$ put*

$$\mathbf{A}_l = \int\bigotimes_j\Big(\mathbf{M}_{j,l}^K(\alpha)^{\otimes a_j}\otimes\mathbf{M}_{j,l}^\Psi(\alpha)^{\otimes b_j}\Big)\,\phi_l(d\alpha),$$

one α in all the factors. Then

$$\int\prod_j K_j^{a_j}\Psi_j^{b_j}\prod_{l<L}\phi_l(d\alpha_{B_l}) = \Big(\bigotimes_j\mathbf{e}_j^{\otimes(a_j+b_j)}\Big)^{\mathsf{T}}\mathbf{A}_0\mathbf{A}_1\cdots\mathbf{A}_{L-1}\Big(\bigotimes_j\boldsymbol{\theta}_{j,\varnothing}^{\otimes(a_j+b_j)}\Big).$$

For a chain of identical steps, with one pair of matrix functions $\mathbf{M}_j^K,\mathbf{M}_j^\Psi$ for each table, the states of all the S_l indexed by one set, $\boldsymbol{\theta}_{j,\varnothing}$ vanishing at the states that do not occur at S_L, and one measure ϕ, every $\mathbf{A}_l$ is one matrix $\mathbf{A}$: the moment sequence along L is the power of one matrix, of size $\prod_j(\text{number of states of table } j)^{a_j+b_j}$, and satisfies a linear recurrence with constant coefficients of that order. With independent laws Gamma_{m_x} on the marks (Definition 1.1(vii)) the moment $\mathbb{E}_{U\sim\mathrm{Dir}_{\mathbf{m}}}\big[\prod_j K_j(U)^{a_j}\Psi_j(U)^{b_j}\big]$ is that integral divided by the rising factorial $(m_{\mathcal{E}})_{\sum_j(a_jr_j+b_jr_j^*)}$; with the law $\mathrm{Dir}_{\mathbf{m}|_{B_l}}$ on each step the entries are the Dirichlet moments $\prod_{x\in B_l}(m_x)_{k_x}/(m_{B_l})_{|\mathbf{k}|}$ of the monomials $\alpha_{B_l}^{\mathbf{k}}$ (Theorem 3.11).

22.4 A bunch of any width

Theorem 22.11 (Gluing across a bunch of any width)**.** *Let F be a family with real data on its balance wall with every proper wall positive, B a bunch of any width with room R, and fix level factorizations with nonnegative terms (Definition 21.15), the children factorization for instance, with the bunch letters $V_{j,k,c}$ and the room letters $L_{j,k,c}$; drop the terms whose bunch letter or room letter vanishes identically, and let C_j be the set of the terms (k,c) left for table j. Open every active letter with one share per term, $a_{j,k,c}$ for the term $V_{j,k,c}L_{j,k,c}$ of K_j with $\sum_{k,c}a_{j,k,c}=s_j$ and $b_{j,k,c}$ for the term $V_{j,k,c}^*L_{j,k,c}^*$ of Ψ_j with $\sum_{k,c}b_{j,k,c}=t_j$, pinned by the scale of B,*

$$\sum_{j,k,c}\Big(\big(k-d_j(B)\big)a_{j,k,c}+\big(r_j(B)-k\big)b_{j,k,c}\Big)=\kappa_B.$$

On every contour of positive real parts at which the two integrals below converge,

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \int_{|\mathbf{a}_j|=s_j,\ |\mathbf{b}_j|=t_j,\ pin} \prod_j \Gamma_{|C_j|}\begin{bmatrix}\mathbf{a}_j\\ s_j\end{bmatrix}\Gamma_{|C_j|}\begin{bmatrix}\mathbf{b}_j\\ t_j\end{bmatrix}$$
$$\times \int_{\Delta_B} u^{\mathbf{m}|_B-\mathbf{1}} \prod_{j,k,c} V_{j,k,c}^{-a_{j,k,c}} {V^*_{j,k,c}}^{-b_{j,k,c}}\, d\omega_B(u) \int_{\Delta_R} v^{\mathbf{m}|_R-\mathbf{1}} \prod_{j,k,c} L_{j,k,c}^{-a_{j,k,c}} {L^*_{j,k,c}}^{-b_{j,k,c}}\, d\omega_R(v),$$

the two inner integrals projective integrals of degree zero, the periods of the bunch word *and the* room word *at the shares. Their letters are the bunch and room letters of the level factorization, which need not be the letters of tables, so their convergence is that of the integrals themselves. The free shares are the terms less the active letters less one. For one table at a full lean $(0,t)$ in level form, one station per level, with the share b_k and the bunch and room letters V_k^*, L_k^* of the station of the level k, $d(B)\le k\le r(B)$, the pins are $\sum_k b_k = t$ and $\sum_k (r(B)-k)\,b_k = \kappa_B$, the free shares are the $c(B)-1$ shares of the levels strictly between $d(B)$ and $r(B)$, and on a contour of such shares*

$$P_F(\mathbf{m};0,t) = \frac{1}{(2\pi i)^{c(B)-1}} \int \frac{\prod_{k=d(B)}^{r(B)}\Gamma(b_k)}{c(B)\,\Gamma(t)} \int_{\Delta_B} u^{\mathbf{m}|_B-\mathbf{1}} \prod_k V_k^{*-b_k}\, d\omega_B(u)$$
$$\times \int_{\Delta_R} v^{\mathbf{m}|_R-\mathbf{1}} \prod_k L_k^{*-b_k}\, d\omega_R(v) \prod_{d(B)<k<r(B)} db_k,$$

with $b_{d(B)} = \frac{1}{c(B)}\big(\kappa_B - \sum_{d(B)<k<r(B)}(r(B)-k)\,b_k\big)$ and $b_{r(B)} = t - b_{d(B)} - \sum_{d(B)<k<r(B)} b_k$. At $c(B)=2$, with $b_{d(B)+1} = z$, the shares are $\frac{\kappa_B - z}{2}$, z and $\frac{2t-\kappa_B-z}{2}$; at $c(B)=1$ no share is free, and the period is $\Gamma_{\substack{2\\1}}\begin{bmatrix}\kappa_B,\ t-\kappa_B\\ t\end{bmatrix}$ times the two inner periods (Corollary 19.14). At width one with factoring weights, every letter active, the free shares are $2N-1$, and this is Theorem 19.13.

For one table in level form at a full lean $(0,t)$ the scale can also be integrated before the shapes. Writing $\Psi(\rho u, v) = \rho^{d^*(B)} \sum_{i=0}^{c(B)} \rho^i V^*_{r(B)-i}(u) L^*_{r(B)-i}(v)$ and rescaling ρ so that the two extreme terms become 1 and $x^{c(B)}$, the period is the integral over $\Delta_B \times \Delta_R$ of a form that factors into a bunch part and a room part, times the scale integral $\int_0^\infty x^{\kappa_B-1}\big(1+\sum_{i=1}^{c(B)-1}\zeta_i x^i + x^{c(B)}\big)^{-t}dx$, whose coefficients

$$\zeta_i = \frac{V^*_{r(B)-i}(u)}{V^*_{r(B)}(u)^{1-i/c(B)}\, V^*_{d(B)}(u)^{i/c(B)}} \cdot \frac{L^*_{r(B)-i}(v)}{L^*_{r(B)}(v)^{1-i/c(B)}\, L^*_{d(B)}(v)^{i/c(B)}}$$

are each a bunch part times a room part: the room receives $c(B)-1$ ratios. At $c(B)=1$ the scale integral is $\Gamma_{\substack{2\\1}}\begin{bmatrix}\kappa_B,\ t-\kappa_B\\ t\end{bmatrix}$, which is Theorem 19.10; its Mellin transform in $(\zeta_1,\dots,\zeta_{c(B)-1})$ at $(z_1,\dots,z_{c(B)-1})$ is $\prod_{k=d(B)}^{r(B)}\Gamma(b_k)/\big(c(B)\Gamma(t)\big)$ at the shares $b_{r(B)-i} = z_i$ of Theorem 22.11, its share kernel with the factor $1/c(B)$ of the pin, at $c(B)=2$ the kernel $\Gamma(z)\Gamma\big(\frac{\kappa_B-z}{2}\big)\Gamma\big(\frac{2t-\kappa_B-z}{2}\big)/\big(2\Gamma(t)\big)$. With the factorization taken to be the canonical one of the seam of the bunch, the bunch word is written through one law, which with the wall is exactly what the bunch contributes (Chapter 28).

Chapter 23

The law of a cell

A table with a bunch of width one across which its weights factor is two cells glued along a hinge that neither of them shows to the other (Lemma 21.12). What a cell family must carry so that its contribution to every family built on it is fixed is its hinge wall and one measure on $(0,\infty)^{2N-1}$, the law of its ratio vector under its base form, for one cell a measure on the half-line, and nothing less (Theorem 23.11). A cell family enters a period only through that law (Theorem 23.9); the law is read in two ways, by the transform of the cell family and by its dual, and the two transforms expand one function on the two sides of one strip (Proposition 23.8). The step that makes all of this compose is Lemma 23.2: a cell sitting at a mark of any family can be integrated away, leaving the family with that mark twisted by the ratio vector of the cell family; pooling (Theorem 19.8) and Theorem 22.3, in which the core sees each cell as one mark, are its cases. The series closure of any cells, at any positive exponents, is one integral over the shared scales of the product of the transforms of the cells, so identical cells enter as one transform to a power (Theorem 23.3). A core with cells at its markers is read the same way: the law of a substitution is the mixture, over the laws of its cell families, of the laws of the twisted core family (Theorem 23.6); at a series node the transforms multiply and at a parallel node the dual transforms multiply (Theorem 23.14); and the period of a family built along a common hinge tree is read from the leaves up, with one law per edge, computed once for each distinct subtree (Theorem 23.17, Proposition 23.18). The calculus extends to bunches of every width (Chapter 28).

23.1 Cells and their laws

Definition 23.1 (The law of a cell family)**.** A *cell family* is a family $F = ((\mathcal{A}_j, \theta_j); s_j, t_j)_{j=1}^{N}$ on $B \sqcup \{g\}$ whose tables are cells with the one hinge g (Definition 21.1), with real exponents, carrying masses $\mathbf{m}$ on B; one cell $\mathcal{A}$ at the exponents (s,t) is the cell family $((\mathcal{A},\theta);s,t)$, and its objects carry the subscript $\mathcal{A}$. Its *hinge wall* is

$$\kappa_F = m_B - \sum_j \big(s_j(r_{\mathcal{A}_j} - 1) + t_j(|B| - r_{\mathcal{A}_j})\big),$$

for one cell the hinge wall $\kappa_{\mathcal{A}}$ of Lemma 21.12. Its *base form* and its *ratio vector* are

$$\phi_F(du) = u^{\mathbf{m-1}} \prod_j K_{\mathcal{A}_j/g}(u)^{-s_j}\, \Psi_{\mathcal{A}_j\setminus g}(u)^{-t_j}\, \gamma^K_{\mathcal{A}_1}(u)^{-\kappa_F}\, d\omega_B(u) \quad \text{on } \Delta_B,$$

$$\boldsymbol{\varrho}_F = \Big(\frac{\gamma^K_{\mathcal{A}_j}}{\gamma^K_{\mathcal{A}_1}},\ \frac{\gamma^\Psi_{\mathcal{A}_j}}{\gamma^K_{\mathcal{A}_1}}\Big)_j :\ \Delta_B \to (0,\infty)^{2N-1},$$

the coordinate $\gamma^K_{\mathcal{A}_1}/\gamma^K_{\mathcal{A}_1} = 1$ omitted, and its *law* is the image $(\boldsymbol{\varrho}_F)_*\phi_F$, a positive measure on $(0,\infty)^{2N-1}$. For $\mathbf{z} = (z_{j,K}, z_{j,\Psi})_j$, also written as the pair $(\mathbf{z}_K, \mathbf{z}_\Psi)$ of $\mathbf{z}_K = (z_{j,K})_j$ and $\mathbf{z}_\Psi = (z_{j,\Psi})_j$, write

$$\boldsymbol{\varrho}_F^{-\mathbf{z}} = \prod_{j\geq 2}\Big(\frac{\gamma^K_{\mathcal{A}_j}}{\gamma^K_{\mathcal{A}_1}}\Big)^{-z_{j,K}} \prod_j \Big(\frac{\gamma^\Psi_{\mathcal{A}_j}}{\gamma^K_{\mathcal{A}_1}}\Big)^{-z_{j,\Psi}},$$

the coordinates of the ratio vector to the powers $-z_{j,K}$ $(j \geq 2)$ and $-z_{j,\Psi}$; the *Mellin transform* of the law, $\int_{\Delta_B} \boldsymbol{\varrho}_F^{-\mathbf{z}}\, d\phi_F$, lies in $[0,\infty]$ for real $\mathbf{z}$ and is defined for complex $\mathbf{z}$ at whose real part it is finite, with modulus at most that value. For one cell the ratio vector is the ratio $\varrho_{\mathcal{A}}$ (Definition 21.1), the base form is

$$\phi_{\mathcal{A}}(du) = u^{\mathbf{m-1}} K_{\mathcal{A}/g}(u)^{\kappa_{\mathcal{A}}-s} K_{\mathcal{A}\setminus g}(u)^{-\kappa_{\mathcal{A}}} \Psi_{\mathcal{A}\setminus g}(u)^{-t}\, d\omega_B(u),$$

the law $(\varrho_{\mathcal{A}})_*\phi_{\mathcal{A}}$ is a measure on $(0,\infty)$, and, with $z = z_{1,\Psi}$, the Mellin transform is $\int_{\Delta_B} \varrho_{\mathcal{A}}^{-z}\, d\phi_{\mathcal{A}} = \int_0^\infty x^{-z}\, d\big((\varrho_{\mathcal{A}})_*\phi_{\mathcal{A}}\big)(x)$. For a cell family with $s_j, t_j > 0$ the *transform*, the *dual transform* and the two *hinge measures* are, for $\mathbf{x}, \mathbf{y} \in (0,\infty)^N$,

$$f_F(\mathbf{x},\mathbf{y}) = \int_{\mathbb{R}^B_{>0}} \alpha^{\mathbf{m-1}} \prod_j K^{-s_j}_{\mathcal{A}_j\setminus g} \Psi^{-t_j}_{\mathcal{A}_j\setminus g} \exp\Big(-\sum_j \frac{x_j}{\gamma^K_{\mathcal{A}_j}} - \sum_j y_j\, \gamma^\Psi_{\mathcal{A}_j}\Big)\, d\alpha,$$

$$\check{f}_F(\mathbf{x},\mathbf{y}) = \int_{\mathbb{R}^B_{>0}} \alpha^{\mathbf{m-1}} \prod_j K^{-s_j}_{\mathcal{A}_j/g} \Psi^{-t_j}_{\mathcal{A}_j/g} \exp\Big(-\sum_j \frac{x_j}{\gamma^\Psi_{\mathcal{A}_j}} - \sum_j y_j\, \gamma^K_{\mathcal{A}_j}\Big)\, d\alpha,$$

with values in $[0,\infty]$, the measure $\mathfrak{r}_F$, the image of $\alpha^{\mathbf{m-1}} \prod_j K^{-s_j}_{\mathcal{A}_j\setminus g} \Psi^{-t_j}_{\mathcal{A}_j\setminus g}\, d\alpha$ under $\alpha \mapsto \big((1/\gamma^K_{\mathcal{A}_j}(\alpha))_j, (\gamma^\Psi_{\mathcal{A}_j}(\alpha))_j\big)$, and the measure $\check{\mathfrak{r}}_F$, the image of $\alpha^{\mathbf{m-1}} \prod_j K^{-s_j}_{\mathcal{A}_j/g} \Psi^{-t_j}_{\mathcal{A}_j/g}\, d\alpha$ under $\alpha \mapsto \big((1/\gamma^\Psi_{\mathcal{A}_j}(\alpha))_j, (\gamma^K_{\mathcal{A}_j}(\alpha))_j\big)$, positive measures on $(0,\infty)^{2N}$. For $c > 0$, $f_F(\mathbf{x},\mathbf{y}) = c^{\kappa_F - |\mathbf{s}|} f_F(\mathbf{x}/c, c\mathbf{y})$ and $\check{f}_F(\mathbf{x},\mathbf{y}) = c^{\kappa_F - |\mathbf{t}|} \check{f}_F(\mathbf{x}/c, c\mathbf{y})$, so each is fixed by its values at $x_1 = 1$. For one cell they are read there: the transform and the dual transform are $f_{\mathcal{A}}(y) = f_F(1,y)$ and $\check{f}_{\mathcal{A}}(y) = \check{f}_F(1,y)$, $y > 0$, and the hinge measures $\mathfrak{r}^\Psi_{\mathcal{A}}$ and $\mathfrak{r}^K_{\mathcal{A}}$ are the images of $e^{-\lambda}\mathfrak{r}_F(d\lambda, d\mu)$ and of $e^{-\lambda}\check{\mathfrak{r}}_F(d\lambda, d\mu)$ under $(\lambda,\mu) \mapsto \mu$, positive measures on $(0,\infty)$.

The base form of a cell is the restriction to Δ_B of the orthant form $x^{\mathbf{m-1}} K^{\kappa_{\mathcal{A}}-s}_{\mathcal{A}/g} K^{-\kappa_{\mathcal{A}}}_{\mathcal{A}\setminus g} \Psi^{-t}_{\mathcal{A}\setminus g} dx$, homogeneous of degree $m_B + (\kappa_{\mathcal{A}} - s)(r_{\mathcal{A}} - 1) - \kappa_{\mathcal{A}} r_{\mathcal{A}} - t(|B| - r_{\mathcal{A}}) = 0$, so it is read on any section of a positive function of degree one. When $\mathcal{A}$ is the cell of a bunch B of width one in a table, its hinge minors are the restriction $\mathcal{B}|B$ and the contraction $\mathcal{B}/R$, $\kappa_{\mathcal{A}}$ is the wall κ_B, $\phi_{\mathcal{A}}$ is the base form ϕ_B, $(\varrho_{\mathcal{A}})_*\phi_{\mathcal{A}}$ is the law of the bunch, $\int \varrho_{\mathcal{A}}^{-b^d} d\phi_{\mathcal{A}}$ is the continued period of the bunch family at the share b^d, and $f_{\mathcal{A}}$ is the bunch transform f_B (Definitions 20.24 and 20.43, Lemma 20.27); the cell kernel of Definition 22.2 is $(\gamma^K_{\mathcal{A}})^{\kappa_{\mathcal{A}}}\phi_{\mathcal{A}}$, and for a cell family $(\gamma^K_{\mathcal{A}_1})^{\kappa_F}\phi_F$. None of these objects mentions a room: a cell carries them by itself, and they are all that a room ever sees of it (Theorem 23.11). The hinge wall is read from the other side of the hinge: with the mass $s + t - \kappa_{\mathcal{A}}$ on g the table $\mathcal{A}$ itself is on its balance wall, and in a two-sum on its balance wall that mass is the hinge wall of the other cell (Lemma 21.12).

23.2 Absorbing a cell

Lemma 23.2 (Absorbing a cell)**.** *Let $F = ((\mathcal{A}_j, \theta_j); s_j, t_j)_{j=1}^N$ be a cell family on $B \sqcup \{g\}$ with masses $\mathbf{m}$ on B, its hinge wall κ_F, base form ϕ_F and ratio vector $\boldsymbol{\varrho}_F$, whose coordinates are*

written $x_{j,K}$ and $x_{j,\Psi}$, $x_{1,K}=1$. Let Z be a finite set disjoint from $B\sqcup\{g\}$, $\mathbf{m}_Z$ masses on Z, and $f_1,\dots,f_p$ positive continuous functions on $(0,\infty)^Z\times(0,\infty)$, each assigned to one letter of F, with real exponents a_i such that the exponents assigned to each letter add to its exponent, s_j for $K_{\mathcal{A}_j}$ and t_j for $\Psi_{\mathcal{A}_j}$. In this statement write L_i, γ_i and x_i for the letter of the hinge minor, the hinge value and the coordinate of the letter of f_i: $L_i=K_{\mathcal{A}_j/g}$, $\gamma_i=\gamma^K_{\mathcal{A}_j}$ and $x_i=x_{j,K}$ when it is $K_{\mathcal{A}_j}=K_{\mathcal{A}_j/g}\,(\gamma^K_{\mathcal{A}_j}+\alpha_g)$, and $L_i=\Psi_{\mathcal{A}_j\setminus g}$, $\gamma_i=\gamma^\Psi_{\mathcal{A}_j}$ and $x_i=x_{j,\Psi}$ when it is $\Psi_{\mathcal{A}_j}=\Psi_{\mathcal{A}_j\setminus g}\,(\gamma^\Psi_{\mathcal{A}_j}+\alpha_g)$. Let $H\ge 0$ be a Borel function on $(0,\infty)^p$. If the form

$$\omega=\alpha_B^{\mathbf{m}-\mathbf{1}}\alpha_Z^{\mathbf{m}_Z-\mathbf{1}}\,H\Big(\big(f_i(\alpha_Z,\gamma_i(\alpha_B))\big)_i\Big)\prod_{i=1}^{p}\Big[L_i(\alpha_B)\,f_i\big(\alpha_Z,\gamma_i(\alpha_B)\big)\Big]^{-a_i}d\alpha_B\,d\alpha_Z$$

is homogeneous of degree zero on $(0,\infty)^{B\sqcup Z}$, then, in $[0,\infty]$,

$$\int_{\{h=1\}}\omega=\int_{(0,\infty)^{2N-1}}\Big(\int_{\{h'=1\}}\omega_{\mathbf{x}}\Big)\,d\big((\boldsymbol{\varrho}_F)_*\phi_F\big)(\mathbf{x}),$$
$$\omega_{\mathbf{x}}=\alpha_Z^{\mathbf{m}_Z-\mathbf{1}}\alpha_g^{\kappa_F-1}\,H\Big(\big(f_i(\alpha_Z,x_i\alpha_g)\big)_i\Big)\prod_i f_i(\alpha_Z,x_i\alpha_g)^{-a_i}\,d\alpha_Z\,d\alpha_g,$$

the integrals taken over any sections of positive functions h, h' of degree one on the two orthants.

For one table the ratio vector is the ratio of the cell. The lemma says that whatever the rest of a family does with a cell, provided it sees the cell through the cell's letters at the hinge, it sees it only through the law: the cell collapses to its hinge, which keeps the mass κ_F, and the letters that see the hinge see it stretched by the coordinates of the ratio vector. Pooling (Theorem 19.8) is the case of one cell family read on the shape before the law is formed; Theorem 22.3, in which the core sees each cell as one mark, is the lemma at every cell of a core, with the hinge values of the cells kept as weights of the core instead of their ratios.

23.3 Closures

Theorem 23.3 (The series closure at positive exponents)**.** *Let every table of F be a series closure, $(\mathcal{B}_j,\theta_j)=\binom{\{h_1,\dots,h_q\}}{q-1}\langle\mathcal{A}_{1j},\dots,\mathcal{A}_{qj}\rangle$ (Corollary 21.7(ii)), with exponents $s_j,t_j>0$, and let f_{F_i} be the transform of the cell family $F_i=((\mathcal{A}_{ij},\theta^{\mathcal{A}_{ij}});s_j,t_j)_j$ of the cells at B_i, on $B_i\sqcup\{g_i\}$ (Definition 23.1). On the balance wall, in $[0,\infty]$,*

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t})=\prod_j\frac{1}{\Gamma(s_j)\Gamma(t_j)}\int\prod_j x_j^{s_j-1}\prod_{j\ge2}y_j^{t_j-1}\;\prod_{i=1}^{q}f_{F_i}\big(\mathbf{x},(1,y_2,\dots,y_N)\big)\;d\mathbf{x}\,dy_2\cdots dy_N,$$

the integral over $(0,\infty)^N\times(0,\infty)^{N-1}$: the cells communicate only through $2N-1$ shared scales. A cell entering k times enters as its transform to the power k: one transform per kind of cell, its multiplicity a power, the order of the cells immaterial; for one table the closure is $\frac{1}{\Gamma(s)\Gamma(t)}\int_0^\infty y^{t-1}\prod_i f_{\mathcal{A}_i}(y)\,dy$. With $|\mathbf{s}|=\sum_j s_j$ and the wall κ_{B_i} of the cell B_i, its hinge wall κ_{F_i} (Theorem 21.10), each transform is one Gramma integrated over the shape of the cell,

$$f_{F_i}(\mathbf{x},\mathbf{y})=\int_{\Delta_{B_i}}\mathsf{G}_{|\mathbf{s}|-\kappa_{B_i};(1,-1)}\Big(\sum_j\frac{x_j}{\gamma^K_{\mathcal{A}_{ij}}(u)},\;\sum_j y_j\,\gamma^\Psi_{\mathcal{A}_{ij}}(u)\Big)$$
$$\times\,u^{\mathbf{m}|_{B_i}-\mathbf{1}}\prod_j K_{\mathcal{A}_{ij}\setminus g_i}(u)^{-s_j}\,\Psi_{\mathcal{A}_{ij}\setminus g_i}(u)^{-t_j}\,d\omega_{B_i}(u),$$

against the form of the family of the hinge minors $F_i \setminus g_i = ((\mathcal{A}_{ij} \setminus g_i, \theta^{\mathcal{A}_{ij}}); s_j, t_j)_j$ *at the masses* $\mathbf{m}|_{B_i}$*. When that family is on its balance wall,* $\kappa_{B_i} = |\mathbf{s}|$*, as at every cell of one table at the centre,* $s = t = \sigma$ *with every mass* σ*, the index is* 0*, the Gramma depends on its two coefficients through their product,* $\mathsf{G}_{0;(1,-1)}(a,b) = \mathsf{G}_{0;(1,-1)}(1,ab)$ *(Theorem 2.4(iii)), and, when the family of the hinge minors has every proper wall positive,*

$$f_{F_i}(\mathbf{x},\mathbf{y}) = P_{F_i\setminus g_i}(\mathbf{m}|_{B_i};\mathbf{s},\mathbf{t})\ \mathbb{E}_{U\sim \mathrm{Breta}^\circ(F_i\setminus g_i;\mathbf{m}|_{B_i};\mathbf{s},\mathbf{t})}\Big[\mathsf{G}_{0;(1,-1)}\Big(1,\ \sum_j \frac{x_j}{\gamma^K_{\mathcal{A}_{ij}}(U)} \sum_j y_j\, \gamma^{\Psi}_{\mathcal{A}_{ij}}(U)\Big)\Big],$$

for one table $P_{\mathcal{A}_i\setminus g_i}(\mathbf{m}|_{B_i}; s, t)\, \mathbb{E}\big[\mathsf{G}_{0;(1,-1)}\big(1, xy\, \varrho_{\mathcal{A}_i}(U)\big)\big]$*: the image under the ratio of the form of the hinge minor, read through* $\mathsf{G}_{0;(1,-1)}$*. So* $k \geq 2$ *copies of one cell family closed in series have the period* $\prod_j(\Gamma(s_j)\Gamma(t_j))^{-1} \int \prod_j x_j^{s_j-1} \prod_{j\geq 2} y_j^{t_j-1} f_{F_1}\big(\mathbf{x}, (1, y_2, \ldots, y_N)\big)^k\, d\mathbf{x}\, dy_2 \cdots dy_N$*.*

For one table the closure of q cells is a node of width one (Definition 20.24) with the bunch $B_1 \sqcup \cdots \sqcup B_{q-1}$, a series connection (Proposition 20.37), against the room B_q. Theorem 20.26 reads it as $\frac{1}{\Gamma(s)\Gamma(t)} \int_0^\infty f_B(y) f_R(y) \frac{dy}{y}$, and Theorem 23.3 is the same integral written symmetrically in all the cells, $\frac{1}{\Gamma(s)\Gamma(t)} \int_0^\infty y^{t-1} \prod_i f_{\mathcal{A}_i}(y)\, dy$ with the transforms of the cells (Definition 23.1), which are the orthant transforms f_i° of Proposition 20.37; for k equal cells at the centre the formula for k copies is Theorem 24.2(i), with $k-1$ copies at a series node and one copy as the room. The table that is one circuit, $\binom{\mathcal{E}}{n-1}$, is the series closure of n single marks, each with the transform $\mathsf{G}_{s-m_e;(1,-1)}(1,y)$ up to its weight (Corollary 18.24). The parallel closure is the dual statement (Proposition 8.15).

23.4 Cores and their markers

A table is built from cells by two-sums at the markers of cores.

Definition 23.4 (Markers; the twisted core)**.** Let the exponents be $s, t > 0$. A *core with markers* is a plain table $\mathcal{H}$ on $\mathcal{E}_\mathcal{H} \sqcup G_\mathcal{H}$ none of whose marks is a loop or a coloop, a core of Definition 21.1, whose *markers* are the marks of $G_\mathcal{H}$, the marks at which cells may be substituted (the marks h_i of Definition 21.1). *Cells at the markers* are plain cells $\mathcal{A}_1, \ldots, \mathcal{A}_k$ on $B_i \sqcup \{g_i\}$ whose hinges are identified with distinct markers $g_1, \ldots, g_k$, the sets $\mathcal{E}_\mathcal{H}$ and B_i disjoint, and $\mathcal{H}\langle\mathcal{A}_1, \ldots, \mathcal{A}_k\rangle$ is their substitution (Definition 21.1), the marks of $\mathcal{E}_\mathcal{H}$ and the markers without a cell left in place. For $\mathbf{x} \in (0,\infty)^k$ the *twisted core* $\mathcal{H}[\mathbf{x}]$ is $\mathcal{H}$ twisted in its cobasis letter by x_i at every g_i (Definition 22.1), carrying the masses $\kappa_{\mathcal{A}_i}$ on the markers g_i and the given masses $\mathbf{m}|_{\mathcal{E}_\mathcal{H}}$ on $\mathcal{E}_\mathcal{H}$; it has the basis weights θ_T and the cobasis weights $\theta_T \prod_{g_i \notin T} x_i$, and its period is that of a table with two systems of weights (Definition 8.1). With the cells at the shapes $u = (u_i)_i$, the twisted core $\mathcal{H}[(\varrho_{\mathcal{A}_i}(u_i))_i]$ is the core read at u of Definition 22.2 with the scale of every marker g_i divided by $\gamma^K_{\mathcal{A}_i}(u_i)$. A core with one marker g_0 left free is a *hinged core*; then $\mathcal{H}[\mathbf{x}]$ is a cell with the hinge g_0, not plain, and its hinge wall, base form, ratio and law are those of Definition 23.1.

Lemma 23.5 (Substitution at the markers)**.** *The substitution* $\mathcal{H}\langle\mathcal{A}_1, \ldots, \mathcal{A}_k\rangle$ *does not depend on the order of the two-sums (Proposition 21.3(i)). Its bases are the sets* $(T \cap \mathcal{E}_\mathcal{H}) \sqcup \bigsqcup_i C_i$ *with* T *a basis of* $\mathcal{H}$ *and, for each* i*,* C_i *a basis of* $\mathcal{A}_i$ *avoiding* g_i *when* $g_i \in T$ *and* $C_i + g_i$ *a basis of* $\mathcal{A}_i$ *when* $g_i \notin T$*, with the product weights. Its rank is* $r_\mathcal{H} + \sum_i (r_{\mathcal{A}_i} - 1)$*, and with* G' *the markers left free (Theorem 21.4)*

$$K_{\mathcal{H}\langle\mathcal{A}_1,\ldots,\mathcal{A}_k\rangle} = \prod_i K_{\mathcal{A}_i/g_i} \cdot K_\mathcal{H}\big(\alpha_{\mathcal{E}_\mathcal{H}}, (\gamma^K_{\mathcal{A}_i})_i, \alpha_{G'}\big),$$

$$\Psi_{\mathcal{H}\langle\mathcal{A}_1,\dots,\mathcal{A}_k\rangle}=\prod_i \Psi_{\mathcal{A}_i\setminus g_i}\cdot\Psi_{\mathcal{H}}\big(\alpha_{\mathcal{E}_\mathcal{H}},(\gamma^{\Psi}_{\mathcal{A}_i})_i,\alpha_{G'}\big).$$

For a hinged core the letters of the two hinge minors $\mathcal{H}\langle\mathcal{A}_1,\dots,\mathcal{A}_k\rangle\setminus g_0$ and $\mathcal{H}\langle\mathcal{A}_1,\dots,\mathcal{A}_k\rangle/g_0$ are the same products with the letters of $\mathcal{H}\setminus g_0$ and $\mathcal{H}/g_0$ in place of $K_\mathcal{H}$ and $\Psi_\mathcal{H}$.

Theorem 23.6 (The law of a substitution)**.** *Let F be a family with real data whose table j is $\mathcal{H}_j\langle\mathcal{A}_{1j},\dots,\mathcal{A}_{kj}\rangle$, the cores $\mathcal{H}_j$ plain on $\mathcal{E}_\mathcal{H}\sqcup G_\mathcal{H}$ with $\{g_1,\dots,g_k\}\subseteq G_\mathcal{H}$, the cells of all tables at g_i forming the cell family $F_i=((\mathcal{A}_{ij},\theta^{\mathcal{A}_{ij}});s_j,t_j)_j$ on $B_i\sqcup\{g_i\}$ (Definition 23.1), with masses on $\mathcal{E}_\mathcal{H}$ and on the marks of the cells. For $\mathbf{x}=(\mathbf{x}_i)_i$, $\mathbf{x}_i=(x_{i,j,K},x_{i,j,\Psi})_j\in(0,\infty)^{2N-1}$ with $x_{i,1,K}=1$, let $F_\mathcal{H}[\mathbf{x}]$ be the family $((\mathcal{H}_j,\theta^{\mathcal{H}_j});s_j,t_j)_j$ twisted at every g_i by $\mathbf{x}_i$, $x_{i,j,K}$ in K_j and $x_{i,j,\Psi}$ in Ψ_j (Definition 22.1), with the masses κ_{F_i} on the markers g_i and the given masses on $\mathcal{E}_\mathcal{H}$.*

(i) If $G_\mathcal{H}=\{g_1,\dots,g_k\}$ and F is on its balance wall, then, in $[0,\infty]$,

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t})=\int P_{F_\mathcal{H}[\mathbf{x}]}\big((\mathbf{m}|_{\mathcal{E}_\mathcal{H}},\kappa_{F_1},\dots,\kappa_{F_k});\mathbf{s},\mathbf{t}\big)\prod_i d\big((\boldsymbol{\varrho}_{F_i})_*\phi_{F_i}\big)(\mathbf{x}_i).$$

With the core $\binom{\{g_1,g_2\}}{1}$ in every table this is the gluing of two cell families F_1 and F_2, $\kappa_{F_1}+\kappa_{F_2}=2\sigma$, σ the total strength (Definition 8.1): the period of the twisted core family is $\int_0^\infty v^{\kappa_{F_1}-1}\prod_j(x_{1,j,K}v+x_{2,j,K})^{-s_j}(x_{1,j,\Psi}v+x_{2,j,\Psi})^{-t_j}\,dv$, a Breta of one bunch with at most $2N$ coefficients (Proposition 15.1), unchanged when $(\kappa_{F_1},\mathbf{x}_1)$ and $(\kappa_{F_2},\mathbf{x}_2)$ are swapped.

(ii) If $G_\mathcal{H}=\{g_0,g_1,\dots,g_k\}$, F is a cell family with the hinge g_0; its hinge wall is that of $F_\mathcal{H}[\mathbf{x}]$, which does not depend on $\mathbf{x}$,

$$\kappa_F=m_{\mathcal{E}_\mathcal{H}}+\sum_i\kappa_{F_i}-\sum_j\big(s_j(r_{\mathcal{H}_j}-1)+t_j(|\mathcal{E}_\mathcal{H}|+k-r_{\mathcal{H}_j})\big),$$

and its law is the mixture of the twisted laws: for every Borel $H\ge0$ on $(0,\infty)^{2N-1}$,

$$\int H\,d\big((\boldsymbol{\varrho}_F)_*\phi_F\big)=\int\Big(\int H\,d\big((\boldsymbol{\varrho}_{F_\mathcal{H}[\mathbf{x}]})_*\phi_{F_\mathcal{H}[\mathbf{x}]}\big)\Big)\prod_i d\big((\boldsymbol{\varrho}_{F_i})_*\phi_{F_i}\big)(\mathbf{x}_i).$$

In particular $\int\boldsymbol{\varrho}_F^{-\mathbf{z}}d\phi_F=\int\big(\int\boldsymbol{\varrho}_{F_\mathcal{H}[\mathbf{x}]}^{-\mathbf{z}}d\phi_{F_\mathcal{H}[\mathbf{x}]}\big)\prod_i d\big((\boldsymbol{\varrho}_{F_i})_*\phi_{F_i}\big)(\mathbf{x}_i)$ for every real $\mathbf{z}$.

For one table with $s,t>0$ the laws are measures on $(0,\infty)$ and the twisted core family is the twisted core $\mathcal{H}[\mathbf{x}]$ of Definition 23.4.

The core is the only place where cells interact. Below a core each cell family is one measure on $(0,\infty)^{2N-1}$, for one table on a half-line; at the core the cell families are fed into the core family as twists of both letters of every table at the markers, of the cobasis letter alone for one table (Lemma 23.2), and the core family, with the masses κ_{F_i} on its markers, is integrated once for each value of the twists. So the work at a core is governed by the core itself and by the number of its markers, not by the sizes of the cells: a cell with a thousand marks and a cell with one mark cost the same once their laws are known. Theorem 19.13 is the gluing of two cell families read through Mellin transforms (Theorem 23.9(iv)).

23.5 Two cells glued

Lemma 23.7 (Two marks)**.** *For $s,t>0$, $\kappa,\kappa'>0$ with $\kappa+\kappa'=s+t$, and $x,x'>0$, let $\binom{\{g,g'\}}{1}[(x,x')]$ be the list $\binom{\{g,g'\}}{1}$ twisted in its cobasis letter by x at g and by x' at g' (Definition 22.1). With the masses κ on g and κ' on g' its period is*

$$P_{\binom{\{g,g'\}}{1}[(x,x')]}\big((\kappa,\kappa');s,t\big)=\int_0^\infty v^{\kappa-1}(1+v)^{-s}(xv+x')^{-t}\,dv$$

$$= x^{-t}\,\Gamma_{\!\overline{2}}\!\begin{bmatrix}\kappa,\ \kappa'\\ s,\ t\end{bmatrix}\ \mathsf{B}^{\{\{0,1\}\}}_{(s,t),\,\kappa';\,I_{\{0,1\}}}\big((1,x'/x)\big)$$
$$= \frac{1}{\Gamma(s)\Gamma(t)}\int_0^\infty y^{t-1}\,\mathsf{G}_{s-\kappa;(1,-1)}(1,xy)\,\mathsf{G}_{s-\kappa';(1,-1)}(1,x'y)\,dy$$

(Proposition 15.1, the two coefficients merging into one of letter exponent $s+t$ when $x=x'$), unchanged when (κ,x) and (κ',x') are swapped. For a family of tables the kernel is the period of the twisted core family of Theorem 23.6(i) with the core $\binom{\{g_1,g_2\}}{1}$ in every table.

Proposition 23.8 (Faces of one law)**.** *Let $F=((\mathcal{A}_j,\theta_j);s_j,t_j)_{j=1}^N$ be a cell family on $B\sqcup\{g\}$ with plain tables, $s_j,t_j>0$, masses $\mathbf{m}$ on B and the hinge wall $\kappa=\kappa_F$; in this statement the points of $(0,\infty)^{2N-1}$ are written $\mathbf{z}=(z_{j,K},z_{j,\Psi})_j$, $z_{1,K}=1$, and $\mathbf{x}'=(x_2,\dots,x_N)$.*

(i) Law forms. *For $\mathbf{x},\mathbf{y}\in(0,\infty)^N$,*

$$f_F(\mathbf{x},\mathbf{y})=\int \mathsf{G}_{|\mathbf{s}|-\kappa;(1,-1)}\Big(\sum_j\frac{x_j}{z_{j,K}},\ \sum_j y_jz_{j,\Psi}\Big)\prod_j z_{j,K}^{-s_j}\,d\big((\boldsymbol{\varrho}_F)_*\phi_F\big)(\mathbf{z}),$$
$$\check f_F(\mathbf{x},\mathbf{y})=\int \mathsf{G}_{|\mathbf{t}|-\kappa;(1,-1)}\Big(\sum_j x_j\frac{z_{1,\Psi}}{z_{j,\Psi}},\ \sum_j y_j\frac{z_{j,K}}{z_{1,\Psi}}\Big)\prod_j\Big(\frac{z_{j,\Psi}}{z_{1,\Psi}}\Big)^{-t_j}z_{1,\Psi}^{-\kappa}\,d\big((\boldsymbol{\varrho}_F)_*\phi_F\big)(\mathbf{z}):$$

the two transforms depend on F only through its hinge wall and its law. For one cell, for $y>0$,

$$f_{\mathcal{A}}(y)=\int_{\Delta_B}\mathsf{G}_{s-\kappa;(1,-1)}\big(1,\varrho_{\mathcal{A}}y\big)\,d\phi_{\mathcal{A}},\qquad \check f_{\mathcal{A}}(y)=\int_{\Delta_B}\mathsf{G}_{t-\kappa;(1,-1)}\big(1,y/\varrho_{\mathcal{A}}\big)\,\varrho_{\mathcal{A}}^{-\kappa}\,d\phi_{\mathcal{A}}.$$

(ii) Hinge measures.

$$f_F(\mathbf{x},\mathbf{y})=\int e^{-\langle\mathbf{x},\boldsymbol{\lambda}\rangle-\langle\mathbf{y},\boldsymbol{\mu}\rangle}\,d\mathfrak{r}_F(\boldsymbol{\lambda},\boldsymbol{\mu}),\qquad \check f_F(\mathbf{x},\mathbf{y})=\int e^{-\langle\mathbf{x},\boldsymbol{\lambda}\rangle-\langle\mathbf{y},\boldsymbol{\mu}\rangle}\,d\check{\mathfrak{r}}_F(\boldsymbol{\lambda},\boldsymbol{\mu}),$$

and $\mathfrak{r}_F$ is the image of the product of $\prod_j z_{j,K}^{-s_j}\,(\boldsymbol{\varrho}_F)_*\phi_F(d\mathbf{z})$ and $p^{\kappa-|\mathbf{s}|-1}dp$ under $(\mathbf{z},p)\mapsto\big((1/(pz_{j,K}))_j,(pz_{j,\Psi})_j\big)$. So f_F and $\check f_F$ are completely monotone in their $2N$ variables, $(-1)^{|\mathbf{n}|}\partial^{\mathbf{n}}f_F\ge 0$ for every multi-index $\mathbf{n}$ on the interior of the set where f_F is finite and the same for $\check f_F$, and log-convex along every segment on which they are finite. For one cell, $f_{\mathcal{A}}(y)=\int e^{-y\lambda}d\mathfrak{r}^{\Psi}_{\mathcal{A}}(\lambda)$ and $\check f_{\mathcal{A}}(y)=\int e^{-y\lambda}d\mathfrak{r}^{K}_{\mathcal{A}}(\lambda)$; $\mathfrak{r}^{\Psi}_{\mathcal{A}}$ is the image of $\alpha^{\mathbf{m}-\mathbf{1}}K_{\mathcal{A}\setminus g}^{-s}\Psi_{\mathcal{A}\setminus g}^{-t}e^{-1/\gamma^K_{\mathcal{A}}}d\alpha$ under $\gamma^{\Psi}_{\mathcal{A}}$ and of $(\varrho_{\mathcal{A}})_*\phi_{\mathcal{A}}(dx)\otimes p^{s-\kappa-1}e^{-p}dp$ under $(x,p)\mapsto x/p$, and $\mathfrak{r}^{K}_{\mathcal{A}}$ the image of $\alpha^{\mathbf{m}-\mathbf{1}}K_{\mathcal{A}/g}^{-s}\Psi_{\mathcal{A}/g}^{-t}e^{-1/\gamma^{\Psi}_{\mathcal{A}}}d\alpha$ under $\gamma^{K}_{\mathcal{A}}$ and of $x^{-\kappa}(\varrho_{\mathcal{A}})_*\phi_{\mathcal{A}}(dx)\otimes p^{t-\kappa-1}e^{-p}dp$ under $(x,p)\mapsto 1/(xp)$; so $f_{\mathcal{A}}$ and $\check f_{\mathcal{A}}$ are decreasing and log-convex wherever finite.

(iii) Mellin transforms. *For real $\mathbf{a},\mathbf{b}\in(0,\infty)^N$ with $\sum_j b_j-\sum_j a_j=\kappa-|\mathbf{s}|$, in $[0,\infty]$,*

$$\int_{(0,\infty)^{2N-1}}\prod_{j\ge2}x_j^{a_j-1}\prod_j y_j^{b_j-1}\,f_F\big((1,\mathbf{x}'),\mathbf{y}\big)\,d\mathbf{x}'\,d\mathbf{y}$$
$$=\prod_j\Gamma(a_j)\Gamma(b_j)\int_{\Delta_B}\boldsymbol{\varrho}_F^{-(\mathbf{s}-\mathbf{a},\mathbf{b})}\,d\phi_F,$$

and for real $\mathbf{a},\mathbf{b}\in(0,\infty)^N$ *with* $\sum_j b_j-\sum_j a_j=\kappa-|\mathbf{t}|$ *the same holds for* $\check f_F$ *with* $\int_{\Delta_B}\boldsymbol{\varrho}_F^{-(\mathbf{b},\mathbf{t}-\mathbf{a})}\,d\phi_F$ *on the right; both Mellin transforms of the law are taken on the hyperplane* $\sum_j(z_{j,K}+z_{j,\Psi})=\kappa$ *of their arguments. For one cell, with* $z=b$*, these are*

$$\int_0^\infty y^{z-1}f_{\mathcal A}(y)\,dy=\Gamma(z)\Gamma(z+s-\kappa)\int_{\Delta_B}\varrho_{\mathcal A}^{-z}\,d\phi_{\mathcal A}\qquad\big(z>\max(0,\kappa-s)\big),$$
$$\int_0^\infty y^{z-1}\check f_{\mathcal A}(y)\,dy=\Gamma(z)\Gamma(z+t-\kappa)\int_{\Delta_B}\varrho_{\mathcal A}^{z-\kappa}\,d\phi_{\mathcal A}\qquad\big(z>\max(0,\kappa-t)\big).$$

(iv) The dual cell family. *The dual tables* $\mathcal A_j^*$*, with the hinge* g*, at the exponents* (t_j,s_j) *form a cell family* F^* *with the hinge wall* κ*, the hinge values* $\gamma^K_{\mathcal A_j^*}=\gamma^\Psi_{\mathcal A_j}$ *and* $\gamma^\Psi_{\mathcal A_j^*}=\gamma^K_{\mathcal A_j}$*, the base form* $(\gamma^\Psi_{\mathcal A_1}/\gamma^K_{\mathcal A_1})^{-\kappa}\phi_F$*, the law the image of* $z_{1,\Psi}^{-\kappa}\,(\boldsymbol{\varrho}_F)_*\phi_F(d\mathbf{z})$ *under* $\mathbf{z}\mapsto(z_{j,\Psi}/z_{1,\Psi},\,z_{j,K}/z_{1,\Psi})_j$*, the transform* $\check f_F$ *and the dual transform* f_F*. For one cell the ratio is* $1/\varrho_{\mathcal A}$*, the base form* $\varrho_{\mathcal A}^{-\kappa}\phi_{\mathcal A}$*, the law the image of* $x^{-\kappa}(\varrho_{\mathcal A})_*\phi_{\mathcal A}(dx)$ *under* $x\mapsto1/x$*, and* $\int\varrho_{\mathcal A^*}^{-z}d\phi_{\mathcal A^*}=\int\varrho_{\mathcal A}^{z-\kappa}d\phi_{\mathcal A}$*.*

(v) Change of transform. *For real* $\mathbf{a},\mathbf{b}$ *with* $0<a_j<s_j$*,* $0<b_j<t_j$ *and* $\sum_j b_j-\sum_j a_j=\kappa-|\mathbf{s}|$*, the left side of (iii) for* $\check f_F$ *at* $(\mathbf{t}-\mathbf{b},\mathbf{s}-\mathbf{a})$ *times* $\prod_j\Gamma(a_j)\Gamma(b_j)$ *equals that for* f_F *at* $(\mathbf{a},\mathbf{b})$ *times* $\prod_j\Gamma(t_j-b_j)\Gamma(s_j-a_j)$*, in* $(0,\infty]$*. For one cell, with* $z=s-a$*: for real* z *with* $\max(0,\kappa-t)<z<\min(s,\kappa)$*, in* $(0,\infty]$*,*

$$\int_0^\infty y^{z-1}\check f_{\mathcal A}(y)\,dy=\frac{\Gamma(z)\Gamma(z+t-\kappa)}{\Gamma(\kappa-z)\Gamma(s-z)}\int_0^\infty y^{\kappa-z-1}f_{\mathcal A}(y)\,dy.$$

When $\mathcal A$ *is the cell of the bunch of a node of width one (Definition 20.24) and* $\int\varrho_{\mathcal A}^{-b}d\phi_{\mathcal A}<\infty$ *at some* b *with* $\max(0,\kappa_{\mathcal A}-s)<b<\min(t,\kappa_{\mathcal A})$*, the expansion of* $f_{\mathcal A}$ *at* $y\to0$ *is the sum of the residues of* $y^{-z}\Gamma(z)\Gamma(z+s-\kappa_{\mathcal A})\int\varrho_{\mathcal A}^{-z}d\phi_{\mathcal A}$ *to the left of the line* $\operatorname{Re}z=b$ *(Theorem 20.34(i)), and that of* $\check f_{\mathcal A}$*, the transform of* $\mathcal A^*$ *read as the bunch of the dual node of width one at the exponents* (t,s) *(Proposition 8.15), is the sum of the residues of* $y^{-z}\Gamma(z)\Gamma(z+t-\kappa_{\mathcal A})\int\varrho_{\mathcal A}^{z-\kappa_{\mathcal A}}d\phi_{\mathcal A}$ *to the left of the line* $\operatorname{Re}z=\kappa_{\mathcal A}-b$*, at the poles of the Gamma pair and at the points* $\kappa_{\mathcal A}-w$*,* w *a pole of the continued* $\int\varrho_{\mathcal A}^{-w}d\phi_{\mathcal A}$ *to the right of the line* $\operatorname{Re}w=b$*: the two transforms expand one function on the two sides of its strip.*

So one law has four faces. The base form and its image, the law, are where the cell family lives; the transform reads the law through Grammas of index $|\mathbf{s}|-\kappa_F$ and is the Laplace transform of the hinge measure $\mathfrak r_F$, carried by the reciprocals of the hinge values by K and the hinge values by Ψ; the dual transform reads the law turned over through Grammas of index $|\mathbf{t}|-\kappa_F$ and is the Laplace transform of $\check{\mathfrak r}_F$, carried by the reciprocals of the hinge values by Ψ and the hinge values by K; and on the Mellin side both are the one function $\int\boldsymbol{\varrho}_F^{-\mathbf{z}}d\phi_F$ with two Gamma products. Passing from one transform to the other costs nothing on the Mellin side, a reflection and a ratio of Gammas, and costs integral transforms on the side of the transforms; for one cell, on the half-line, the two expansions at $y\to0$ are read on opposite sides of the strip: the transform expands where the law is large, the dual transform where it is small.

Theorem 23.9 (Two cell families glued)**.** *Let* F_1 *and* F_2 *be cell families with plain tables on* $B\sqcup\{g\}$ *and* $R\sqcup\{g\}$*, at the exponents* $(s_j,t_j)_j$ *with* $s_j,t_j>0$*, and let* $F_1\oplus_g F_2$*, whose table* j *is the two-sum of the tables* j *of* F_1 *and* F_2 *(Lemma 21.12), carry masses* $\mathbf{m}$ *on its balance wall, so that* $\kappa_{F_1}+\kappa_{F_2}=2\sigma$*,* σ *the total strength (Definition 8.1); let* $0<\kappa_{F_1}<2\sigma$*. In this statement the points of the laws of* F_1 *and* F_2 *are written* $\mathbf{z}$ *and* $\mathbf{z}'$*,* $\mathcal G(\mathbf{z},\mathbf{z}')=\int_0^\infty v^{\kappa_{F_1}-1}\prod_j(z_{j,K}v+z'_{j,K})^{-s_j}(z_{j,\Psi}v+z'_{j,\Psi})^{-t_j}\,dv$ *is*

the period of the twisted core family of Theorem 23.6(i) with the core $\binom{\{g_1,g_2\}}{1}$ *in every table, the transforms are read at* $x_1 = 1$*, with* $\mathbf{x}' = (x_2, \dots, x_N)$*, and the hinge measures of* F_1 *act in the variables* $(\boldsymbol{\lambda}, \boldsymbol{\mu})$*, those of* F_2 *in* $(\boldsymbol{\lambda}', \boldsymbol{\mu}')$*. Then, in* $[0, \infty]$*,*

$$P_{F_1 \oplus_g F_2}(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \iint \mathcal{G}(\mathbf{z}, \mathbf{z}')\, d\big((\boldsymbol{\varrho}_{F_1})_* \phi_{F_1}\big)(\mathbf{z})\, d\big((\boldsymbol{\varrho}_{F_2})_* \phi_{F_2}\big)(\mathbf{z}') \tag{i}$$

$$= \prod_j \frac{1}{\Gamma(s_j)\Gamma(t_j)} \int \prod_{j \geq 2} x_j^{s_j - 1} \prod_j y_j^{t_j - 1}\, f_{F_1} f_{F_2}\, d\mathbf{x}'\, d\mathbf{y}$$

$$= \prod_j \frac{1}{\Gamma(s_j)\Gamma(t_j)} \int \prod_{j \geq 2} x_j^{t_j - 1} \prod_j y_j^{s_j - 1}\, \check{f}_{F_1} \check{f}_{F_2}\, d\mathbf{x}'\, d\mathbf{y} \tag{ii}$$

$$= \frac{1}{\Gamma(s_1)} \iint e^{-\lambda_1 - \lambda_1'} \prod_{j \geq 2} (\lambda_j + \lambda_j')^{-s_j} \prod_j (\mu_j + \mu_j')^{-t_j}\, d\mathfrak{r}_{F_1}\, d\mathfrak{r}_{F_2}$$

$$= \frac{1}{\Gamma(t_1)} \iint e^{-\lambda_1 - \lambda_1'} \prod_{j \geq 2} (\lambda_j + \lambda_j')^{-t_j} \prod_j (\mu_j + \mu_j')^{-s_j}\, d\check{\mathfrak{r}}_{F_1}\, d\check{\mathfrak{r}}_{F_2}, \tag{iii}$$

and these are finite exactly when every proper wall of $F_1 \oplus_g F_2$ *is positive. On every contour of the level shares of Theorem 19.13 on which its stacked Gammas have arguments of positive real part and the two Mellin transforms below converge absolutely (Definition 23.1),*

$$P_{F_1 \oplus_g F_2}(\mathbf{m}; \mathbf{s}, \mathbf{t}) = 2^{N-1} \int_{\sum_j \delta_j^d = \frac{1}{2}(|\mathbf{s}| - \kappa_{F_1})} \prod_j \Gamma_2 \begin{bmatrix} a_j^d, & b_j^d, & a_j^r, & b_j^r \\ & & s_j, & t_j \end{bmatrix}$$
$$\times \int_{\Delta_B} \boldsymbol{\varrho}_{F_1}^{-(\mathbf{a}^r, \mathbf{b}^d)}\, d\phi_{F_1} \int_{\Delta_R} \boldsymbol{\varrho}_{F_2}^{-(\mathbf{a}^d, \mathbf{b}^r)}\, d\phi_{F_2}, \tag{iv}$$

the formula of Theorem 19.13, the periods of its bunch family and room family at the level shares being these two Mellin transforms. For one table the laws are $(\varrho_{\mathcal{A}})_* \phi_{\mathcal{A}}$ *and* $(\varrho_{\mathcal{A}'})_* \phi_{\mathcal{A}'}$ *and the kernel of (i) is the period of Lemma 23.7; (ii) reads* $\frac{1}{\Gamma(s)\Gamma(t)} \int_0^\infty y^{t-1} f_{\mathcal{A}} f_{\mathcal{A}'}\, dy = \frac{1}{\Gamma(s)\Gamma(t)} \int_0^\infty y^{s-1} \check{f}_{\mathcal{A}} \check{f}_{\mathcal{A}'}\, dy$*, its first form Theorem 20.26(i) with the room transform* $f_R(y) = y^t f_{\mathcal{A}'}(y)$*; (iii) reads* $\frac{1}{\Gamma(s)} \iint (\lambda + \lambda')^{-t}\, d\mathfrak{r}_{\mathcal{A}}^{\Psi}\, d\mathfrak{r}_{\mathcal{A}'}^{\Psi} = \frac{1}{\Gamma(t)} \iint (\lambda + \lambda')^{-s}\, d\mathfrak{r}_{\mathcal{A}}^{K}\, d\mathfrak{r}_{\mathcal{A}'}^{K}$*; and (iv) holds on a line* $\operatorname{Re} z = z_0$ *with* $\max(0, \kappa_{\mathcal{A}} - s) < z_0 < \min(t, \kappa_{\mathcal{A}})$ *on which* $\int \varrho_{\mathcal{A}}^{-z_0} d\phi_{\mathcal{A}}$ *and* $\int \varrho_{\mathcal{A}'}^{z_0 - t} d\phi_{\mathcal{A}'}$ *are finite, as*

$$P_{\mathcal{A} \oplus_g \mathcal{A}'}(\mathbf{m}; s, t) = \frac{1}{\Gamma(s)\Gamma(t)} \frac{1}{2\pi i} \int_{\operatorname{Re} z = z_0} \Gamma(z)\Gamma(z + s - \kappa_{\mathcal{A}})\Gamma(t - z)\Gamma(\kappa_{\mathcal{A}} - z)$$
$$\times \int_{\Delta_B} \varrho_{\mathcal{A}}^{-z}\, d\phi_{\mathcal{A}} \int_{\Delta_R} \varrho_{\mathcal{A}'}^{z - t}\, d\phi_{\mathcal{A}'}\, dz.$$

The period of a two-sum is a pairing of two laws by one kernel, the period of the twisted core family on two marks, for one table the period of two marks. Read through the Grammas the pairing is one integral over the scales of the two transforms, symmetric in the two sides; for one table, read through the hinge measures, it is the moment of order $-t$ of a sum: under $\mathfrak{r}_{\mathcal{A}}^{\Psi}$ the variable is the hinge value $\gamma_{\mathcal{A}}^{\Psi}$ of the cell (Proposition 23.8(ii)), and gluing the two cells into one table adds their hinge values by Ψ, as $\Psi = \Psi_{\mathcal{A} \setminus g} \Psi_{\mathcal{A}' \setminus g} (\gamma_{\mathcal{A}}^{\Psi} + \gamma_{\mathcal{A}'}^{\Psi})$ says.

23.6 What a cell retains

Definition 23.10 (One weighted mark)**.** For $\mathbf{x}_0 = (x_{0,j,K}, x_{0,j,\Psi})_{j=1}^N$ with $x_{0,1,K} = 1$, a point of $(0, \infty)^{2N-1}$, and a mark e with the mass m_e, the *one-mark cell family of ratio vector* $\mathbf{x}_0$ has in

table j the bases $\{e\}$ and $\{g\}$, with the weights $x_{0,j,K}$ and 1 in its letter K_j and the weights 1 and $x_{0,j,\Psi}$ in its letter Ψ_j (Definition 21.1): $K_j = x_{0,j,K}\alpha_e + \alpha_g$ and $\Psi_j = \alpha_g + x_{0,j,\Psi}\alpha_e$. Its hinge values are $x_{0,j,K}\alpha_e$ and $x_{0,j,\Psi}\alpha_e$, its ratio vector is the constant $\mathbf{x}_0$, its hinge wall is m_e, and its law is $\delta_{\mathbf{x}_0}$. For one table and $x_0 > 0$, the *one-mark cell of ratio* x_0 is the plain table $\left(\binom{\{e,g\}}{1}, (1, x_0^{1/2})\right)$ on $\{e,g\}$, the bases $\{e\}$ and $\{g\}$ with the weights 1 and $x_0^{1/2}$. Its hinge minors have $K_{\setminus g} = \alpha_e$, $K_{/g} = x_0^{1/2}$, $\Psi_{\setminus g} = 1$ and $\Psi_{/g} = x_0^{1/2}\alpha_e$, its ratio is the constant x_0, its hinge wall is m_e, and its law is $x_0^{(m_e-s)/2}\,\delta_{x_0}$.

Theorem 23.11 (The law is what a cell family retains)**.** *Let F and F' be cell families with plain tables, at the exponents $(s_j,t_j)_j$ with $s_j,t_j>0$, with masses on their marks other than the hinge and one hinge wall $\kappa \in (0,2\sigma)$, σ the total strength (Definition 8.1), and let there be a real $\mathbf{z} = (z_{j,K}, z_{j,\Psi})_j$ with $0 < z_{j,K} < s_j$, $0 < z_{j,\Psi} < t_j$ and $\sum_j (z_{j,K} + z_{j,\Psi}) = \kappa$ at which $\int \boldsymbol{\varrho}_F^{-\mathbf{z}} d\phi_F$ and $\int \boldsymbol{\varrho}_{F'}^{-\mathbf{z}} d\phi_{F'}$ are finite (Definition 23.1). The following are equivalent.*

(a) $(\boldsymbol{\varrho}_F)_*\phi_F = (\boldsymbol{\varrho}_{F'})_*\phi_{F'}$.

(b) $P_{F\oplus_g F''} = P_{F'\oplus_g F''}$, *in* $[0,\infty]$, *for every cell family F'' with the hinge wall $2\sigma-\kappa$, the masses of F, F' and F'' kept.*

(c) (b) holds for the one-mark cell families F'' of ratio vector $\mathbf{x}_0$ and mass $2\sigma-\kappa$ (Definition 23.10), for every $\mathbf{x}_0$ in a nonempty open subset of $(0,\infty)^{2N-1}$.

(d) $\int \boldsymbol{\varrho}_F^{-\mathbf{w}} d\phi_F = \int \boldsymbol{\varrho}_{F'}^{-\mathbf{w}} d\phi_{F'}$ *at every complex $\mathbf{w}$ with real part $\mathbf{z}$.*

So the hinge wall and the law are the whole of what a cell family contributes to the families built on it, and the one-mark cell families, whose laws are single points, already separate any two laws. For one table the plain one-mark cells of ratio x_0 suffice in (c), and (d) is the agreement of $\int \varrho_{\mathcal{A}}^{-w} d\phi_{\mathcal{A}}$ and $\int \varrho_{\mathcal{A}'}^{-w} d\phi_{\mathcal{A}'}$ on the line $\operatorname{Re} w = z_{1,\Psi}$, $\max(0,\kappa-s) < z_{1,\Psi} < \min(t,\kappa)$.

What determines the contribution of a cell family to a larger construction is its hinge wall, which balance hands to the other side of the hinge, and its law, one positive measure on $(0,\infty)^{2N-1}$, on the half-line for one cell. Anything finer about the cells, their marks, their masses one by one, their letters, is invisible from outside, and anything coarser fails already against one weighted mark. A cell family is therefore replaceable, in every family it can sit in, by any other cell family of the same wall and the same law, and a cell family whose law is one point is a mark. Theorem 21.16 says the same at any width for the joint law of the bunch letters; at width one the joint law collapses to the law of the ratio vector.

Corollary 23.12 (Cells that are marks)**.** *Let F be a cell family with plain tables and $s_j,t_j>0$, and $\mathcal{A}$ a plain cell with exponents $s,t>0$.*

(i) The law of F is carried by a single point, $(\boldsymbol{\varrho}_F)_*\phi_F = \phi_F(\Delta_B)\,\delta_{\mathbf{x}_0}$, exactly when the ratio vector is constant, $\boldsymbol{\varrho}_F \equiv \mathbf{x}_0$; then $\phi_F(\Delta_B) \in (0,\infty]$, finite whenever F sits in a gluing of finite period, and in every gluing F acts as $\phi_F(\Delta_B)$ times the one-mark cell family of ratio vector $\mathbf{x}_0$ and mass κ_F. For one cell with $\varrho_{\mathcal{A}} \equiv x_0$ this is $\phi_{\mathcal{A}}(\Delta_B)\,x_0^{(s-\kappa_{\mathcal{A}})/2}$ times the one-mark cell of ratio x_0 and mass $\kappa_{\mathcal{A}}$.

(ii) If $\mathcal{A}/g$ is the dual table of $\mathcal{A}\setminus g$ with the identity on B and the same weights, then $\varrho_{\mathcal{A}} \equiv 1$ and $\phi_{\mathcal{A}}(\Delta_B) = P_{\mathcal{A}\setminus g}(\mathbf{m}; \kappa_{\mathcal{A}}, s+t-\kappa_{\mathcal{A}})$.

(iii) If a table $(\mathcal{B},\theta)$ is identically self-dual*, its bases closed under complement with $\theta_{\mathcal{E}\setminus T} = \theta_T$, then for every mark g and masses on the balance wall with every proper wall positive,*

$$P_F(\mathbf{m}; s, t) = \Gamma_{\binom{2}{1}}\begin{bmatrix} m_g, & s+t-m_g \\ & s+t \end{bmatrix} P_{F\setminus g}\big(\mathbf{m}|_{\mathcal{E}\setminus g}; s+t-m_g, m_g\big),$$

$F = ((\mathcal{B},\theta); s, t)$ and $F \setminus g = ((\mathcal{B} \setminus g, \theta); s + t - m_g, m_g)$ the family of the deletion.

So (iii) splits off any mark of an identically self-dual table, by one Beta corner, at every pair of exponents, and Proposition 19.12, every letter active, is (i) read across a bunch of width one, the ratio vector being constant. The relation is a consequence of structure alone: the mark g and the rest of the table see each other through a ratio that is identically one, so the hinge integral separates. For a table that is its own dual only up to a relabelling of its marks the hypothesis of (iii) fails, and (iii) does not apply.

23.7 Series and parallel nodes

Definition 23.13 (Series and parallel cores)**.** For $q \geq 2$ and the markers $G = \{g_0, g_1, \dots, g_q\}$ a *series core* is a table with the bases of the list $\binom{G}{q}$ and a *parallel core* a table with the bases of the list $\binom{G}{1}$, with any positive weights. With cells $\mathcal{A}_1, \dots, \mathcal{A}_q$ at $g_1, \dots, g_q$ and the hinge g_0, $\binom{G}{q}\langle \mathcal{A}_1, \dots, \mathcal{A}_q\rangle$ and $\binom{G}{1}\langle \mathcal{A}_1, \dots, \mathcal{A}_q\rangle$, the cores with unit weights, are the *series connection* of the cells, whose bunch $\bigsqcup_i B_i$ is the series connection of the parts B_i of Proposition 20.37, and their *parallel connection*; at the vertices of a hinge tree series and parallel cores are *series nodes* and *parallel nodes*.

A series bunch of marks is the series connection of its marks, each a one-mark cell, and a parallel bunch the parallel connection (Proposition 19.3); and the series closure $\binom{\{h_1,\dots,h_q\}}{q-1}\langle \mathcal{A}_1, \dots, \mathcal{A}_q\rangle$ of Corollary 21.7(ii) is the series connection of $\mathcal{A}_1, \dots, \mathcal{A}_{q-1}$ glued to $\mathcal{A}_q$ along g_0.

Theorem 23.14 (Series and parallel nodes)**.** *Let $F_1, \dots, F_q$, $q \geq 2$, be cell families with plain tables at the exponents $(s_j, t_j)_j$, $s_j, t_j > 0$, the table j of F_i being $\mathcal{A}_{ij}$, and $G = \{g_0, \dots, g_q\}$.*

(i) Series. *The cell family F whose table j is $\mathcal{A}_j = \binom{G}{q}\langle \mathcal{A}_{1j}, \dots, \mathcal{A}_{qj}\rangle$ has $\kappa_F = \sum_i \kappa_{F_i} - (q-1)|\mathbf{s}|$, its hinge values combine in every table as $1/\gamma^K_{\mathcal{A}_j} = \sum_i 1/\gamma^K_{\mathcal{A}_{ij}}$ and $\gamma^\Psi_{\mathcal{A}_j} = \sum_i \gamma^\Psi_{\mathcal{A}_{ij}}$, and*

$$f_F = \prod_{i=1}^{q} f_{F_i}, \qquad \mathfrak{r}_F = \mathfrak{r}_{F_1} * \cdots * \mathfrak{r}_{F_q},$$

the convolution on $(0,\infty)^{2N}$. For one table, $\mathcal{A} = \binom{G}{q}\langle \mathcal{A}_1, \dots, \mathcal{A}_q\rangle$ has $f_{\mathcal{A}} = \prod_i f_{\mathcal{A}_i}$ and $\mathfrak{r}^\Psi_{\mathcal{A}} = \mathfrak{r}^\Psi_{\mathcal{A}_1} * \cdots * \mathfrak{r}^\Psi_{\mathcal{A}_q}$, the convolution on $(0,\infty)$, and the series core twisted by $\mathbf{x}$ at $g_1, \dots, g_q$ has, on the simplex of its markers $g_1, \dots, g_q$ with the coordinates v, the ratio and the base form

$$\Big(\sum_i \frac{1}{v_i}\Big)\Big(\sum_i x_i v_i\Big), \qquad \prod_i v_i^{\kappa_{\mathcal{A}_i}-1}\, e_{q-1}(v)^{\kappa_{\mathcal{A}}-s}\Big(\prod_i v_i\Big)^{-\kappa_{\mathcal{A}}} d\omega_{\{g_1,\dots,g_q\}}(v).$$

(ii) Parallel. *The cell family F whose table j is $\mathcal{A}_j = \binom{G}{1}\langle \mathcal{A}_{1j}, \dots, \mathcal{A}_{qj}\rangle$ has $\kappa_F = \sum_i \kappa_{F_i} - (q-1)|\mathbf{t}|$, its hinge values combine as $\gamma^K_{\mathcal{A}_j} = \sum_i \gamma^K_{\mathcal{A}_{ij}}$ and $1/\gamma^\Psi_{\mathcal{A}_j} = \sum_i 1/\gamma^\Psi_{\mathcal{A}_{ij}}$, and*

$$\check{f}_F = \prod_{i=1}^{q} \check{f}_{F_i}, \qquad \check{\mathfrak{r}}_F = \check{\mathfrak{r}}_{F_1} * \cdots * \check{\mathfrak{r}}_{F_q};$$

for one table $\check{f}_{\mathcal{A}} = \prod_i \check{f}_{\mathcal{A}_i}$ and $\mathfrak{r}^K_{\mathcal{A}} = \mathfrak{r}^K_{\mathcal{A}_1} * \cdots * \mathfrak{r}^K_{\mathcal{A}_q}$.

(iii) Extremes of the ratio. *For one table, with plain cells $\mathcal{A}_1, \dots, \mathcal{A}_q$ at the exponents (s,t): in a series connection $\sqrt{\inf \varrho_{\mathcal{A}}} = \sum_i \sqrt{\inf \varrho_{\mathcal{A}_i}}$ (Proposition 20.37(i)) and $\sup \varrho_{\mathcal{A}} = \infty$; in a parallel connection $1/\sqrt{\sup \varrho_{\mathcal{A}}} = \sum_i 1/\sqrt{\sup \varrho_{\mathcal{A}_i}}$ and $\inf \varrho_{\mathcal{A}} = 0$, with $1/\sqrt{\infty} = 0$.*

(iv) Reaches. *For one table: if every $f_{\mathcal{A}_i}$ has a lattice expansion of reach ζ_i (Definition 20.28), the series connection has $f_{\mathcal{A}}$ with a lattice expansion of reach $\big(\sum_i \sqrt{\zeta_i}\big)^2$ (Proposition 20.37(ii)); if every $\check{f}_{\mathcal{A}_i}$ has one of reach ζ_i, the parallel connection has $\check{f}_{\mathcal{A}}$ with one of reach $\big(\sum_i \sqrt{\zeta_i}\big)^2$.*

A series node adds the hinge values by Ψ of its cells and a parallel node their hinge values by K; in the matching transform each is a product, and in the matching hinge measure a convolution. In the other transform neither node is a product: the dual orthant form of a series connection does not factor, since $K_{\mathcal{A}/g_0} = \prod_i K_{\mathcal{A}_i/g_i}\, e_{q-1}\big((\gamma^K_{\mathcal{A}_i})_i\big)$ and $1/\gamma^K_{\mathcal{A}} = \sum_i 1/\gamma^K_{\mathcal{A}_i}$ mix the cells. What changes at the edges where the kind of node changes is the transform, not the cells (Proposition 23.8(v)). The ceilings of Section 20.8 are read on a bunch as a whole, where the letters $K_{\mathcal{A}/g_0}$ and $\Psi_{\mathcal{A}/g_0}$ of the hinge minors of a series connection mix the cells and their zeros can raise a ceiling above the reach; at a node the cells are separate factors and the reach is read cell by cell (Lemma 20.30). So ceilings are to be applied to the prime nodes of a hinge tree, and reaches combined across series and parallel nodes by (iv).

23.8 Hinge trees

Definition 23.15 (Hinge tree)**.** A *hinge tree* of a table on $\mathcal{E}$ is a finite tree $\mathfrak{T}$ with a core $\mathcal{H}_v$ on $\mathcal{E}_v \sqcup G_v$ at each vertex v, its *node*, where the $\mathcal{E}_v$ partition $\mathcal{E}$ and $G_v = \{g_{v,\mathfrak{e}}\}$ has one marker for each edge $\mathfrak{e}$ at v, such that the table is obtained from the $\mathcal{H}_v$ by the two-sums identifying $g_{v,\mathfrak{e}}$ with $g_{w,\mathfrak{e}}$ for every edge $\mathfrak{e} = \{v,w\}$. Rooted at a vertex o, every vertex $v \neq o$ has a parent edge $\mathfrak{e}_v$, and the *subtree cell* $\mathcal{A}_v$ is the substitution of the $\mathcal{H}_w$ over the vertices w below v, v included, with the hinge $g_{v,\mathfrak{e}_v}$; its cells are the subtree cells of the vertices directly below v. The tables of a family $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_j$ have a *common hinge tree* when one tree $\mathfrak{T}$, with the same sets $\mathcal{E}_v$ and markers G_v, is a hinge tree of every table, table j with the nodes $\mathcal{H}_{v,j}$; the nodes then form the *node families* $F_{\mathcal{H}_v} = ((\mathcal{H}_{v,j}, \theta^{\mathcal{H}_{v,j}}); s_j, t_j)_j$ and, rooted at o, the subtree cells $\mathcal{A}_{v,j}$ the cell families $F_v = ((\mathcal{A}_{v,j}, \theta^{\mathcal{A}_{v,j}}); s_j, t_j)_j$ of the vertices $v \neq o$ (Definition 23.1).

Theorem 23.16 (A connected table is a tree of prime tables)**.** *Call a connected table on at least four marks* prime *when it has no bunch of width one with at least two marks on each side. Every connected table on at least three marks whose weights factor across each bunch of width one at which it is decomposed, a list or a determinantal table for instance (Theorem 12.19), is obtained by substitutions along a tree from prime tables and the series and parallel nodes $\binom{S}{|S|-1}$ and $\binom{S}{1}$, $|S| \geq 3$ (Definition 23.13), the weights carried along. With no two series nodes and no two parallel nodes adjacent in the tree, the tree, the* canonical hinge tree *(Definition 23.15), is unique up to the names of the markers. The prime nodes of a list are therefore invariants of the list.*

By Lemma 23.5, applied leaf by leaf, the substitution along a tree does not depend on the order of the two-sums: its bases are the sets $\bigsqcup_v (T_v \cap \mathcal{E}_v)$ with T_v a basis of $\mathcal{H}_v$ and every edge's marker in exactly one of the two bases at its ends. Every connected table has a hinge tree with one vertex, and decomposing at bunches of width one with at least two marks on each side, the weights factoring across each such bunch, markers counted as marks, refines it until no node has such a bunch. A node on at least four marks without one is prime (Theorem 23.16); the nodes on three marks, with the bases of $\binom{G}{2}$ or of $\binom{G}{1}$, $|G| = 3$, are series and parallel nodes, and merging adjacent

series nodes, and adjacent parallel nodes, gives the series and parallel nodes of any size; with no two series and no two parallel nodes adjacent this is the canonical hinge tree of Theorem 23.16.

Theorem 23.17 (The period along a hinge tree)**.** *Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^{N}$ have real data on its balance wall and its tables a common hinge tree rooted at o, with the node families $F_{\mathcal{H}_v}$ and the cell families F_v of the vertices $v \neq o$ (Definition 23.15), and let $F_{\mathcal{H}_v}[\mathbf{x}]$ be $F_{\mathcal{H}_v}$ twisted at the markers of the edges to the vertices w directly below v by $\mathbf{x}_w \in (0,\infty)^{2N-1}$, with the masses κ_{F_w} there and $\mathbf{m}|_{\mathcal{E}_v}$ on $\mathcal{E}_v$ (Theorem 23.6).*

(i) For $v \neq o$, κ_{F_v} is the hinge wall of $F_{\mathcal{H}_v}[\mathbf{x}]$, and

$$\int H\, d\big((\boldsymbol{\varrho}_{F_v})_*\phi_{F_v}\big) = \int \Big(\int H\, d\big((\boldsymbol{\varrho}_{F_{\mathcal{H}_v}[\mathbf{x}]})_*\phi_{F_{\mathcal{H}_v}[\mathbf{x}]}\big)\Big) \prod_w d\big((\boldsymbol{\varrho}_{F_w})_*\phi_{F_w}\big)(\mathbf{x}_w)$$

for every Borel $H \geq 0$ on $(0,\infty)^{2N-1}$.

(ii) The period is

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \int P_{F_{\mathcal{H}_o}[\mathbf{x}]}\big((\mathbf{m}|_{\mathcal{E}_o}, (\kappa_{F_w})_w);\mathbf{s},\mathbf{t}\big) \prod_w d\big((\boldsymbol{\varrho}_{F_w})_*\phi_{F_w}\big)(\mathbf{x}_w),$$

the product over the vertices w directly below the root.

(iii) The law of F_v is determined by the tables $\mathcal{H}_{w,j}$ and the masses on $\mathcal{E}_w$ for the vertices w below v, and by the exponents; nothing above v enters it.

For one table the cell families are the subtree cells $\mathcal{A}_v$, with laws on $(0,\infty)$.

Where the active letters read every subtree cell by one hinge value, as at a full lean of one table, every cell of the tree is pinned (Theorem 22.5), and Chapter 26 writes the period along the tree as a product and carries it to every load.

Proposition 23.18 (What the work depends on)**.** *In Theorem 23.17:*

(i) Two vertices whose subtree cells are carried onto each other, in every table, by one bijection keeping the tables, the weights, the masses and the hinge have equal hinge walls and equal laws. So the laws to be computed are one for each orbit of subtree cells under such bijections.

(ii) Let $s_j, t_j > 0$. At a series node v whose cell families directly below fall into orbits $c_1, \dots, c_p$ with multiplicities $k_1, \dots, k_p$, $f_{F_v} = \prod_l f_{c_l}^{k_l}$ and $\kappa_{F_v} = \sum_l k_l \kappa_{c_l} - \big(\sum_l k_l - 1\big)|\mathbf{s}|$, f_{c_l} and κ_{c_l} the transform and the hinge wall of a member of c_l; at a parallel node $\check{f}_{F_v} = \prod_l \check{f}_{c_l}^{k_l}$ and $\kappa_{F_v} = \sum_l k_l \kappa_{c_l} - \big(\sum_l k_l - 1\big)|\mathbf{t}|$. The multiplicities enter as exponents.

(iii) A change at a vertex v_0 of the weights, of the masses keeping their total, or of the tables $\mathcal{H}_{v_0,j}$ keeping their ranks and their numbers of marks, changes no hinge wall and changes the laws of the cell families F_v only for the vertices v on the path from v_0 to the root. A change of masses at two vertices v_0, v_1 that keeps the total mass changes the hinge wall κ_{F_v} exactly for the vertices v whose subtree contains one of v_0, v_1 and not the other, the edges on the path between v_0 and v_1, by the change of the total mass below $\mathfrak{e}_v$.

A hinge tree is read from the leaves up by a computation whose reusable data are the laws on the edges. Its cost is governed by the prime nodes, where cells interact through the node's own integral, and by the number of distinct subtrees, since equal subtrees have equal laws; series and parallel nodes cost no integration in the matching transform, and repeated subtrees enter as powers, as the hinge tree procedure makes explicit.

Definition 23.19 (The hinge tree procedure)**.** *Given*: a common hinge tree of the tables of a family (Definition 23.15), the masses on the marks of its nodes, exponents $s_j, t_j > 0$, and a root. *Reusable data*: for every orbit of subtree cells (Proposition 23.18(i)) its hinge wall κ and its law, kept in one of three representations: (a) the transform f and the dual transform $\check f$ on a grid of $(\mathbf{x}, \mathbf{y})$ with $x_1 = 1$, of y for one table; (b) the Mellin transform $\int \boldsymbol{\varrho}^{-\mathbf{z}} d\phi$ of the law on a vertical subspace of its domain of convergence, for one table $\int \varrho^{-z} d\phi$ on a vertical line of its strip; (c) for one table, the lattice expansion of f at $y \to 0$, the residues of $y^{-z}\Gamma(z)\Gamma(z+s-\kappa)\int \varrho^{-z} d\phi$ to the left of the line (Theorem 20.34(i)). *Operations*, from the leaves up:

(1) a one-mark leaf, the one-mark cell family of ratio vector $\mathbf{x}_0$ (Definition 23.10), has $\kappa = m_e$, the law $\delta_{\mathbf{x}_0}$ and the transforms

$$f(\mathbf{x},\mathbf{y}) = \prod_j x_{0,j,K}^{-s_j}\, \mathsf{G}_{|\mathbf{s}|-m_e;(1,-1)}\Big(\sum_j \frac{x_j}{x_{0,j,K}},\ \sum_j y_j x_{0,j,\Psi}\Big),$$
$$\check f(\mathbf{x},\mathbf{y}) = \prod_j x_{0,j,\Psi}^{-t_j}\, \mathsf{G}_{|\mathbf{t}|-m_e;(1,-1)}\Big(\sum_j \frac{x_j}{x_{0,j,\Psi}},\ \sum_j y_j x_{0,j,K}\Big);$$

for one table the one-mark cell of ratio x_0 has the law $x_0^{(m_e-s)/2}\,\delta_{x_0}$ and

$$f(y) = x_0^{(m_e-s)/2}\mathsf{G}_{s-m_e;(1,-1)}(1, x_0 y), \qquad \check f(y) = x_0^{(m_e-s)/2-m_e}\mathsf{G}_{t-m_e;(1,-1)}(1, y/x_0);$$

(2) at a series node multiply the transforms of the vertices directly below, in (a) pointwise, in (b) by Mellin convolution of the Mellin transforms of Proposition 23.8(iii), for one table $\Gamma(z)\Gamma(z+s-\kappa)\int \varrho^{-z} d\phi$, in (c) by the product of lattice expansions (Lemma 20.30); at a parallel node the same with the dual transforms;

(3) along an edge where the kind of node changes, change the transform by Proposition 23.8(v): in (b) a reflection and a ratio of Gammas, in (a) a Mellin transform followed by an inverse Mellin transform, each one integral on $(0,\infty)^{2N-1}$, on the half-line for one table;

(4) at a prime node evaluate the Mellin transform of the law of the twisted node family, or its transform, as a period of the twisted node family, and integrate it against the laws of the vertices directly below (Theorem 23.6(ii));

(5) at the root evaluate Theorem 23.6(i); for a series root, with the cell families F_i directly below and their transforms read at $x_1 = 1$, $\mathbf{x}' = (x_2, \dots, x_N)$, the period is

$$\prod_j \frac{1}{\Gamma(s_j)\Gamma(t_j)} \int \prod_{j\ge 2} x_j^{s_j-1} \prod_j y_j^{t_j-1} \prod_i f_{F_i}\, d\mathbf{x}'\, d\mathbf{y},$$
$$\text{for one table}\quad \frac{1}{\Gamma(s)\Gamma(t)} \int_0^\infty y^{t-1} \prod_i f_{\mathcal{A}_i}(y)\, dy,$$

and for a parallel root the same with s_j and t_j swapped and the dual transforms (Theorem 23.9(ii)).

Output: the period, and with it every law on every edge, ready to be reused when the tree is changed (Chapter 24).

Corollary 23.20 (Series-parallel families)**.** *Let the tables of a family with exponents $s_j, t_j > 0$ have a common hinge tree whose nodes are series and parallel nodes and whose leaves are one-mark cell families, and at every edge joining a series node to a parallel node let the law of the subtree below*

have a Mellin transform finite at a real $\mathbf{z}$ *with* $0 < z_{j,K} < s_j$ *and* $0 < z_{j,\Psi} < t_j$ *for every* j *(Proposition 23.8(v)). Then its period is obtained from the transforms of the leaves, Grammas of the marks (Definition 23.19(1)), by pointwise products, by two integral transforms on* $(0,\infty)^{2N-1}$ *for each edge joining a series node to a parallel node, and by one final integral on* $(0,\infty)^{2N-1}$*; the number of integrations depends on the alternations of the tree and not on the number of marks, and subtrees repeated at a node enter as powers. For one table the integral transforms are on the half-line.*

Chapter 24

Repetition and the change of query

A construction that repeats a cell should not repeat the work, and a query that changes one weight or one mass should not restart the computation. A cell family repeated k times at a series node enters its period as the k-th power of its transform, and repetition without bound forces its hinge wall to be $\sum_j s_j$; for one cell the growth in k is then factorial, with the base $A_1/\min(s,t)$, A_1 the period of the cell with its hinge deleted, and a prefactor read from one further constant of the cell and one leading coefficient of the room (Theorems 24.1 and 24.2); a chain of repeated cell families is a power of one positive operator (Proposition 24.4); the weight of a hinge enters through a Mellin convolution whose two expansions are the two closings of the node of Section 20.7 (Theorem 24.5); and a change of data at one node moves only the laws on one path of the tree (Proposition 24.6).

24.1 Repetition at a node

For a cell family F with plain tables $\mathcal{A}_j$ and $k \geq 1$, F_k^{s} and F_k^{p} are the cell families whose table j is the series and the parallel connection of k copies of $\mathcal{A}_j$ (Definition 23.13), with $F_1^{\mathrm{s}} = F_1^{\mathrm{p}} = F$; for one plain cell $\mathcal{A}$ they are written $\mathcal{A}_k^{\mathrm{s}}$ and $\mathcal{A}_k^{\mathrm{p}}$. The cell family is *series-balanced* when $\kappa_F = |\mathbf{s}|$ and *parallel-balanced* when $\kappa_F = |\mathbf{t}|$; by Definition 23.1 the first says that the deletions $\mathcal{A}_j \setminus g$, at the exponents (s_j, t_j), form a family on its balance wall at the masses $\mathbf{m}$, $m_B = \sum_j \big(s_j r_{\mathcal{A}_j} + t_j(|B| - r_{\mathcal{A}_j})\big)$, and the second that the contractions $\mathcal{A}_j/g$ do; for one cell they say $\kappa_{\mathcal{A}} = s$ and $\kappa_{\mathcal{A}} = t$.

Theorem 24.1 (How often a cell family repeats)**.** *Let F be a cell family with plain tables and real exponents.*

(i) $\kappa_{F_k^{\mathrm{s}}} = |\mathbf{s}| + k(\kappa_F - |\mathbf{s}|)$ *and* $\kappa_{F_k^{\mathrm{p}}} = |\mathbf{t}| + k(\kappa_F - |\mathbf{t}|)$.

(ii) If F' is a cell family with $F_k^{\mathrm{s}} \oplus_g F'$ on its balance wall and of convergent period, then $0 < |\mathbf{s}| + k(\kappa_F - |\mathbf{s}|) < 2\sigma$, σ the total strength (Definition 8.1). So series connections of any number of copies of F occur in convergent periods only if F is series-balanced; otherwise $k < |\mathbf{s}|/(|\mathbf{s}| - \kappa_F)$ when $\kappa_F < |\mathbf{s}|$ and $k < |\mathbf{t}|/(\kappa_F - |\mathbf{s}|)$ when $\kappa_F > |\mathbf{s}|$. For parallel connections the same holds with $|\mathbf{t}|$ in place of $|\mathbf{s}|$ and $|\mathbf{s}|$ in place of $|\mathbf{t}|$.

The hinge wall of a series connection drifts by $\kappa_F - |\mathbf{s}|$ for every copy, and the room must absorb the drift; only a series-balanced cell family repeats without limit. It is the cell family whose deletions at the hinge form a balanced family, and for one cell the period of that deletion is the number that governs the repetition.

Theorem 24.2 (Series repetition)**.** *Let F be a series-balanced cell family on $B \sqcup \{g\}$ and $F' = ((\mathcal{A}'_j, \theta'_j); s_j, t_j)_j$ a cell family on $R \sqcup \{g\}$ with $\kappa_{F'} = |\mathbf{t}|$, plain tables, exponents $s_j, t_j > 0$, so that $F \overset{\mathrm{s}}{_k}\!\oplus_g F'$ is on its balance wall for every k; in this statement write $P(k)$ for its period, at the masses of the copies and of F', and read the transforms at $x_1 = 1$, $\mathbf{x}' = (x_2, \dots, x_N)$.*

(i) In $[0, \infty]$,

$$P(k) = \prod_j \frac{1}{\Gamma(s_j)\Gamma(t_j)} \int \prod_{j \geq 2} x_j^{s_j - 1} \prod_j y_j^{t_j - 1} \, f_F^k f_{F'} \, d\mathbf{x}' \, d\mathbf{y},$$

the k-th moment of the image under f_F of the measure

$$\prod_j \frac{1}{\Gamma(s_j)\Gamma(t_j)} \prod_{j \geq 2} x_j^{s_j - 1} \prod_j y_j^{t_j - 1} \, f_{F'}(\mathbf{x}, \mathbf{y}) \, d\mathbf{x}' \, d\mathbf{y}.$$

Where finite, $P(k)^2 \leq P(k-1)P(k+1)$, and for $z \geq 0$, with $P(0)$ the period at $\mathbf{m}|_R$ of the family of the contractions $((\mathcal{A}'_j/g, \theta'_j); s_j, t_j)_j$, the hinge of F' contracted,

$$\sum_{k \geq 0} P(k) \frac{z^k}{k!} = \prod_j \frac{1}{\Gamma(s_j)\Gamma(t_j)} \int \prod_{j \geq 2} x_j^{s_j - 1} \prod_j y_j^{t_j - 1} \, e^{z f_F} f_{F'} \, d\mathbf{x}' \, d\mathbf{y}.$$

For one cell, $P(k) = \frac{1}{\Gamma(s)\Gamma(t)} \int_0^\infty y^{t-1} f_{\mathcal{A}}(y)^k f_{\mathcal{A}'}(y) \, dy$ and $P(0) = \int \varrho_{\mathcal{A}'}^{-t} d\phi_{\mathcal{A}'} = P_{\mathcal{A}'/g}(\mathbf{m}|_R; s, t)$.

(ii) For one cell $\mathcal{A}$ and one cell $\mathcal{A}'$, at the exponents (s, t), let $\mathcal{A} \backslash g$ have every proper wall positive at the masses of $\mathcal{A}$ and the exponents (s, t), and put

$$A_1 = \int_{\Delta_B} d\phi_{\mathcal{A}} = P_{\mathcal{A}\backslash g}(\mathbf{m}|_B; s, t), \qquad A_0 = 2A_1(\log\Gamma)'(1) - \int_{\Delta_B} \log \varrho_{\mathcal{A}} \, d\phi_{\mathcal{A}}.$$

Then $\int \varrho_{\mathcal{A}}^{-z} d\phi_{\mathcal{A}}$ is finite on a neighbourhood of $z = 0$, and for every $\varepsilon \in (0, 1)$ at which $\int \varrho_{\mathcal{A}}^{\varepsilon} d\phi_{\mathcal{A}} < \infty$ there is C with $\big| f_{\mathcal{A}}(y) - A_1(-\log y) - A_0 \big| \leq C y^{\varepsilon}$ for all $y > 0$.

(iii) Let moreover $\int \varrho_{\mathcal{A}'}^{-z} d\phi_{\mathcal{A}'}$ be finite on a neighbourhood of $z = \max(0, t - s)$, and let the polynomial of the room *be*

$$\mathcal{R}(v) = \begin{cases} \Gamma(s-t) \int d\phi_{\mathcal{A}'} & (s > t), \\ \Gamma(t-s) \int \varrho_{\mathcal{A}'}^{s-t} d\phi_{\mathcal{A}'} & (s < t), \\ v \int d\phi_{\mathcal{A}'} + 2(\log\Gamma)'(1) \int d\phi_{\mathcal{A}'} - \int \log \varrho_{\mathcal{A}'} \, d\phi_{\mathcal{A}'} & (s = t), \end{cases}$$

with the coefficients $\mathcal{R}(v - A_0/A_1) = \sum_i \mathcal{R}_i v^i$; let $P(1) < \infty$. Then there is $\varepsilon > 0$ such that for every $\vartheta \in \big(\min(s,t)/(\min(s,t) + \varepsilon), 1\big)$

$$P(k) = \frac{A_1^k \, e^{\min(s,t) A_0/A_1}}{\Gamma(s)\Gamma(t)} \sum_i \mathcal{R}_i \, \frac{\Gamma(k + i + 1)}{\min(s,t)^{k+i+1}} \big(1 + O(\vartheta^k)\big).$$

In particular $P(k) \sim \frac{c \, e^{\min(s,t) A_0/A_1}}{\Gamma(s)\Gamma(t)} \Gamma(k + 1 + j) A_1^k \min(s,t)^{-k-1-j}$, with $j = 1$ and $c = \int d\phi_{\mathcal{A}'}$ when $s = t$ and $j = 0$ and $c = \mathcal{R}$ otherwise: the growth is factorial, with the base $A_1/\min(s,t)$.

(iv) Under the hypotheses of (iii) the series of (i) converges for $0 \leq z < \min(s,t)/A_1$ and diverges at $z = \min(s,t)/A_1$.

So a repeated cell family enters its construction as a power, and the whole sequence $P(k)$ is the sequence of moments of one positive measure: log-convex, with an exponential generating function that is one integral. For one cell the factorial growth is not a property of the room: the transform of a series-balanced cell grows like $A_1\log(1/y)$ at small scales, its k-th power concentrates where $\log(1/y)$ is of the order $k/\min(s,t)$, and there only two numbers of the cell survive, the period A_1 of the cell with its hinge deleted and the constant A_0, and only the first lattice term of the room, through $\min(s,t)$ and $\mathcal{R}$. The error is exponentially small, not a power of $1/k$: the next terms of both lattice expansions sit at distance ε to the right and contribute in the ratio $\big(\min(s,t)/(\min(s,t)+\varepsilon)\big)^k$. Theorem 23.3 reads the series closure of any cells, for any family, through their transforms; for k equal cells at the centre it is (i) with $k-1$ copies at the series node and one copy as the room.

Corollary 24.3 (Parallel repetition)**.** *Let F be a parallel-balanced cell family on $B\sqcup\{g\}$ and $F'=((\mathcal{A}'_j,\theta'_j);s_j,t_j)_j$ a cell family on $R\sqcup\{g\}$ with $\kappa_{F'}=|\mathbf{s}|$, plain tables, exponents $s_j,t_j>0$, and in this statement write $P(k)$ for the period of $F_k^{\mathrm{p}}\oplus_g F'$, the transforms read at $x_1=1$, $\mathbf{x}'=(x_2,\dots,x_N)$. Then*

$$P(k)=\prod_j\frac{1}{\Gamma(s_j)\Gamma(t_j)}\int\prod_{j\ge2}x_j^{t_j-1}\prod_j y_j^{s_j-1}\,\check f_F^{\,k}\check f_{F'}\,d\mathbf{x}'\,d\mathbf{y},$$

with $P(0)$ the period at $\mathbf{m}|_R$ of the family of the deletions $((\mathcal{A}'_j\setminus g,\theta'_j);s_j,t_j)_j$; for one cell, $P(k)=\frac{1}{\Gamma(s)\Gamma(t)}\int_0^\infty y^{s-1}\check f_{\mathcal{A}}(y)^k\check f_{\mathcal{A}'}(y)\,dy$. For one cell $\mathcal{A}$ and one cell $\mathcal{A}'$ let $\mathcal{A}/g$ have every proper wall positive at the masses of $\mathcal{A}$ and the exponents (s,t), and put

$$A_1=\int\varrho_{\mathcal{A}}^{-t}d\phi_{\mathcal{A}}=P_{\mathcal{A}/g}(\mathbf{m}|_B;s,t),\qquad A_0=2A_1(\log\Gamma)'(1)+\int\varrho_{\mathcal{A}}^{-t}\log\varrho_{\mathcal{A}}\,d\phi_{\mathcal{A}}.$$

Then Theorem 24.2(ii) to (iv) hold with s and t swapped and with these A_1 and A_0, the dual transform $\check f_{\mathcal{A}}$ in place of the transform $f_{\mathcal{A}}$, the finiteness of $\int\varrho_{\mathcal{A}}^{-z}d\phi_{\mathcal{A}}$ near $z=t$ in place of near $z=0$, the condition $\int\varrho_{\mathcal{A}}^{-t-\varepsilon}d\phi_{\mathcal{A}}<\infty$ in place of $\int\varrho_{\mathcal{A}}^{\varepsilon}d\phi_{\mathcal{A}}<\infty$, the finiteness of $\int\varrho_{\mathcal{A}'}^{-z}d\phi_{\mathcal{A}'}$ near $z=\min(s,t)$ as the hypothesis on $\mathcal{A}'$, and the polynomial of the room

$$\mathcal{R}(v)=\begin{cases}\Gamma(t-s)\int\varrho_{\mathcal{A}'}^{-s}d\phi_{\mathcal{A}'} & (s<t),\\ \Gamma(s-t)\int\varrho_{\mathcal{A}'}^{-t}d\phi_{\mathcal{A}'} & (s>t),\\ v\int\varrho_{\mathcal{A}'}^{-s}d\phi_{\mathcal{A}'}+2(\log\Gamma)'(1)\int\varrho_{\mathcal{A}'}^{-s}d\phi_{\mathcal{A}'}+\int\varrho_{\mathcal{A}'}^{-s}\log\varrho_{\mathcal{A}'}\,d\phi_{\mathcal{A}'} & (s=t),\end{cases}$$

whose leading coefficient is the constant c of the equivalent in (iii).

24.2 Chains

Proposition 24.4 (A chain is a power of one operator)**.** *Let a* chain cell family *U have in every table a hinged core $\mathcal{U}_j$ (Definition 23.4) with one further marker g_{in}, its hinge g_{out}, own marks $\mathcal{E}_{\mathcal{U}}$ with masses, and real exponents (s_j,t_j); further fixed cell families may be substituted into U beforehand. For a cell family F_0 let $F_{l+1}=U\langle F_l\rangle$, table by table, the cell at g_{in}.*

(i) $\kappa_{F_{l+1}}=\kappa_{F_l}+\kappa_U$, with $\kappa_U=m_{\mathcal{E}_{\mathcal{U}}}-\sum_j\big(s_j(r_{\mathcal{U}_j}-1)+t_j(|\mathcal{E}_{\mathcal{U}}|+1-r_{\mathcal{U}_j})\big)$ the hinge wall of U with the mass 0 on g_{in}. For a fixed cell family F', the families $F_l\oplus_g F'$ are all on their balance walls exactly when $F_0\oplus_g F'$ is and $\kappa_U=0$; then $\kappa_{F_l}=\kappa_{F_0}$.

(ii) Let $\kappa_U = 0$, and in this statement write λ_l for the law of F_l and $\lambda^U_{\mathbf{x}}$ for the law of U twisted at g_{in} by $\mathbf{x} \in (0,\infty)^{2N-1}$ (Definition 22.1) with the mass κ_{F_0} there. On positive measures μ and nonnegative functions H on $(0,\infty)^{2N-1}$ put

$$\mathcal{Q}\mu = \int \lambda^U_{\mathbf{x}}\, d\mu(\mathbf{x}), \qquad (\mathcal{Q}^* H)(\mathbf{x}) = \int H\, d\lambda^U_{\mathbf{x}},$$

$$h_{F'}(\mathbf{x}) = \int \Big(\int_0^\infty v^{\kappa_{F_0}-1} \prod_j (x_{j,K} v + x'_{j,K})^{-s_j} (x_{j,\Psi} v + x'_{j,\Psi})^{-t_j}\, dv \Big)\, d\big((\varrho_{F'})_* \phi_{F'}\big)(\mathbf{x}'),$$

the inner integral the period of the twisted core family of Theorem 23.6(i) with the core $\binom{\{g_1,g_2\}}{1}$ in every table. Then $\lambda_l = \mathcal{Q}^l \lambda_0$ and $P_{F_l \oplus_g F'} = \int (\mathcal{Q}^{*l} h_{F'})\, d\lambda_0$; for $z \geq 0$, $\sum_l z^l P_{F_l \oplus_g F'} = \int \sum_l z^l (\mathcal{Q}^{*l} h_{F'})\, d\lambda_0$, in $[0,\infty]$.

(iii) If $H > 0$ and $M > 0$ have $\mathcal{Q}^* H \leq MH$ and $h_{F'} \leq CH$, then $P_{F_l \oplus_g F'} \leq C M^l \int H\, d\lambda_0$; if $H' \geq 0$ and $M' > 0$ have $\mathcal{Q}^* H' \geq M' H'$ and $h_{F'} \geq c\, H'$, then $P_{F_l \oplus_g F'} \geq c\, M'^l \int H'\, d\lambda_0$.

(iv) Let the tables be plain and $s_j, t_j > 0$. If U is the series core on $\{g_{\text{out}}, g_{\text{in}}, g'\}$ with a fixed cell family F'' at g', then $f_{F_{l+1}} = f_{F''} f_{F_l}$ and $\kappa_U = \kappa_{F''} - |\mathbf{s}|$; if it is the parallel core, then $\check{f}_{F_{l+1}} = \check{f}_{F''} \check{f}_{F_l}$ and $\kappa_U = \kappa_{F''} - |\mathbf{t}|$.

For one table the laws are measures on $(0,\infty)$, the twist is one number, and the inner integral of $h_{F'}$ is the period of Lemma 23.7.

A chain is one kernel applied l times: the law of the chain cell family twisted at g_{in}, computed once, carries the law of the chain from one length to the next, and the period at length l pairs the l-th iterate with the room. The work for all lengths up to l is l applications of one operator, and for one length $\lceil \log_2 l \rceil$ compositions of kernels. A series chain cell family is diagonal in the transform and a parallel one in the dual transform, so for them the operator is a multiplication and the length is an exponent; a chain cell family that alternates the two kinds mixes the two hinge values, and its operator is not diagonal in either. Theorem 22.8 is the same chain read on functions of the twists, a family glued to copies of itself at two marks, with the pinned case $P_F(\mathbf{m};\mathbf{s},\mathbf{t})^k / \Gamma_2 \binom{m_{g_{\text{in}}},\ m_{g_{\text{out}}}}{m_{g_{\text{in}}} + m_{g_{\text{out}}}}^{k-1}$; Proposition 24.4 reads it on laws, and positive test functions bound it from both sides. Every polynomial Gamma moment of a chain is the power of one finite matrix (Theorem 27.5).

24.3 The weight of a hinge

Theorem 24.5 (The weight of a hinge)**.** *For plain cells $\mathcal{A}$ on $B \sqcup \{g\}$ and $\mathcal{A}'$ on $R \sqcup \{g\}$ with exponents $s, t > 0$, and $w > 0$, let $w\mathcal{A}$ be $\mathcal{A}$ with the weights of its bases through g multiplied by w, so that in $(w\mathcal{A}) \oplus_g \mathcal{A}'$ the bases made of a basis of $\mathcal{A}/g$ and a basis of $\mathcal{A}' \setminus g$, the second kind of Lemma 21.2, carry the factor w; let it be on its balance wall, put $q = w^2$, and in this statement write $\Pi(q) = q^{(s-\kappa_{\mathcal{A}})/2} P_{(w\mathcal{A}) \oplus_g \mathcal{A}'}(\mathbf{m}; s, t)$.*

(i) For a cell family F with plain tables $\mathcal{A}_j$ and $\mathbf{w} \in (0,\infty)^N$, let $\mathbf{w}F$ be F with the weights of the bases through g multiplied by w_j in table j. Its hinge wall is κ_F, its ratio vector has the coordinates $(w_1/w_j)\, \gamma^K_{\mathcal{A}_j} / \gamma^K_{\mathcal{A}_1}$ and $w_1 w_j\, \gamma^\Psi_{\mathcal{A}_j} / \gamma^K_{\mathcal{A}_1}$, the hinge values of F being read, $\phi_{\mathbf{w}F} = w_1^{\kappa_F} \prod_j w_j^{-s_j}\, \phi_F$, and, for $s_j, t_j > 0$, $f_{\mathbf{w}F}(\mathbf{x},\mathbf{y}) = f_F(\mathbf{w} \circ \mathbf{x}, \mathbf{w} \circ \mathbf{y})$ and $\check{f}_{\mathbf{w}F}(\mathbf{x},\mathbf{y}) = \prod_j w_j^{-s_j - t_j}\, \check{f}_F(\mathbf{x}/\mathbf{w}, \mathbf{y}/\mathbf{w})$, the products and quotients taken coordinatewise. For one cell, $\varrho_{w\mathcal{A}} = w^2 \varrho_{\mathcal{A}}$, $\phi_{w\mathcal{A}} = w^{\kappa_{\mathcal{A}} - s} \phi_{\mathcal{A}}$, $f_{w\mathcal{A}}(y) = w^{\kappa_{\mathcal{A}} - s} f_{\mathcal{A}}(w^2 y)$ and $\check{f}_{w\mathcal{A}}(y) = w^{-\kappa_{\mathcal{A}} - s} \check{f}_{\mathcal{A}}(y/w^2)$.

(ii) $\Pi(q) = \frac{1}{\Gamma(s)\Gamma(t)} \int_0^\infty y^{t-1} f_{\mathcal{A}}(qy) f_{\mathcal{A}'}(y)\, dy$, *a decreasing function of* q, *and for real* z *with* $\max(0, \kappa_{\mathcal{A}} - s) < z < \min(t, \kappa_{\mathcal{A}})$, *in* $(0, \infty]$,

$$\int_0^\infty q^{z-1} \Pi(q)\, dq = \frac{\Gamma(z)\Gamma(z+s-\kappa_{\mathcal{A}}) \int \varrho_{\mathcal{A}}^{-z} d\phi_{\mathcal{A}} \cdot \Gamma(t-z)\Gamma(\kappa_{\mathcal{A}} - z) \int \varrho_{\mathcal{A}'}^{z-t} d\phi_{\mathcal{A}'}}{\Gamma(s)\Gamma(t)}.$$

(iii) If this is finite at a real c *in that interval, then* Π *is finite and continuous on* $(0, \infty)$ *and is the value there of the function* $\frac{1}{2\pi i} \int_{(c)} q^{-z} (\cdots)\, dz$, *with* $(\cdots)$ *the right side of the display in (ii), holomorphic on the sector* $|\arg q| < 2\pi$ *of the logarithmic cover of* $\mathbb{C} \setminus \{0\}$.

(iv) In the setting of Section 20.7, with $\mathcal{A}$ *the cell of the bunch and* $\mathcal{A}'$ *that of the room, let* $f_{\mathcal{A}}$ *have a lattice expansion* $\sum_{\eta,j} \beta_{\eta,j} y^\eta (-\log y)^j$ *of every reach above* $\operatorname{reach}(B)$ *(Definition 20.28), and let* $\inf \varrho_{\mathcal{A}'} > 0$. *Then for* $0 < q < \inf \varrho_{\mathcal{A}'} / \operatorname{reach}(B)$, *absolutely,*

$$\Pi(q) = \frac{1}{\Gamma(s)\Gamma(t)} \sum_{\eta,j} \beta_{\eta,j}\, q^\eta \sum_{i=0}^{j} \binom{j}{i} (-\log q)^{j-i} \times (-\partial_z)^i \Big[\Gamma(z)\Gamma(z+s-\kappa_{\mathcal{A}'}) \int \varrho_{\mathcal{A}'}^{-z} d\phi_{\mathcal{A}'} \Big]_{z=t+\eta};$$

at $q = 1$ *this is the closing of Theorem 20.34(ii) toward the level* d. *Swapping* $\mathcal{A}$ *and* $\mathcal{A}'$, q^{-t} *times the same expansion in* $1/q$ *holds for* $q > \operatorname{reach}(R)/\inf \varrho_{\mathcal{A}}$, *and is the closing toward the level* r. *The two ranges never overlap.*

The closings of a node of Section 20.7 are therefore not two separate devices but the two expansions, at $q \to 0$ and at $q \to \infty$, of one function of the weight of its hinge, holomorphic on two sheets around the origin and given everywhere by the contour integral of (iii), whose integrand is the product of the Mellin transforms of the two sides over $\Gamma(s)\Gamma(t)$ (Proposition 23.8(iii)). The unweighted period is the value at $q = 1$; a closing reaches it when 1 lies inside its range, its terms do not tend to zero when 1 lies beyond it, and at the common end of the two ranges the root rate is one and domination decides nothing (Theorem 20.39(ii) to (iv), the ranges being read at the reaches of the two sides); and the coefficients of each expansion are the reusable lattice data of one side paired with the Mellin data of the other, the same for every weight.

24.4 Changing masses and weights

Proposition 24.6 (Carrying a calculation through a change)**.** *Let the tables of a family have a common hinge tree rooted at* o *(Definition 23.15), with every law computed by Definition 23.19.*

(i) A change at a vertex v' *of the weights, of the masses keeping their total, or of the tables* $\mathcal{H}_{v',j}$ *keeping their ranks and their numbers of marks, is carried through by recomputing the laws at the vertices on the path from* v' *to* o, *each from the new law of the vertex directly below it on the path and the old laws of the other vertices directly below it, and then the root.*

(ii) A change of the weight of the hinge of the edge $\mathfrak{e}_v$ *by the factor* w_j *in table* j *replaces the law of* F_v *by* $w_1^{\kappa_{F_v}} \prod_j w_j^{-s_j}$ *times its image under* $(x_{j,K}, x_{j,\Psi})_j \mapsto \big((w_1/w_j)\, x_{j,K},\, w_1 w_j\, x_{j,\Psi}\big)_j$ *(Theorem 24.5(i)), for one table by* $w^{\kappa_{\mathcal{A}_v} - s}$ *times its image under* $x \mapsto w^2 x$; *nothing below* v *changes, and above* v *(i) applies along the path from* v *to* o.

(iii) A change of masses at two vertices v', v'' *keeping the total mass changes the hinge walls named in Proposition 23.18(iii), those on the edges of the path between* v' *and* v'', *and is carried through by recomputing the laws on the paths from* v' *and from* v'' *to* o.

A query about one part of a construction is answered by the part of the computation that sees it. The laws on the edges off the path are kept, and with them the work that made them; a construction with many equal subtrees, or one asked many queries about one of its nodes, pays for each subtree once and for each query along one path.

Chapter 25

Holds and the lean convolution

A table built along a hinge tree is read from the laws of its subtrees, and at a prime node the twisted core is integrated over its own simplex once for every value of the twists (Definition 23.19(4)). Holding the marks removes that integral, and with it the dependence of the reusable data on the query. Every mark of every letter of a family can be twisted, and a twist can be *held* at a load, by a Mellin transform. Twists separate any word in positive letters into its factors, its period becoming one fibre integral of the periods of the factors (Theorem 25.4), with the convergence read off the Newton sums (Theorem 25.2); the chapter opens with these words. Holding every mark separates the letters of the family completely: the hold is the product of the periods of its letters alone, the periods of its tables at their full leans, each read at its own load (Lemma 25.11). Undoing the hold writes the period at all exponents, every mass and every twist as one fibre integral of dimension $(2N-1)(n-1)$ over the splits of the masses among the letters (Theorem 25.12). The periods at the full leans of a table built along a hinge tree are the products of those of its nodes over Beta corners at its edges, with no integral at all (Theorem 26.5), so the period of a family of such tables is one fibre integral of node data (Theorem 26.13).

25.1 Newton words

Twists separate any product of powers of positive letters into its factors, and nothing in this uses the exchange property. The convergence criterion of Theorem 8.5, whose sectors rest on the greedy bases that need the exchange property (Lemma 8.3), extends to such products through the Gramma and its domain (Theorem 25.2), and on its domain the separation holds (Theorem 25.4). The holds of the next section are the case of the letters of a family (Lemma 25.11).

Definition 25.1 (Positive letters; Newton words and sums)**.** A *positive letter* on $\mathcal{E}$ is a nonzero homogeneous polynomial $L = \sum_k c_k x^{t_k}$ of degree $\deg L \geq 1$ with positive coefficients c_k on distinct exponents $t_k \in \mathbb{N}^{\mathcal{E}}$, its *support*; its Newton polytope is $\mathcal{N}_L = \operatorname{conv}\{t_k\}$, in the hyperplane $|x| = \deg L$. A *product of powers* of positive letters $W = \prod_i L_i^{-w_i}$, with exponents $w_i \in \mathbb{C}$, has the degree $D = \sum_i w_i \deg L_i$, and for masses $\mathbf{m} \in \mathbb{C}^{\mathcal{E}}$ with $m_{\mathcal{E}} = D$ its period $P_W(\mathbf{m})$ is the integral of the form $\alpha^{\mathbf{m}-\mathbf{1}} W \, d\alpha$ over a section (Lemma 16.2), wherever it converges absolutely; it does not depend on the section. It is a *Newton word* when every $w_i > 0$, with the *Newton sum* $\mathcal{N}(W) = \sum_i w_i \mathcal{N}_{L_i}$, in the hyperplane $|x| = D$. A Newton word is *split into factors* when it is written $W = W_1 \cdots W_p$, each factor a product of some of its letters with their exponents. The family word of a family is a product of powers of its letters, with $P_W(\mathbf{m}) = P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$, and a Newton word in its active letters when its exponents are nonnegative; for a table $\mathcal{N}_K = P(\mathcal{H})$ and $\mathcal{N}_\Psi = P(\mathcal{H}^*)$, and for a family $\mathcal{N}(W)$ is the Newton sum $\mathcal{N}_F$ of Theorem 8.19.

Theorem 25.2 (Convergence of a Newton word)**.** *$P_W(\mathbf{m})$ converges exactly when $\mathcal{N}(W)$ has dimension $n-1$ and $\operatorname{Re}\mathbf{m} \in \operatorname{ri}\mathcal{N}(W)$; it is then holomorphic in $\mathbf{m}$ on the balance hyperplane. For a family of tables this is the condition that every proper wall be positive (Theorems 8.7 and 8.19(iii)).*

Proposition 25.3 (One positive letter)**.** *Let $L = \sum_k c_k x^{t_k}$ be a positive letter with $\dim\mathcal{N}_L = n-1$, $\mathbf{a} \in \mathbb{C}^{\mathcal{E}}$ with $\operatorname{Re}|\mathbf{a}| > 0$, and $w = |\mathbf{a}|/\deg L$.*

(i) $P_{L^{-w}}(\mathbf{a}) = \deg L\, \mathsf{G}_{\mathbf{a};(t_k)_k}\big((c_k)_k\big)/\Gamma(w)$*, both sides converging together.*

(ii) $P_{L^{-w}}(\mathbf{a})$ *converges exactly when* $\operatorname{Re}\mathbf{a} \in (\operatorname{Re} w)\operatorname{ri}\mathcal{N}_L$*.*

(iii) For real $\mathbf{a}$ at which it converges, every $\boldsymbol{\eta} \in \mathbb{R}^{\mathcal{E}}$ with $|\boldsymbol{\eta}| = 0$ and every $\varepsilon \in (0,1)$,

$$\big|P_{L^{-w}}(\mathbf{a}+i\boldsymbol{\eta})\big| \le \min\Big(1,\ \big(\sin\tfrac{\pi\varepsilon}{2}\big)^{-w} e^{-(1-\varepsilon)h_L(\boldsymbol{\eta})}\Big)\, P_{L^{-w}}(\mathbf{a}),$$

with h_L the support function of $\{y :\ |\langle t_k, y\rangle| < \frac{\pi}{2}$ for every $k\}$, a norm on $\mathbb{R}^{\mathcal{E}}$.

Theorem 25.4 (Separation into factors)**.** *Let $W = W_1 \cdots W_p$ be split into factors with $\dim\mathcal{N}(W_i) = n-1$ for every i, of degrees D_i, and let $\mathbf{m} \in \mathbb{C}^{\mathcal{E}}$ have $m_{\mathcal{E}} = D$. Points $(\mathbf{c}_i)_i$ with $\mathbf{c}_i \in \operatorname{ri}\mathcal{N}(W_i)$ and $\sum_i \mathbf{c}_i = \operatorname{Re}\mathbf{m}$ exist exactly when $\operatorname{Re}\mathbf{m} \in \operatorname{ri}\mathcal{N}(W)$, and on each of them, for a fixed mark e_0 and all twists $\mathbf{x}_i \in (0,\infty)^{\mathcal{E}}$ of the factors,*

$$\int_{\alpha_{e_0}=1} \alpha^{\mathbf{m}-\mathbf{1}} \prod_i W_i(\mathbf{x}_i \circ \alpha)\, d\alpha' = \int_{\mathbf{a}_1+\cdots+\mathbf{a}_p=\mathbf{m},\ |\mathbf{a}_i|=D_i\ (i<p)} \ \prod_i P_{W_i}(\mathbf{a}_i)\, \mathbf{x}_i^{-\mathbf{a}_i},$$

a fibre integral of dimension $(p-1)(n-1)$, absolutely convergent, P_{W_i} the period of the factor W_i at its own masses.

Corollary 25.5 (Exponents add on one letter)**.** *For a positive letter L with $\dim\mathcal{N}_L = n-1$, exponents $w, w' > 0$ and $\operatorname{Re}\mathbf{m} \in (w+w')\operatorname{ri}\mathcal{N}_L$,*

$$P_{L^{-w-w'}}(\mathbf{m}) = \int_{\mathbf{a}+\mathbf{a}'=\mathbf{m},\ |\mathbf{a}|=w\deg L} P_{L^{-w}}(\mathbf{a})\, P_{L^{-w'}}(\mathbf{a}').$$

At $L = e_1(x) = \sum_{e\in\mathcal{E}} x_e$, $P_{L^{-w}}(\mathbf{a}) = \Gamma_1^n \begin{bmatrix}\mathbf{a}\\ w\end{bmatrix}$ and this is Theorem 4.6; for an identically self-dual table $\Psi = K$, and the lean convolution is this identity at $L = K$, $w = s$, $w' = t$, $P_{\mathcal{H}}(\mathbf{m}; s, t) = P_{\mathcal{H}}(\mathbf{m}; s+t, 0)$.

Proposition 25.6 (Simplicial letters)**.** *If the support of a positive letter L consists of n linearly independent exponents $t_1, \dots, t_n$, so that L is* simplicial*, with the configuration $t = (t_1, \dots, t_n)$, then for $\mathbf{a}$ with $|\mathbf{a}| = w\deg L$ and the shares $\mathbf{b} = t^{-1}\mathbf{a}$,*

$$P_{L^{-w}}(\mathbf{a}) = \frac{\deg L}{|\det t|}\, \Gamma_1^n \begin{bmatrix}\mathbf{b}\\ w\end{bmatrix} \prod_k c_k^{-b_k}, \qquad |\mathbf{b}| = w,$$

converging exactly when $\operatorname{Re}\mathbf{b} > 0$: the Gramma of Proposition 25.3(i) at a square configuration (Corollary 2.6). A table that is one molecule has a simplicial basis letter exactly when it has n bases.

Lemma 25.7 (Concatenation of Grammas)**.** *Let $t^{(1)}, \dots, t^{(p)}$, $p \ge 2$, be configurations on $\mathcal{E}$ with $t^{(2)}, \dots, t^{(p)}$ spanning $\mathbb{R}^{\mathcal{E}}$, $\boldsymbol{\xi}^{(1)}, \dots, \boldsymbol{\xi}^{(p)}$ coefficients, and $\mathbf{c}_i \in \operatorname{int}\operatorname{cone}(t^{(i)})$ for $i \ge 2$ with $\operatorname{Re}\nu - \sum_{i\ge 2}\mathbf{c}_i \in \operatorname{int}\operatorname{cone}(t^{(1)})$. Then*

$$\mathsf{G}_{\nu;t^{(1)}\oplus\cdots\oplus t^{(p)}}\big(\boldsymbol{\xi}^{(1)}\oplus\cdots\oplus\boldsymbol{\xi}^{(p)}\big)$$
$$=\frac{1}{(2\pi i)^{(p-1)n}}\int_{\mathbf{c}_2+i\mathbb{R}^{\mathcal{E}}}\cdots\int_{\mathbf{c}_p+i\mathbb{R}^{\mathcal{E}}}\mathsf{G}_{\nu-\sum_{i\geq 2}\mathbf{w}_i;t^{(1)}}(\boldsymbol{\xi}^{(1)})\prod_{i\geq 2}\mathsf{G}_{\mathbf{w}_i;t^{(i)}}(\boldsymbol{\xi}^{(i)})\,d\mathbf{w}_2\cdots d\mathbf{w}_p,$$

absolutely convergent: a Gramma of a concatenated configuration is the Mellin convolution of the Grammas of its parts.

For one table the concatenation $(\mathbf{1}_T)_T\oplus(\mathbf{1}_{\mathcal{E}\setminus T})_T$ with the coefficients $\boldsymbol{\theta}\oplus\lambda\boldsymbol{\theta}$ is the Gramma $\mathsf{G}_{\mathbf{m};(\mathbf{1}_T)_T\oplus(\mathbf{1}_{\mathcal{E}\setminus T})_T}(\boldsymbol{\theta}\oplus\lambda\boldsymbol{\theta})=\int x^{\mathbf{m}-\mathbf{1}}e^{-K(x)-\lambda\Psi(x)}dx$, and Lemma 25.7 writes it as $(2\pi i)^{-n}\int\mathsf{G}_{\mathbf{m}-\mathbf{b};(\mathbf{1}_T)_T}(\boldsymbol{\theta})\,\mathsf{G}_{\mathbf{b};(\mathbf{1}_{\mathcal{E}\setminus T})_T}(\boldsymbol{\theta})\,\lambda^{-|\mathbf{b}|/r^*}d\mathbf{b}$, by the torus homogeneity of $\mathsf{G}_{\mathbf{b};(\mathbf{1}_{\mathcal{E}\setminus T})_T}$. The Mellin transform in λ at t pins $|\mathbf{b}|=r^*t$, the pin contributing the factor r^*, and through Proposition 25.10(i) returns $\Gamma(s)\Gamma(t)/r$ times the lean convolution of Theorem 25.12 at $\mathbf{x}=\mathbf{1}$; Proposition 26.22 states the resulting identity $\int_0^\infty\lambda^{t-1}\mathsf{G}_{\mathbf{m};(\mathbf{1}_T)_T\oplus(\mathbf{1}_{\mathcal{E}\setminus T})_T}(\boldsymbol{\theta}\oplus\lambda\boldsymbol{\theta})\,d\lambda=\Gamma(s)\Gamma(t)P_{\mathcal{H}}(\mathbf{m};s,t)/r$. So at fixed masses the lean is the Mellin variable of the relative scale λ of the two letters, and the two-step integration separates what the masses fix, the Gramma of the concatenated configuration, from what the exponents choose, one Mellin transform in one variable.

25.2 Holds and the periods at the full leans

Definition 25.8 (Holding)**.** Let $F=((\mathcal{B}_j,\theta_j);s_j,t_j)_{j=1}^N$ be a family on $\mathcal{E}$, $n=|\mathcal{E}|\geq 2$, with exponents $s_j,t_j>0$, whose tables are each one molecule, table j of rank r_j and corank $r_j^*=n-r_j$, so that $0<r_j<n$ and the bases of every table span $\mathbb{R}^{\mathcal{E}}$: a vector orthogonal to every $\mathbf{1}_T$, $T\in\mathcal{B}_j$, is constant by Lemma 7.8, and then zero since $r_j>0$. $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ is the period (Theorem 8.7) on the balance wall $m_{\mathcal{E}}=\sum_j(r_js_j+r_j^*t_j)$, and $F[\mathbf{x}]$ is F twisted by $\mathbf{x}=(\mathbf{x}_j^K,\mathbf{x}_j^\Psi)_j$ (Definition 22.1). For $G\subseteq\mathcal{E}$, masses $\mathbf{m}$ and real loads $\boldsymbol{\beta}=(\boldsymbol{\beta}_j^K,\boldsymbol{\beta}_j^\Psi)_j$, $\boldsymbol{\beta}_j^K,\boldsymbol{\beta}_j^\Psi\in\mathbb{R}^G$, with $\boldsymbol{\beta}_1^K$ omitted, *holding the marks of G at $\boldsymbol{\beta}$* is the Mellin transform in the twists of every letter but K_1 at the marks of G, the twist of K_1 and the twists at the other marks kept at $\mathbf{1}$,

$$\mathrm{Hold}_G(\boldsymbol{\beta})=\int_{((0,\infty)^G)^{2N-1}}\prod_{j\geq 2}(\mathbf{x}_j^K)^{\boldsymbol{\beta}_j^K-\mathbf{1}}\prod_{j=1}^N(\mathbf{x}_j^\Psi)^{\boldsymbol{\beta}_j^\Psi-\mathbf{1}}\,P_{F[\mathbf{x}]}(\mathbf{m};\mathbf{s},\mathbf{t})\,d\mathbf{x},$$

in $[0,\infty]$ for real masses and loads; for complex masses or loads it is taken where it converges absolutely, that is where it is finite at the real parts.

The twists of every letter but K_1 are held. By the torus relation of Definition 22.1, a twist of every mark of one letter by one factor multiplies the period by that factor to the power $-r_js_j$, or $-r_j^*t_j$ for a cobasis letter, so that a hold of every mark is taken with one twist of each held letter fixed; and a twist of every letter by one vector $\boldsymbol{\lambda}$ multiplies the period by $\boldsymbol{\lambda}^{-\mathbf{m}}$, so that the twist of K_1 is kept at $\mathbf{1}$. A twist is a change of weights: Proposition 26.20 carries product weights on the bases into twists.

Definition 25.9 (Loads; admissible points)**.** For a split of the masses among the letters of F, $\mathbf{m}=\sum_j(\mathbf{a}_j+\mathbf{b}_j)$, $\mathbf{a}_j$ is the *K_j-load* and $\mathbf{b}_j$ the *Ψ_j-load*, as a K-share of a pattern loads its marks and a Ψ-share the marks it leaves out (Definition 12.24); for one table, $\mathbf{m}=\mathbf{a}+\mathbf{b}$ with the K-load $\mathbf{a}$ and the Ψ-load $\mathbf{b}$. The periods of a table $\mathcal{H}$ of F, with the weights $\boldsymbol{\theta}$, of rank r and corank r^*, at its two full leans are read as functions of their loads, $P_{\mathcal{H}}(\mathbf{a};|\mathbf{a}|/r,0)$ and $P_{\mathcal{H}}(\mathbf{b};0,|\mathbf{b}|/r^*)$, the

exponent of the one active letter being the total load divided by its degree. Its letters give the Grammas (Definition 2.1)

$$\mathsf{G}_{\mathbf{a};(\mathbf{1}_T)_{T\in\mathcal{H}}}(\boldsymbol{\theta})=\int_{\mathbb{R}^{\mathcal{E}}_{>0}} x^{\mathbf{a}-\mathbf{1}}e^{-K_{\mathcal{H}}(x)}dx,\qquad \mathsf{G}_{\mathbf{b};(\mathbf{1}_{\mathcal{E}\setminus T})_{T\in\mathcal{H}}}(\boldsymbol{\theta})=\int_{\mathbb{R}^{\mathcal{E}}_{>0}} x^{\mathbf{b}-\mathbf{1}}e^{-\Psi_{\mathcal{H}}(x)}dx.$$

A real load $\mathbf{a}$ with $|\mathbf{a}|=rs$, $s>0$, is *admissible for the full basis lean* when $\mathbf{a}\in s\cdot\operatorname{ri}P(\mathcal{H})$, $P(\mathcal{H})$ the base polytope of $\mathcal{H}$ (Theorem 7.18) and ri the relative interior, and a real $\mathbf{b}$ with $|\mathbf{b}|=r^*t$, $t>0$, is *admissible for the full cobasis lean* when $\mathbf{b}\in t\cdot\operatorname{ri}P(\mathcal{H}^*)$, $P(\mathcal{H}^*)$ the base polytope of the dual table. A real point $\mathbf{c}=(\mathbf{c}_j^K,\mathbf{c}_j^\Psi)_j$ is *admissible* for $(\mathbf{m};\mathbf{s},\mathbf{t})$ when $\sum_j(\mathbf{c}_j^K+\mathbf{c}_j^\Psi)=\operatorname{Re}\mathbf{m}$, every $\mathbf{c}_j^K$ is admissible for the full basis lean of table j at s_j and every $\mathbf{c}_j^\Psi$ for its full cobasis lean at t_j; for one table it is named by its Ψ-load $\mathbf{c}=\mathbf{c}_1^\Psi$, with $\operatorname{Re}\mathbf{m}-\mathbf{c}$ admissible for the full basis lean and $\mathbf{c}$ for the full cobasis lean.

Proposition 25.10 (The periods at the two full leans)**.** *In (i), (ii) and (iv) $\mathcal{H}$ is a table of F, with the weights $\boldsymbol{\theta}$, of rank r and corank r^*.*

(i) For $\mathbf{a}\in\mathbb{C}^{\mathcal{E}}$ with $\operatorname{Re}|\mathbf{a}|>0$ and $s=|\mathbf{a}|/r$, $P_{\mathcal{H}}(\mathbf{a};s,0)=r\,\mathsf{G}_{\mathbf{a};(\mathbf{1}_T)_T}(\boldsymbol{\theta})/\Gamma(s)$, both sides converging together; likewise $P_{\mathcal{H}}(\mathbf{b};0,t)=r^*\mathsf{G}_{\mathbf{b};(\mathbf{1}_{\mathcal{E}\setminus T})_T}(\boldsymbol{\theta})/\Gamma(t)$ with $t=|\mathbf{b}|/r^*$. By Cremona, $P_{\mathcal{H}}(\mathbf{b};0,t)=P_{\mathcal{H}}(t\mathbf{1}-\mathbf{b};t,0)$.

(ii) $P_{\mathcal{H}}(\mathbf{a};s,0)$ converges exactly when $\operatorname{Re}a_S>(\operatorname{Re}s)\,d(S)$ for every nonempty proper S, which for real $s>0$ is $\operatorname{Re}\mathbf{a}\in s\cdot\operatorname{ri}P(\mathcal{H})$; $P_{\mathcal{H}}(\mathbf{b};0,t)$ converges exactly when $\operatorname{Re}b_S>(\operatorname{Re}t)\,d^*(S)$ for every nonempty proper S, which for real $t>0$ is $\operatorname{Re}\mathbf{b}\in t\cdot\operatorname{ri}P(\mathcal{H}^*)$.

(iii) At every gauge α the occupation $R_j(\alpha)$ of table j lies in $\operatorname{ri}P(\mathcal{B}_j)$ and its dual occupation $R_j^*(\alpha)$ in $\operatorname{ri}P(\mathcal{B}_j^*)$ (Theorem 7.16). At a native gauge $\alpha^\star$ of real masses $\mathbf{m}$ on the balance wall (Definition 8.17), which exists when every proper wall is positive, the native loads *$\mathbf{a}_j^\star=s_jR_j(\alpha^\star)$ and $\mathbf{b}_j^\star=t_jR_j^*(\alpha^\star)$ are a split of $\mathbf{m}$ among the letters of F, and $\mathbf{c}=(\mathbf{a}_j^\star,\mathbf{b}_j^\star)_j$ is admissible.*

(iv) On a vertical line the periods at the full leans decay exponentially: for admissible real $\mathbf{a}$, every $\mathbf{y}\in\mathbb{R}^{\mathcal{E}}$ with $|\mathbf{y}|=0$ and every $\varepsilon\in(0,1)$,

$$\big|P_{\mathcal{H}}(\mathbf{a}+i\mathbf{y};s,0)\big|\le\min\Big(1,\ \big(\sin\tfrac{\pi\varepsilon}{2}\big)^{-s}e^{-(1-\varepsilon)h(\mathbf{y})}\Big)\,P_{\mathcal{H}}(\mathbf{a};s,0),$$

with h the support function of the set $\{y:\ |\langle\mathbf{1}_T,y\rangle|<\frac{\pi}{2}$ for every basis $T\}$, a norm on $\mathbb{R}^{\mathcal{E}}$; likewise at the full cobasis lean with the vectors $\mathbf{1}_{\mathcal{E}\setminus T}$.

Items (i), (ii) and (iv) hold for every positive letter with a Newton polytope of dimension $n-1$, in the form of Proposition 25.3.

Lemma 25.11 (Holding every mark separates the letters)**.** *Fix $e_0\in\mathcal{E}$ and let $\mathbf{m}\in\mathbb{C}^{\mathcal{E}}$ have $m_{\mathcal{E}}=\sum_j(r_js_j+r_j^*t_j)$. For real loads $\boldsymbol{\beta}=(\boldsymbol{\beta}_j^K,\boldsymbol{\beta}_j^\Psi)_j$ on $\mathcal{E}\setminus e_0$, $\boldsymbol{\beta}_1^K$ omitted, let $\mathbf{a}_j$ ($j\ge2$) extend $\boldsymbol{\beta}_j^K$ by $a_{j,e_0}=r_js_j-|\boldsymbol{\beta}_j^K|$, let $\mathbf{b}_j$ extend $\boldsymbol{\beta}_j^\Psi$ by $b_{j,e_0}=r_j^*t_j-|\boldsymbol{\beta}_j^\Psi|$, and put $\mathbf{a}_1=\mathbf{m}-\sum_{j\ge2}\mathbf{a}_j-\sum_j\mathbf{b}_j$. Then, in $[0,\infty]$ for real $\mathbf{m}$,*

$$\operatorname{Hold}_{\mathcal{E}\setminus e_0}(\boldsymbol{\beta})=\prod_{j=1}^{N}P_{\mathcal{B}_j}(\mathbf{a}_j;s_j,0)\,P_{\mathcal{B}_j}(\mathbf{b}_j;0,t_j),$$

the twists at e_0 being 1; for complex $\mathbf{m}$ and complex $\boldsymbol{\beta}$ the same holds whenever the integral converges at the real parts.

The lemma is the whole mechanism. Every letter but K_1 sees its own twists and K_1 sees none; a Mellin transform in all of them at once absorbs every mark of each twisted letter into its own load, and what is left of K_1 is its own period at the remaining load. Nothing is integrated against anything: the hold is a product.

25.3 The lean convolution

Theorem 25.12 (The lean convolution)**.** *Let $\mathbf{m} \in \mathbb{C}^{\mathcal{E}}$ have $m_{\mathcal{E}} = \sum_j (r_j s_j + r_j^* t_j)$.*

(i) Admissible points for $(\mathbf{m}; \mathbf{s}, \mathbf{t})$ exist exactly when every proper wall of $\operatorname{Re}\mathbf{m}$ is positive; they form a convex set, and for real $\mathbf{m}$ the native loads (Proposition 25.10(iii)) are one of them.

(ii) On every admissible point and for every twist $\mathbf{x} = (\mathbf{x}_j^K, \mathbf{x}_j^\Psi)_j$ (Definition 22.1),

$$P_{F[\mathbf{x}]}(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \int_{\substack{\sum_j (\mathbf{a}_j + \mathbf{b}_j) = \mathbf{m} \\ |\mathbf{a}_j| = r_j s_j \ (j \geq 2),\ |\mathbf{b}_j| = r_j^* t_j}} \prod_{j=1}^{N} P_{\mathcal{B}_j}(\mathbf{a}_j; s_j, 0)\, P_{\mathcal{B}_j}(\mathbf{b}_j; 0, t_j)\, (\mathbf{x}_j^K)^{-\mathbf{a}_j} (\mathbf{x}_j^\Psi)^{-\mathbf{b}_j},$$

the fibre integral of Definition 4.1, of dimension $(2N-1)(n-1)$, absolutely convergent; in the coordinates of the loads of every letter but K_1 at the marks other than a fixed mark e_0 it is $(2\pi i)^{-(2N-1)(n-1)} \int \cdots$ over the imaginary translate through the admissible point, the loads at e_0 and $\mathbf{a}_1$ being fixed by the pins. At $\mathbf{x} = \mathbf{1}$ it is the period.

(iii) The modulus of the integrand is at most its value at the real point,

$$\prod_j P_{\mathcal{B}_j}(\mathbf{c}_j^K; s_j, 0)\, P_{\mathcal{B}_j}(\mathbf{c}_j^\Psi; 0, t_j)\, (\mathbf{x}_j^K)^{-\mathbf{c}_j^K} (\mathbf{x}_j^\Psi)^{-\mathbf{c}_j^\Psi},$$

and it decays exponentially in the imaginary part of the load of every letter but K_1, at the rate of Proposition 25.10(iv) for its table.

With exponents $s_j, t_j \geq 0$, not all zero, the same holds over the active letters, p of them, any one of them in the place of K_1, in dimension $(p-1)(n-1)$.

For one table, at $\mathcal{H} = \binom{\{1,2\}}{1}$ the lean convolution is Corollary 4.7, and at the circuit $\binom{\mathcal{E}}{n-1}$ it is Corollary 18.24, the periods at the full leans being those of Proposition 26.9. Opening each of them on its share side (Proposition 4.2) gives the atom formula of Corollary 18.16, one share per basis and letter: the atom formula opens every letter over its bases and every mass over the letters at once, while the lean convolution keeps each letter closed, read at its full lean, and opens only the split of each mass among the letters.

Corollary 25.13 (What a family retains)**.** *The Grammas $\mathsf{G}_{\mathbf{a};(\mathbf{1}_T)_{T \in \mathcal{B}_j}}(\boldsymbol{\theta}_j)$, $j = 1, \ldots, N$, each one function of the n variables $\mathbf{a}$, determine every period of F and of all its twists: at all exponents $s_j, t_j \geq 0$, not all zero, at all masses on the balance wall with every proper wall positive, and at every twist. At the exponents $(\mathbf{s}, \mathbf{t})$ only the values of the Gramma of table j on the hyperplanes $|\mathbf{a}| = r_j s_j$ and $|t_j \mathbf{1} - \mathbf{b}| = r_j t_j$ enter, through $P_{\mathcal{B}_j}(\mathbf{a}; s_j, 0) = r_j\, \mathsf{G}_{\mathbf{a};(\mathbf{1}_T)_T}(\boldsymbol{\theta}_j)/\Gamma(s_j)$ and $P_{\mathcal{B}_j}(\mathbf{b}; 0, t_j) = r_j\, \mathsf{G}_{t_j \mathbf{1} - \mathbf{b};(\mathbf{1}_T)_T}(\boldsymbol{\theta}_j)/\Gamma(t_j)$. Conversely the periods of table j at its full basis leans determine its Gramma, through Proposition 25.10(i).*

A cell of a hinge tree retains, for one pair of exponents, one measure on the half-line (Theorem 23.11); a family retains, for all exponents and all masses at once, one function of the loads for each of its tables. The two retentions serve different queries; Lemma 25.16 relates them, and Section 26.6 compares them.

25.4 Holding some marks

Theorem 25.14 (Pinned holds)**.** *Let every proper wall of* $\operatorname{Re}\mathbf{m}$ *be positive,* e_0 *a fixed mark,* $\varnothing \neq G \subseteq \mathcal{E}\setminus e_0$*, and* $\boldsymbol{\beta}=(\boldsymbol{\beta}_j^K,\boldsymbol{\beta}_j^\Psi)_j$*,* $\boldsymbol{\beta}_1^K$ *omitted, the restriction to* G *of the loads of an admissible point. Then for every real* $\boldsymbol{\eta}=(\boldsymbol{\eta}_j^K,\boldsymbol{\eta}_j^\Psi)_j$ *of the same shape the hold* $\operatorname{Hold}_G(\boldsymbol{\beta}+i\boldsymbol{\eta})$ *converges absolutely and equals the fibre integral of Theorem 25.12(ii) at* $\mathbf{x}=\mathbf{1}$ *with the* $(2N-1)|G|$ *further pins* $\mathbf{a}_j|_G=\boldsymbol{\beta}_j^K+i\boldsymbol{\eta}_j^K$ *(*$j\geq 2$*) and* $\mathbf{b}_j|_G=\boldsymbol{\beta}_j^\Psi+i\boldsymbol{\eta}_j^\Psi$*,*

$$\operatorname{Hold}_G(\boldsymbol{\beta}+i\boldsymbol{\eta})=\int_{\sum_j(\mathbf{a}_j+\mathbf{b}_j)=\mathbf{m},\ |\mathbf{a}_j|=r_js_j\ (j\geq 2),\ |\mathbf{b}_j|=r_j^*t_j,\ \text{the pins on } G}\ \prod_{j=1}^{N}P_{\mathcal{B}_j}(\mathbf{a}_j;s_j,0)\,P_{\mathcal{B}_j}(\mathbf{b}_j;0,t_j),$$

of dimension $(2N-1)(n-1-|G|)$*, in the coordinates of the loads of every letter but* K_1 *at the marks off* $G\cup e_0$ *the integral* $(2\pi i)^{-(2N-1)(n-1-|G|)}\int\cdots$*. At* $G=\mathcal{E}\setminus e_0$ *it is Lemma 25.11.*

For one mark the hold has a closed form in the minors at that mark. For a mark g that is neither a loop nor a coloop of any table, the patterns of the bunch $\{g\}$ in table j are $\varnothing$ and $\{g\}$, with the children the deletion $\mathcal{B}_j\setminus g$, of rank r_j and corank r_j^*-1, and the contraction $\mathcal{B}_j/g$, of rank r_j-1 and corank r_j^* (Definition 12.1). For K-loads a_j and Ψ-loads b_j at g the children family of $\{g\}$ (Definition 12.24) at the K-shares (s_j-a_j,a_j) and the Ψ-shares (b_j,t_j-b_j) of the patterns $\varnothing$ and $\{g\}$ is

$$F_{\{g\}}\big((s_j-a_j,a_j),(b_j,t_j-b_j)\big)_j=\Big(\big((\mathcal{B}_j\setminus g,\theta_j);\ s_j-a_j,\ b_j\big),\ \big((\mathcal{B}_j/g,\theta_j);\ a_j,\ t_j-b_j\big)\Big)_j,$$

a family of $2N$ tables on $\mathcal{E}\setminus g$ whose word is $\prod_j K_{j\setminus g}^{a_j-s_j}\Psi_{j\setminus g}^{-b_j}K_{j/g}^{-a_j}\Psi_{j/g}^{b_j-t_j}$. At masses $\mathbf{m}|_{\mathcal{E}\setminus g}$ with $\sum_j(a_j+b_j)=m_g$ it is on its balance wall: its degree is $\sum_j\big((s_j-a_j)r_j+b_j(r_j^*-1)+a_j(r_j-1)+(t_j-b_j)r_j^*\big)=\sum_j(r_js_j+r_j^*t_j)-m_g$.

Proposition 25.15 (Holding one mark)**.** *Let* g *be a mark that is neither a loop nor a coloop of any table,* $\mathbf{m}$ *real masses on the balance wall,* a_j *(*$j\geq 2$*) and* b_j *(*$j\leq N$*) real, and* $a_1=m_g-\sum_{j\geq 2}a_j-\sum_j b_j$*. The hold*

$$\operatorname{Hold}_{\{g\}}\big((a_j)_{j\geq 2},(b_j)_j\big)=\int_{(0,\infty)^{2N-1}}\prod_{j\geq 2}(x_j^K)^{a_j-1}\prod_{j=1}^{N}(x_j^\Psi)^{b_j-1}\,P_{F[\mathbf{x}@g]}(\mathbf{m};\mathbf{s},\mathbf{t})\,d\mathbf{x},\qquad x_1^K=1,$$

is finite exactly when $0<a_j<s_j$ *and* $0<b_j<t_j$ *for every* j *and every proper wall of* $F_{\{g\}}\big((s_j-a_j,a_j),(b_j,t_j-b_j)\big)_j$ *at* $\mathbf{m}|_{\mathcal{E}\setminus g}$ *is positive, and then*

$$\operatorname{Hold}_{\{g\}}\big((a_j)_{j\geq 2},(b_j)_j\big)=\prod_{j=1}^{N}\Gamma_1^2\begin{bmatrix}a_j,\ s_j-a_j\\ s_j\end{bmatrix}\Gamma_1^2\begin{bmatrix}b_j,\ t_j-b_j\\ t_j\end{bmatrix}\,P_{F_{\{g\}}((s_j-a_j,a_j),(b_j,t_j-b_j))_j}\big(\mathbf{m}|_{\mathcal{E}\setminus g}\big);$$

the identity holds as well for complex loads and complex masses whose real parts are such data. Where the loads are those at g *of an admissible point, Theorem 25.14 writes the same value as the lean convolution with the pins at* g*. If* $m_g>0$*, then for every letter of* F *whose exponent* u *exceeds* m_g*, as the twists at* g *of all the other letters decrease to* 0*, the twist of that letter staying* 1*,* $P_{F[\mathbf{x}@g]}(\mathbf{m};\mathbf{s},\mathbf{t})$ *increases, in* $(0,\infty]$*, to* $\Gamma_1^2\begin{bmatrix}m_g,\ u-m_g\\ u\end{bmatrix}$ *times the period at* $\mathbf{m}|_{\mathcal{E}\setminus g}$ *of the children family of* $\{g\}$ *at the shares that put the whole mass* m_g *on that letter:* (s_j-m_g,m_g) *if it is* K_j*,* (m_g,t_j-m_g) *if it is* Ψ_j*,* $(s_{j'},0)$ *for every other letter* $K_{j'}$ *and* $(0,t_{j'})$ *for every other letter* $\Psi_{j'}$*.*

The ends of the twist are the faces of the children family at which every letter but one has the mark g switched off: the chosen letter keeps both its minors and every other letter keeps one. For one table the two limits are those of $P_{\mathcal{H}[x@g]}$ as $x \downarrow 0$ and of $x^{m_g} P_{\mathcal{H}[x@g]}$ as $x \uparrow \infty$ (Definition 22.1), and a weight on a mark driven to one end of its range leaves the deletion and the contraction of the mark, two tables carrying three active letters between them. With Proposition 26.20 and Definition 22.1, a weight w on the bases through g is the twist w^{-2} up to the factor w^{-m_g-t}, so the period behaves like w^{-m_g-t} times the first limit as $w \to \infty$ and like w^{m_g-t} times the second as $w \to 0$, where these are finite.

Lemma 25.16 (The Mellin transform of a law is the period of a children family)**.** *Let $F = ((\mathcal{A}_j, \theta_j); s_j, t_j)_{j=1}^N$ be a cell family on $B \sqcup \{g\}$ with masses $\mathbf{m}$ on B, hinge wall κ_F, base form ϕ_F and ratio vector $\boldsymbol{\varrho}_F$ (Definition 23.1). In this statement let $\mathbf{z} = (z_{j,K}, z_{j,\Psi})_j$ have $\sum_j (z_{j,K} + z_{j,\Psi}) = \kappa_F$, and write $\boldsymbol{\varrho}_F^{-\mathbf{z}} = \prod_{j \geq 2} \left(\gamma^K_{\mathcal{A}_j} / \gamma^K_{\mathcal{A}_1}\right)^{-z_{j,K}} \prod_j \left(\gamma^\Psi_{\mathcal{A}_j} / \gamma^K_{\mathcal{A}_1}\right)^{-z_{j,\Psi}}$, the coordinates of the ratio vector to the powers $-z_{j,K}$ $(j \geq 2)$ and $-z_{j,\Psi}$. For real $\mathbf{z}$, in $[0, \infty]$,*

$$\int_{\Delta_B} \boldsymbol{\varrho}_F^{-\mathbf{z}} \, d\phi_F = P_{F_{\{g\}}((z_{j,K},\, s_j - z_{j,K}),(t_j - z_{j,\Psi},\, z_{j,\Psi}))_j}(\mathbf{m}),$$

the period of the children family of the bunch $\{g\}$ of F (Definition 12.24), its tables $\mathcal{A}_j \setminus g$ at the exponents $(z_{j,K}, t_j - z_{j,\Psi})$ and $\mathcal{A}_j / g$ at $(s_j - z_{j,K}, z_{j,\Psi})$, on its balance wall at $\mathbf{m}$. Let moreover $s_j, t_j > 0$, and put the mass $\sum_j (s_j + t_j) - \kappa_F$ on g, which puts the family of the tables $\mathcal{A}_j$ on its balance wall. For complex $\mathbf{z}$ whose real part has $0 < \operatorname{Re} z_{j,K} < s_j$ and $0 < \operatorname{Re} z_{j,\Psi} < t_j$ for every j and is a point at which $\int \boldsymbol{\varrho}_F^{-\operatorname{Re}\mathbf{z}} d\phi_F$ is finite,

$$\int_{(0,\infty)^{2N-1}} \prod_{j \geq 2} (x_j^K)^{s_j - z_{j,K} - 1} \prod_{j=1}^N (x_j^\Psi)^{t_j - z_{j,\Psi} - 1} \, P_{F[\mathbf{x}@g]}\Big(\big(\mathbf{m}, \textstyle\sum_j (s_j + t_j) - \kappa_F\big); \mathbf{s}, \mathbf{t}\Big) \, d\mathbf{x}$$
$$= \prod_{j=1}^N \Gamma_{\binom{2}{1}}\begin{bmatrix} s_j - z_{j,K}, & z_{j,K} \\ & s_j \end{bmatrix} \Gamma_{\binom{2}{1}}\begin{bmatrix} t_j - z_{j,\Psi}, & z_{j,\Psi} \\ & t_j \end{bmatrix} \int_{\Delta_B} \boldsymbol{\varrho}_F^{-\mathbf{z}} \, d\phi_F,$$

$F[\mathbf{x}@g]$ the family of the tables $\mathcal{A}_j$ twisted at g, $x_1^K = 1$ (Definition 22.1). So the Mellin transform of the law of a cell family is the Mellin transform of its own period in the twists of its hinge, divided by $2N$ Beta corners.

Corollary 25.17 (Identically self-dual tables twisted at one mark)**.** *Let the family be one table $\mathcal{H}$ at the exponents (s, t), identically self-dual (Corollary 23.12(iii)), g a mark, and $\mathbf{m}$ on the balance wall with every proper wall positive. For every $x > 0$,*

$$P_{\mathcal{H}[x@g]}(\mathbf{m}; s, t) = P_{\mathcal{H}\setminus g}\big(\mathbf{m}|_{\mathcal{E}\setminus g};\ s + t - m_g,\ m_g\big) \, P_{\binom{\{g,g'\}}{1}[(x,1)]}\big((m_g, s + t - m_g); s, t\big),$$

the second factor the period $\int_0^\infty v^{m_g - 1}(1 + v)^{-s}(1 + xv)^{-t} dv$ of the twisted list on two marks (Lemma 23.7); and the hold at g is $\Gamma_{\binom{2}{1}}\begin{bmatrix} m_g - b, & s - m_g + b \\ & s \end{bmatrix} \Gamma_{\binom{2}{1}}\begin{bmatrix} b, & t - b \\ & t \end{bmatrix}$ times the same period of $\mathcal{H} \setminus g$ for every b in its strip: the children family does not depend on the split. At $x = 1$ this is Corollary 23.12(iii), and Corollary 4.7 recovers it from the hold,

$$\frac{1}{2\pi i} \int \Gamma_{\binom{2}{1}}\begin{bmatrix} m_g - b, & s - m_g + b \\ & s \end{bmatrix} \Gamma_{\binom{2}{1}}\begin{bmatrix} b, & t - b \\ & t \end{bmatrix} db = \Gamma_{\binom{2}{1}}\begin{bmatrix} m_g, & s + t - m_g \\ & s + t \end{bmatrix}.$$

Chapter 26

Periods at the full leans and networks along a hinge tree

At a full lean the period of a two-sum is the product of the periods of its two cells over one Beta corner (Theorem 19.10), and along any hinge tree this is Corollary 26.11, which for one table at a full lean is Theorem 26.5 at the loads $\mathbf{m}$. Along a hinge tree this needs only bookkeeping, and the bookkeeping is affine: every marker receives a load that is a fixed affine function of the loads of the marks, the same function at every pair of exponents. So the periods of a substitution at its full leans are products of those of its nodes, read at affine loads, over Beta corners at its edges, with no integral. Where the active letters read every cell by one hinge value, the period along a hinge tree is the product of the periods of the nodes over Beta corners at the edges: at a full lean of a table whose weights factor at its bunches of width one, a product of stacked Gammas, monomials in the weights and the periods of the prime nodes of its canonical hinge tree, and k copies glued along any tree cost one period and a power. Blocks aggregate exactly where every active letter reads them by one hinge value, their total or the inverse of the sum of the reciprocals of their marks (Theorem 26.12). The nodes whose periods at the full leans cost nothing are characterized by counting bases. The period of a family of such tables, at all exponents, every mass and every twist, is then one fibre integral of node data, of dimension $(2N-1)(n-1)$: the lean convolution of Chapter 25 with the periods of every letter at its full lean read along the hinge tree of its table (Theorem 26.13).

26.1 Molecules and marker loads

Lemma 26.1 (Substitutions of molecules)**.** *For a core $\mathcal{H}$ and cells $\mathcal{A}_1, \dots, \mathcal{A}_q$ at its marks (Definition 21.1), the substitution $\mathcal{H}\langle \mathcal{A}_1, \dots, \mathcal{A}_q \rangle$ is one molecule exactly when $\mathcal{H}$ and the $\mathcal{A}_i$, as tables on their marks and hinges, are each one molecule. In particular the two-sum $\mathcal{A} \oplus_g \mathcal{A}'$ of two cells is one molecule exactly when $\mathcal{A}$ and $\mathcal{A}'$ are.*

So a substitution of nodes that are molecules is one molecule, and a table with every proper wall positive, which is one molecule by Proposition 8.16, has every cell of its hinge trees one molecule.

Definition 26.2 (Branches of a hinge tree)**.** Let $\mathcal{B}$ be a table on $\mathcal{E}$, $|\mathcal{E}| = n$, of rank r and corank r^*, with a hinge tree $\mathfrak{T}$ (Definition 23.15) whose nodes $\mathcal{H}_v$ on $\mathcal{E}_v \sqcup G_v$ are each one molecule, of rank r_v and corank $r_v^* = |\mathcal{E}_v| + |G_v| - r_v$; the weights of $\mathcal{B}$ are the products of the weights of the nodes (Lemma 21.12). For an edge $\mathfrak{e} = \{v, w\}$ of $\mathfrak{T}$ and its end v, the *branch* $\mathfrak{T}_v^{\mathfrak{e}}$ is the component

of $\mathfrak{T}-\mathfrak{e}$ containing v, $\mathcal{E}_v^{\mathfrak{e}}$ the union of the $\mathcal{E}_u$ over its vertices, and $\mathcal{A}_v^{\mathfrak{e}}$ the substitution of its nodes, a cell on $\mathcal{E}_v^{\mathfrak{e}} \sqcup \{g_{v,\mathfrak{e}}\}$ of rank $r_v^{\mathfrak{e}}$ and corank $r_v^{*\mathfrak{e}} = |\mathcal{E}_v^{\mathfrak{e}}| + 1 - r_v^{\mathfrak{e}}$; $\mathcal{B}$ is the two-sum of $\mathcal{A}_v^{\mathfrak{e}}$ and $\mathcal{A}_w^{\mathfrak{e}}$.

Definition 26.3 (Marker loads; node loads)**.** For a table with a hinge tree as in Definition 26.2 and loads $\mathbf{a}, \mathbf{b} \in \mathbb{C}^{\mathcal{E}}$ with $|\mathbf{a}| = rs$ and $|\mathbf{b}| = r^*t$, the *marker loads* at the end v of the edge $\mathfrak{e}$ are

$$k_{v,\mathfrak{e}} = s\, r_v^{\mathfrak{e}} - a_{\mathcal{E}_v^{\mathfrak{e}}}, \qquad l_{v,\mathfrak{e}} = t\, r_v^{*\mathfrak{e}} - b_{\mathcal{E}_v^{\mathfrak{e}}},$$

and the *node loads* of v are $\mathbf{a}_v = \big(\mathbf{a}|_{\mathcal{E}_v}, (k_{v,\mathfrak{e}})_{\mathfrak{e}\ni v}\big)$ and $\mathbf{b}_v = \big(\mathbf{b}|_{\mathcal{E}_v}, (l_{v,\mathfrak{e}})_{\mathfrak{e}\ni v}\big)$, the load of the marker $g_{v,\mathfrak{e}}$ being $k_{v,\mathfrak{e}}$, respectively $l_{v,\mathfrak{e}}$.

Lemma 26.4 (Node loads)**.** *In Definition 26.3:*

(i) $k_{v,\mathfrak{e}} + k_{w,\mathfrak{e}} = s$ *and* $l_{v,\mathfrak{e}} + l_{w,\mathfrak{e}} = t$ *on every edge.*

(ii) $|\mathbf{a}_v| = r_v s$ *and* $|\mathbf{b}_v| = r_v^* t$ *at every node.*

(iii) If $\mathbf{a}+\mathbf{b} = \mathbf{m}$ *with* $\mathbf{m}$ *on the balance wall of* $\mathcal{B}$*, then* $k_{v,\mathfrak{e}} + l_{v,\mathfrak{e}} = s + t - \kappa_{\mathcal{A}_v^{\mathfrak{e}}} = \kappa_{\mathcal{A}_w^{\mathfrak{e}}}$*: the node masses* $\mathbf{a}_v + \mathbf{b}_v$ *are* $\mathbf{m}|_{\mathcal{E}_v}$ *on the marks and the hinge walls of the branches on the markers, the masses of the twisted core in Theorem 23.6.*

26.2 The periods of a substitution at its full leans

Theorem 26.5 (Periods at the full leans along a hinge tree)**.** *In Definition 26.3, for real loads* $\mathbf{a}$ *with* $|\mathbf{a}| = rs$*, if every marker load* $k_{v,\mathfrak{e}}$ *lies in* $(0, s)$*, then, in* $(0, \infty]$*,*

$$P_{\mathcal{B}}(\mathbf{a}; s, 0) = \frac{\prod_v P_{\mathcal{H}_v}(\mathbf{a}_v; s, 0)}{\prod_{\mathfrak{e}=\{v,w\}} \Gamma_2^{\,1}\!\begin{bmatrix} k_{v,\mathfrak{e}}, & k_{w,\mathfrak{e}} \\ & s \end{bmatrix}},$$

and if some marker load lies outside $(0, s)$*, then* $P_{\mathcal{B}}(\mathbf{a}; s, 0) = +\infty$*. So* $P_{\mathcal{B}}(\mathbf{a}; s, 0)$ *is finite exactly when every marker load lies in* $(0, s)$ *and the period of every node at its full basis lean is finite at its node loads. The same holds at the full cobasis leans, with* $\mathbf{b}$*, the loads* $l_{v,\mathfrak{e}}$ *and* t*. For complex loads both identities hold on the tube over the real loads at which they are finite, both sides being holomorphic there.*

In the language of bunches this is Theorem 19.10 at every bunch of width one of the tree at once: the bunch $\mathcal{E}_v^{\mathfrak{e}}$ has, at $(s, 0)$, the wall $k_{w,\mathfrak{e}}$, and its two cells are $\mathcal{A}_v^{\mathfrak{e}}$ and $\mathcal{A}_w^{\mathfrak{e}}$ (Lemma 21.12). What the tree adds is that the loads of all markers are affine in the loads of the marks, fixed once for every pair of exponents, so that the periods of the substitution at its full leans are evaluated at any loads by evaluating each node once.

Corollary 26.6 (Convergence is decided at the nodes)**.** *Let* $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$ *have exponents* $s_j, t_j > 0$*, and let table* j *carry a hinge tree* $\mathfrak{T}_j$ *as in Definition 26.2, its nodes* $\mathcal{H}_{j,v}$ *on* $\mathcal{E}_{j,v} \sqcup G_{j,v}$ *each one molecule, with the node loads of Definition 26.3 read in table* j*. For masses* $\mathbf{m}$ *on the balance wall of* F *every proper wall of* F *is positive exactly when there is a real split* $\mathbf{m} = \sum_j (\mathbf{a}_j + \mathbf{b}_j)$ *with* $|\mathbf{a}_j| = r_j s_j$ *and* $|\mathbf{b}_j| = r_j^* t_j$ *at which every node of every table has*

$$(\mathbf{a}_{j,v})_S > s_j\, d_{j,v}(S) \quad \text{and} \quad (\mathbf{b}_{j,v})_S > t_j\, d_{j,v}^*(S) \qquad (\varnothing \neq S \subsetneq \mathcal{E}_{j,v} \sqcup G_{j,v}),$$

$d_{j,v}$ and $d_{j,v}^*$ the counts of $\mathcal{H}_{j,v}$. This is a system of $\sum_j \sum_v 2(2^{|\mathcal{E}_{j,v}|+|G_{j,v}|} - 2)$ *strict linear inequalities in* $(2N-1)(n-1)$ *unknowns, a number linear in the number of nodes when the nodes have bounded size, against the* $2^n - 2$ *walls of* F*; the native loads of* F *solve it.*

26.3 What a node costs

Lemma 26.7 (Bases outnumber marks)**.** *A table on $n \geq 2$ marks that is one molecule has at least n bases, and exactly n only when its rank is 1 or $n-1$, that is, as a list, when it is $\binom{\mathcal{E}}{1}$ or $\binom{\mathcal{E}}{n-1}$.*

Corollary 26.8 (The cost of a node)**.** *For a node $\mathcal{H}_v$ that is one molecule on $n_v = |\mathcal{E}_v| + |G_v|$ marks with $|\mathcal{H}_v|$ bases, the share side of its period at each of its two full leans (Proposition 4.2) is a fibre integral of dimension $|\mathcal{H}_v| - n_v \geq 0$. The dimension is zero exactly when $\mathcal{H}_v$ has the bases of $\binom{\mathcal{E}_v \sqcup G_v}{n_v - 1}$ or of $\binom{\mathcal{E}_v \sqcup G_v}{1}$, with any weights: the series and the parallel nodes up to their weights, whose periods at the full leans are stacked Gammas times monomials in the weights (Proposition 25.6; Proposition 26.9, next); a prime node on at least four marks has $|\mathcal{H}_v| > n_v$.*

Proposition 26.9 (Series and parallel nodes at their full leans)**.** *On a set $\mathcal{X}$ of $q+1$ marks let $\binom{\mathcal{X}}{q}$ carry the weight θ_e on its basis $\mathcal{X} \setminus e$ and $\binom{\mathcal{X}}{1}$ the weight θ_e on its basis $\{e\}$, the series and the parallel node with weights (Definition 23.13). Then*

$$P_{\binom{\mathcal{X}}{q}}(\mathbf{a}; s, 0) = \Gamma_{\substack{q+1\\1}}\begin{bmatrix}(s-a_e)_e\\ s\end{bmatrix}\prod_e \theta_e^{a_e - s}, \qquad P_{\binom{\mathcal{X}}{q}}(\mathbf{b}; 0, t) = \Gamma_{\substack{q+1\\1}}\begin{bmatrix}(b_e)_e\\ t\end{bmatrix}\prod_e \theta_e^{-b_e},$$

$$P_{\binom{\mathcal{X}}{1}}(\mathbf{a}; s, 0) = \Gamma_{\substack{q+1\\1}}\begin{bmatrix}(a_e)_e\\ s\end{bmatrix}\prod_e \theta_e^{-a_e}, \qquad P_{\binom{\mathcal{X}}{1}}(\mathbf{b}; 0, t) = \Gamma_{\substack{q+1\\1}}\begin{bmatrix}(t-b_e)_e\\ t\end{bmatrix}\prod_e \theta_e^{b_e - t},$$

with $|\mathbf{a}| = qs$, $|\mathbf{b}| = t$ at the series node and $|\mathbf{a}| = s$, $|\mathbf{b}| = qt$ at the parallel node; each converges exactly when every Gamma above has an argument of positive real part. These are Proposition 25.6 at the configurations $(\mathbf{e}_x)_{x\in\mathcal{X}}$, of the letters K of $\binom{\mathcal{X}}{1}$ and Ψ of $\binom{\mathcal{X}}{q}$, and $(\mathbf{1} - \mathbf{e}_x)_{x\in\mathcal{X}}$, of the letters K of $\binom{\mathcal{X}}{q}$ and Ψ of $\binom{\mathcal{X}}{1}$.

Corollary 26.10 (Series-parallel tables at their full leans)**.** *In Definition 26.2 let every node of $\mathfrak{T}$ be a series or a parallel node (Definition 23.13), the node v on $\mathcal{E}_v \sqcup G_v$ carrying the weight $\theta_{v,x}$ on its basis that omits x if it is a series node and on its basis $\{x\}$ if it is a parallel node, and write $(\mathbf{a}_v)_x$ and $(\mathbf{b}_v)_x$ for the node loads at $x \in \mathcal{E}_v \sqcup G_v$ (Definition 26.3). Then*

$$P_{\mathcal{B}}(\mathbf{a}; s, 0) = \frac{1}{\Gamma(s)} \prod_{e \text{ at series}} \Gamma(s - a_e) \prod_{e \text{ at parallel}} \Gamma(a_e) \prod_{\mathfrak{e} \text{ series–parallel}} \frac{\Gamma(s - k_{\mathfrak{e}})}{\Gamma(k_{\mathfrak{e}})}$$
$$\times \prod_{v \text{ series}} \prod_x \theta_{v,x}^{(\mathbf{a}_v)_x - s} \prod_{v \text{ parallel}} \prod_x \theta_{v,x}^{-(\mathbf{a}_v)_x},$$

$$P_{\mathcal{B}}(\mathbf{b}; 0, t) = \frac{1}{\Gamma(t)} \prod_{e \text{ at series}} \Gamma(b_e) \prod_{e \text{ at parallel}} \Gamma(t - b_e) \prod_{\mathfrak{e} \text{ series–parallel}} \frac{\Gamma(l_{\mathfrak{e}})}{\Gamma(t - l_{\mathfrak{e}})}$$
$$\times \prod_{v \text{ series}} \prod_x \theta_{v,x}^{-(\mathbf{b}_v)_x} \prod_{v \text{ parallel}} \prod_x \theta_{v,x}^{(\mathbf{b}_v)_x - t},$$

the products over the marks by the kind of their node, over the edges joining a series node to a parallel node, with $k_{\mathfrak{e}}$, $l_{\mathfrak{e}}$ the marker loads at the series end, and over the nodes and their marks and markers x; an edge joining two nodes of one kind contributes no Gamma. Each of these periods is finite exactly when every Gamma above its line has an argument with positive real part.

The period of a series-parallel table at a full lean is written down from its tree in time linear in the size of the tree, one Gamma for each mark, two for each change of kind along an edge and a monomial in the weights of each node, while the table may have a number of bases exponential in n. The atom formula of the same period (Corollary 18.16) has one share for each basis.

Corollary 26.11 (Periods along a hinge tree read by one hinge value)**.** *Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^{N}$ have real data on its balance wall with every proper wall positive, let its tables have a common hinge tree $\mathfrak{T}$ rooted at o, with the node families $F_{\mathcal{H}_v}$ (Definition 23.15), and let the active letters read every subtree cell by one hinge value: for every $v \neq o$ there is a function γ_v with $\gamma^{K}_{\mathcal{A}_{v,j}} = \gamma_v$ whenever $s_j \neq 0$ and $\gamma^{\Psi}_{\mathcal{A}_{v,j}} = \gamma_v$ whenever $t_j \neq 0$. With σ the total strength (Definition 8.1),*

$$P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \frac{\prod_v P_{F_{\mathcal{H}_v}}(\mathbf{m}_v; \mathbf{s}, \mathbf{t})}{\prod_{edges\ \mathfrak{e}} \Gamma_{\begin{smallmatrix}2\\1\end{smallmatrix}}\!\left[\begin{smallmatrix}\kappa_{\mathfrak{e}}, & 2\sigma - \kappa_{\mathfrak{e}}\\ & 2\sigma\end{smallmatrix}\right]},$$

each node family on its balance wall with every proper wall positive, its masses $\mathbf{m}_v$ those of its marks and, on the marker at an end of the edge $\mathfrak{e}$, the wall of the marks across $\mathfrak{e}$: $\kappa_{\mathfrak{e}}$ on one side and $2\sigma - \kappa_{\mathfrak{e}}$ on the other. For one table at a full lean, $(0, t)$ or $(s, 0)$, one letter is active, the hypothesis holds on every hinge tree, and this is Theorem 26.5 at the loads $\mathbf{m}$. With the canonical hinge tree of a connected table whose weights factor across each bunch of width one at which it is decomposed, a list or a determinantal table for instance (Theorem 23.16), a series or a parallel node, with any weights on its bases, contributes at a full lean a stacked Gamma times a monomial in its weights (Proposition 26.9), so the period at a full lean of such a table is a product of stacked Gammas, monomials in the weights and the periods of its prime nodes. In particular connected tables $\mathcal{A}_1, \ldots, \mathcal{A}_k$ at $(0, t)$, each on its balance wall with every proper wall positive, glued along any tree, every gluing joining a mark of mass $\kappa_{\mathfrak{e}}$ of one to a mark of mass $t - \kappa_{\mathfrak{e}}$ of another, have the period

$$\frac{\prod_v P_{\mathcal{A}_v}(\mathbf{m}_v; 0, t)}{\prod_{\mathfrak{e}} \Gamma_{\begin{smallmatrix}2\\1\end{smallmatrix}}\!\left[\begin{smallmatrix}\kappa_{\mathfrak{e}}, & t - \kappa_{\mathfrak{e}}\\ & t\end{smallmatrix}\right]},$$

whatever the shape of the tree; for k copies of one table glued at the masses $(\kappa, t - \kappa)$ this is $\Gamma_{\begin{smallmatrix}2\\1\end{smallmatrix}}\!\left[\begin{smallmatrix}\kappa, & t - \kappa\\ & t\end{smallmatrix}\right] \big(P_{\mathcal{A}}(\mathbf{m}; 0, t)/\Gamma_{\begin{smallmatrix}2\\1\end{smallmatrix}}\!\left[\begin{smallmatrix}\kappa, & t - \kappa\\ & t\end{smallmatrix}\right]\big)^{k}$. On the chain $F^{\triangleright k}$ of Theorem 22.8, with every proper wall positive and the active letters reading each copy by one hinge value, the product is $P_F^k/\Gamma_{\begin{smallmatrix}2\\1\end{smallmatrix}}\!\left[\begin{smallmatrix}m_{g_{\mathrm{in}}}, & m_{g_{\mathrm{out}}}\\ & 2\sigma\end{smallmatrix}\right]^{k-1}$, the display of that theorem.

Where the active letters read every cell through one hinge value, as at a full lean of one table, where only one letter sees a hinge, Ψ at $(0, t)$ and K at $(s, 0)$, every cell is pinned, every hinge integral is the Beta corner of a linear letter (Proposition 15.1 with one coefficient), and the period of the whole construction is the product of the periods of its nodes over the Beta corners of its hinges. Nothing is integrated against anything.

26.4 Blocks aggregate

Theorem 26.12 (Blocks read by one hinge value aggregate exactly)**.** *Let F be a family substituted with blocks (Corollary 21.7(i)) into the tables $\mathcal{H}_j$ of a core family $F_{\mathcal{H}} = ((\mathcal{H}_j, \theta^{\mathcal{H}_j}); s_j, t_j)_j$, with unit weights in the blocks, the block B_i of ℓ_i marks. The active letters read B_i* through its total *when every table with $s_j \neq 0$ has a parallel block and every table with $t_j \neq 0$ a series block at B_i, and through $e_{\ell_i}/e_{\ell_i - 1} = \big(\sum_{x \in B_i} \alpha_x^{-1}\big)^{-1}$ when every table with $s_j \neq 0$ has a series block and every table with $t_j \neq 0$ a parallel block (Corollary 21.7(i)). Let $U \sim \mathrm{Dir}_{\mathbf{m}}$ (Definition 3.10), with the block totals $|U_{B_i}|$.*

(i) If the active letters read every block through its total, the joint law of all the active letters, $\big(K_j(U)\big)_{s_j\neq 0}$ and $\big(\Psi_j(U)\big)_{t_j\neq 0}$, with the totals $(|U_{B_i}|)_i$ themselves, is that of $\big(K_{\mathcal{H}_j}(U')\big)_{s_j\neq 0}$, $\big(\Psi_{\mathcal{H}_j}(U')\big)_{t_j\neq 0}$ and U' for $U'\sim \mathrm{Dir}_{(m_{B_i})_i}$: every nonnegative function of these variables, and every absolutely integrable one, has the same expectation on both sides.

(ii) Let the active letters read B_i through its total for $i\in I$ and through e_{ℓ_i}/e_{ℓ_i-1} for $i\notin I$, and let σ be the total strength (Definition 8.1). The wall of a block is $\kappa_{B_i}=m_{B_i}$ for $i\in I$ and $\kappa_{B_i}=m_{B_i}-(\ell_i-1)\,2\sigma$ for $i\notin I$, and on the balance wall, in $[0,\infty]$,

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t})=\prod_{i\in I}\Gamma_{\substack{\ell_i\\1}}\begin{bmatrix}\mathbf{m}|_{B_i}\\ m_{B_i}\end{bmatrix}\prod_{i\notin I}\Gamma_{\substack{\ell_i\\1}}\begin{bmatrix}(2\sigma-m_x)_{x\in B_i}\\ 2\sigma-\kappa_{B_i}\end{bmatrix}\;P_{F_{\mathcal{H}}}\big((\kappa_{B_i})_i;\mathbf{s},\mathbf{t}\big),$$

a stacked Gamma read as $+\infty$ when one of its upper arguments is not positive; both sides are finite together when these are positive.

(iii) If the active letters read every block through its total, then at fixed pooled masses m_{B_i}, dividing each among any number of marks leaves the expectation $\mathbb{E}_{U\sim\mathrm{Dir}_{\mathbf{m}}}[W(U)]$ of the family word unchanged and multiplies the period by the stacked Gammas $\Gamma_{\substack{|B_i|\\1}}\begin{bmatrix}\mathbf{m}|_{B_i}\\ m_{B_i}\end{bmatrix}$ alone: lengthening the blocks creates no new integral.

A block read through its total by some active letters and through $e_\ell/e_{\ell-1}$ by others keeps the block as one mark of Theorem 22.3, with its kernel and its hinge values.

26.5 The network theorem

The lean convolution of a family of substitutions, the periods of its letters at their full leans written along the hinge trees of its tables, is one fibre integral whose integrand is a product of node data at affine loads. Read as one integral over all the loads, it has dimension $(2N-1)(n-1)$ for every family whose tables carry hinge trees, and for series-parallel tables its integrand is a written-down stacked Gamma times an exponential of the loads. Integrated from the leaves up, when the tables share one hinge tree, the same integral is computed node by node with one rule at every node, prime or not (Theorem 26.16): a node enters through the periods of its tables at their full leans and its cell families through the Mellin transforms of their laws; for one table this is the hinge tree procedure of Chapter 23.

Theorem 26.13 (The network)**.** *Let $F=((\mathcal{B}_j,\theta_j);s_j,t_j)_{j=1}^N$ be a family on $\mathcal{E}$ with exponents $s_j,t_j>0$ whose table j carries a hinge tree $\mathfrak{T}_j$ as in Definition 26.2, its nodes $\mathcal{H}_{j,v}$ each one molecule, and let $\mathbf{m}$ be on the balance wall of F with every proper wall positive. Then every table is one molecule, and on every admissible point (Definition 25.9) and for every twist $\mathbf{x}$ (Definition 22.1),*

$$P_{F[\mathbf{x}]}(\mathbf{m};\mathbf{s},\mathbf{t})=\int\prod_{j=1}^{N}\frac{\prod_{v\in\mathfrak{T}_j}P_{\mathcal{H}_{j,v}}(\mathbf{a}_{j,v};s_j,0)\,P_{\mathcal{H}_{j,v}}(\mathbf{b}_{j,v};0,t_j)}{\prod_{\mathfrak{e}=\{v,w\}\in\mathfrak{T}_j}\Gamma_{\substack{2\\1}}\begin{bmatrix}k_{j;v,\mathfrak{e}},\;k_{j;w,\mathfrak{e}}\\ s_j\end{bmatrix}\Gamma_{\substack{2\\1}}\begin{bmatrix}l_{j;v,\mathfrak{e}},\;l_{j;w,\mathfrak{e}}\\ t_j\end{bmatrix}}\;(\mathbf{x}_j^K)^{-\mathbf{a}_j}(\mathbf{x}_j^\Psi)^{-\mathbf{b}_j},$$

the fibre integral of Theorem 25.12 over the loads $(\mathbf{a}_j,\mathbf{b}_j)_j$ of the marks, of dimension $(2N-1)(n-1)$, with the node loads $\mathbf{a}_{j,v},\mathbf{b}_{j,v}$ and the marker loads $k_{j;v,\mathfrak{e}},l_{j;v,\mathfrak{e}}$ of Definition 26.3 read in table j at its loads $(\mathbf{a}_j,\mathbf{b}_j)$ and its exponents (s_j,t_j). At every admissible point the periods of every node at both full leans are finite and every marker load of table j lies in $(0,s_j)$, respectively $(0,t_j)$;

the native loads of F are an admissible point. The nodes enter only through their periods at the two full leans, as functions of their loads, the same functions for all exponents, all masses and all twists.

Corollary 26.14 (Series-parallel periods)**.** *In Theorem 26.13 let every node of every table be a series or a parallel node with the weights of Corollary 26.10, $\theta_{j,v,x}$ at the node v of $\mathfrak{T}_j$. Then*

$$\prod_j \Gamma(s_j)\Gamma(t_j)\, P_{F[\mathbf{x}]}(\mathbf{m};\mathbf{s},\mathbf{t}) = \int \prod_j \Bigg[\prod_{e \text{ at series}} \Gamma(s_j - a_{j,e})\Gamma(b_{j,e}) \prod_{e \text{ at parallel}} \Gamma(a_{j,e})\Gamma(t_j - b_{j,e}) \times \prod_{\mathfrak{e} \text{ series–parallel}} \frac{\Gamma(s_j - k_{j,\mathfrak{e}})\,\Gamma(l_{j,\mathfrak{e}})}{\Gamma(k_{j,\mathfrak{e}})\,\Gamma(t_j - l_{j,\mathfrak{e}})} \prod_{v \text{ series}} \prod_x \theta_{j,v,x}^{(\mathbf{a}_{j,v})_x - (\mathbf{b}_{j,v})_x - s_j} \times \prod_{v \text{ parallel}} \prod_x \theta_{j,v,x}^{(\mathbf{b}_{j,v})_x - (\mathbf{a}_{j,v})_x - t_j} \, (\mathbf{x}_j^K)^{-\mathbf{a}_j} (\mathbf{x}_j^\Psi)^{-\mathbf{b}_j} \Bigg],$$

the kinds of the nodes and the marker loads $k_{j,\mathfrak{e}}$, $l_{j,\mathfrak{e}}$ at the series end read in $\mathfrak{T}_j$, the fibre integral of Theorem 26.13, of dimension $(2N-1)(n-1)$, on any point at which every Gamma above the line has an argument of positive real part. Every period of a family of series-parallel tables with any weights on their nodes, at all exponents, at all masses with positive walls and at every twist, is a fibre integral of dimension $(2N-1)(n-1)$ of an explicit stacked Gamma times an exponential of the loads, whatever the numbers of bases, and at a full lean of one table no integral is left (Corollary 26.10).

Proposition 26.15 (Pooling a pair)**.** *In Corollary 26.14, for one table twisted in its cobasis letter by $\mathbf{x}$ (Definition 22.1), let e, f be two marks of one series node v whose twists times the squares of their weights agree, $x_e\theta_{v,e}^2 = x_f\theta_{v,f}^2$, and $c_e = s - m_e$, $c_f = s - m_f$. Their loads enter the integrand through $\Gamma(c_e + b_e)\Gamma(b_e)\Gamma(c_f + b_f)\Gamma(b_f)$ and otherwise through $b_{\{e,f\}} = b_e + b_f$ alone, and at fixed $b_{\{e,f\}}$*

$$\frac{1}{2\pi i} \int \Gamma(c_e + b_e)\Gamma(b_e)\Gamma\big(c_f + b_{\{e,f\}} - b_e\big)\Gamma\big(b_{\{e,f\}} - b_e\big)\, db_e = \Gamma_{\,1}^{\,4}\!\left[\begin{matrix} c_e + c_f + b_{\{e,f\}},\ c_e + b_{\{e,f\}},\ c_f + b_{\{e,f\}},\ b_{\{e,f\}} \\ c_e + c_f + 2b_{\{e,f\}} \end{matrix}\right].$$

For two marks of one parallel node v with $x_e\theta_{v,e}^{-2} = x_f\theta_{v,f}^{-2}$, at fixed $b_{\{e,f\}}$, the pair gives

$$\Gamma_{\,1}^{\,4}\!\left[\begin{matrix} m_e + m_f - b_{\{e,f\}},\ m_e + t - b_{\{e,f\}},\ m_f + t - b_{\{e,f\}},\ 2t - b_{\{e,f\}} \\ m_e + m_f + 2t - 2b_{\{e,f\}} \end{matrix}\right].$$

Each pooled pair lowers the dimension of the fibre by one, and disjoint pairs can be pooled at once.

The pooled pair is a series pair read as one cell: its factor is $\Gamma_{\,1}^{\,2}\left[\begin{matrix} c_e + b_{\{e,f\}},\ c_f + b_{\{e,f\}} \\ c_e + c_f + 2b_{\{e,f\}} \end{matrix}\right] \Gamma(c_e + c_f + b_{\{e,f\}})\Gamma(b_{\{e,f\}})$, the Beta corner being the Mellin transform of the law of the pair at $b_{\{e,f\}}$ and the two Gammas those of its hinge in the periods of the node at its full leans (Theorem 26.16). A series bunch of three or more marks at one node can be pooled pair by pair only once: the pooled factor of a pair is no longer of the form $\Gamma(c+b)\Gamma(b)$, and the class is a circuit of its marks (Corollary 18.24).

26.6 Nodes in hold form

Theorem 26.16 (Nodes in hold form)**.** *Let F be a substituted family (Definition 21.1) whose tables are each one molecule, with exponents $s_j, t_j > 0$, table j being $\mathcal{H}_j\langle \mathcal{A}_{1j}, \dots, \mathcal{A}_{kj}\rangle$ with the cores $\mathcal{H}_j$ on $\mathcal{E}_{\mathcal{H}} \sqcup G_{\mathcal{H}}$ and the cells $\mathcal{A}_{ij}$ on $B_i \sqcup \{g_i\}$ at the markers $g_1, \dots, g_k$ (Definition 23.4), and let $F_i = ((\mathcal{A}_{ij}, \theta^{\mathcal{A}_{ij}}); s_j, t_j)_j$ be the cell family at g_i (Definition 23.1). For loads $(\mathbf{a}_j, \mathbf{b}_j)_j$ on the marks and markers of the cores write $\mathbf{z}_i = (a_{j,g_i}, b_{j,g_i})_j$ for their values at g_i, and in this statement write $\int \boldsymbol{\varrho}_{F_i}^{-\mathbf{z}_i} d\phi_{F_i}$ for the Mellin transform of the law of F_i of Lemma 25.16 at $\mathbf{z}_i$.*

(i) Root. *If $G_{\mathcal{H}} = \{g_1, \dots, g_k\}$ and F is on its balance wall with every proper wall positive, let $\mathcal{F}$ be the fibre of the loads of the cores with the pins $\sum_j (\mathbf{a}_j + \mathbf{b}_j) = (\mathbf{m}|_{\mathcal{E}_{\mathcal{H}}}, \kappa_{F_1}, \dots, \kappa_{F_k})$, $|\mathbf{a}_j| = r_{\mathcal{H}_j} s_j$ $(j \geq 2)$ and $|\mathbf{b}_j| = r^*_{\mathcal{H}_j} t_j$. On the node loads at the cores (Definition 26.3, in every table) of any admissible point of F and for twists $\mathbf{x}$ of F with every coordinate 1 off $\mathcal{E}_{\mathcal{H}}$,*

$$P_{F[\mathbf{x}]}(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \int_{\mathcal{F}} \prod_{j=1}^{N} P_{\mathcal{H}_j}(\mathbf{a}_j; s_j, 0)\, P_{\mathcal{H}_j}(\mathbf{b}_j; 0, t_j)\, (\mathbf{x}_j^K)^{-\mathbf{a}_j|_{\mathcal{E}_{\mathcal{H}}}} (\mathbf{x}_j^{\Psi})^{-\mathbf{b}_j|_{\mathcal{E}_{\mathcal{H}}}} \prod_{i=1}^{k} \int \boldsymbol{\varrho}_{F_i}^{-\mathbf{z}_i}\, d\phi_{F_i},$$

of dimension $(2N-1)(|\mathcal{E}_{\mathcal{H}}| + k - 1)$, every $\int \boldsymbol{\varrho}_{F_i}^{-\mathbf{z}_i} d\phi_{F_i}$ finite at the real point.

(ii) Hinged core. *If $G_{\mathcal{H}} = \{g_0, g_1, \dots, g_k\}$, let F' be the cell family with the hinge g_0 whose table j is $\mathcal{H}_j\langle \mathcal{A}_{1j}, \dots, \mathcal{A}_{kj}\rangle$, with the hinge wall $\kappa_{F'}$, and for $\mathbf{z} = (z_{j,K}, z_{j,\Psi})_j$ with $\sum_j (z_{j,K} + z_{j,\Psi}) = \kappa_{F'}$ let $\mathcal{F}_{\mathbf{z}}$ be the fibre of the loads of the cores with the pins $\sum_j (\mathbf{a}_j + \mathbf{b}_j) = \big(\mathbf{m}|_{\mathcal{E}_{\mathcal{H}}}, \kappa_{F_1}, \dots, \kappa_{F_k}, \sum_j (s_j + t_j) - \kappa_{F'}\big)$, $|\mathbf{a}_j| = r_{\mathcal{H}_j} s_j$ $(j \geq 2)$, $|\mathbf{b}_j| = r^*_{\mathcal{H}_j} t_j$, $a_{j,g_0} = s_j - z_{j,K}$ $(j \geq 2)$ and $b_{j,g_0} = t_j - z_{j,\Psi}$. For $\mathbf{z}$ whose real part is $(s_j - c^K_{j,g_0}, t_j - c^{\Psi}_{j,g_0})_j$, $\mathbf{c}$ the node loads at the cores of an admissible point of the family of the tables of F' with the mass $\sum_j (s_j + t_j) - \kappa_{F'}$ on g_0,*

$$\prod_{j=1}^{N} \Gamma_1^2 \begin{bmatrix} s_j - z_{j,K}, & z_{j,K} \\ & s_j \end{bmatrix} \Gamma_1^2 \begin{bmatrix} t_j - z_{j,\Psi}, & z_{j,\Psi} \\ & t_j \end{bmatrix} \int \boldsymbol{\varrho}_{F'}^{-\mathbf{z}}\, d\phi_{F'}$$
$$= \int_{\mathcal{F}_{\mathbf{z}}} \prod_{j=1}^{N} P_{\mathcal{H}_j}(\mathbf{a}_j; s_j, 0)\, P_{\mathcal{H}_j}(\mathbf{b}_j; 0, t_j) \prod_{i=1}^{k} \int \boldsymbol{\varrho}_{F_i}^{-\mathbf{z}_i}\, d\phi_{F_i},$$

of dimension $(2N-1)(|\mathcal{E}_{\mathcal{H}}| + k - 1)$.

The cores and the cells are molecules by Lemma 26.1.

Corollary 26.17 (The glue and the series and parallel rules in hold form)**.** *On the lines of Theorem 26.16:*

(i) For one table with $\mathcal{H} = \binom{\{g_1, g_2\}}{1}$ and the cells $\mathcal{A}$ and $\mathcal{A}'$, Theorem 26.16(i) is the integral of Theorem 23.9(iv), with the same integrand; for a family with the core $\binom{\{g_1, g_2\}}{1}$ in every table it is the integral of Theorem 19.13 over the scale shares.

(ii) For one table and a series node $\binom{G}{q}$, Theorem 26.16(ii) reads

$$\Gamma(z)\Gamma(z + s - \kappa_{\mathcal{A}}) \int \varrho_{\mathcal{A}}^{-z} d\phi_{\mathcal{A}} = \int_{z_1 + \dots + z_q = z} \prod_{i=1}^{q} \Gamma(z_i)\Gamma(z_i + s - \kappa_{\mathcal{A}_i}) \int \varrho_{\mathcal{A}_i}^{-z_i} d\phi_{\mathcal{A}_i},$$

the Mellin transform of $f_{\mathcal{A}}$ as the Mellin convolution of those of the $f_{\mathcal{A}_i}$ (Proposition 23.8(iii)): the Mellin transform, on these lines, of the product rule $f_{\mathcal{A}} = \prod_i f_{\mathcal{A}_i}$ of Theorem 23.14(i).

(iii) For one table and a parallel node $\binom{G}{1}$ *it reads, with* $z' = \kappa_{\mathcal{A}} - z$ *and* $z'_i = \kappa_{\mathcal{A}_i} - z_i$,

$$\Gamma(z')\Gamma(z' + t - \kappa_{\mathcal{A}}) \int \varrho_{\mathcal{A}}^{z' - \kappa_{\mathcal{A}}} d\phi_{\mathcal{A}} = \int_{z'_1 + \cdots + z'_q = z'} \prod_{i=1}^{q} \Gamma(z'_i)\Gamma(z'_i + t - \kappa_{\mathcal{A}_i}) \int \varrho_{\mathcal{A}_i}^{z'_i - \kappa_{\mathcal{A}_i}} d\phi_{\mathcal{A}_i},$$

the Mellin convolution of the transforms of the $\check{f}_{\mathcal{A}_i}$*: the Mellin transform, on these lines, of the product rule* $\check{f}_{\mathcal{A}} = \prod_i \check{f}_{\mathcal{A}_i}$ *of Theorem 23.14(ii).*

So the three rules of the hinge tree procedure, the glue and the series and parallel products (Definition 23.19), are one rule read at three nodes, on the lines that the network certifies, the rules themselves holding on their own wider ranges; and the same rule applies at a prime node, where the procedure integrates the twisted core over its simplex for every value of the twists (Definition 23.19(4)). In Theorem 26.16 the prime node enters through the periods of its tables at their full leans, functions of its loads that do not depend on the twists, on the exponents or on the masses, and the cell families enter through the Mellin transforms of their laws on imaginary translates, for one table the representation (b) of Definition 23.19; Theorem 26.16(i) is Theorem 23.6(i) with the twisted core replaced by its lean convolution and the integration against the laws carried out through Mellin transforms.

26.7 The procedure and its cost

Definition 26.18 (The network procedure)**.** *Given*: a hinge tree of every table of a family (Definition 23.15) with the weights and the marks of its nodes; exponents $s_j, t_j > 0$ and masses $\mathbf{m}$ on the balance wall, or several of each; optionally twists $\mathbf{x}$, or product weights (Proposition 26.20 below). *Reusable data*: for every orbit of nodes, over all the tables, under bijections keeping the table and its weights, the Gramma $\mathsf{G}_{\mathbf{a};(\mathbf{1}_T)_T}(\boldsymbol{\theta})$ of its table, a function of the loads alone (Corollary 25.13), kept as (a) the closed form at series and parallel nodes (Proposition 26.9); (b) the share side, a fibre integral of dimension $|\mathcal{H}_v| - n_v$ (Corollary 26.8); (c) for an identically self-dual node, the reduction to the deletion of one mark (Corollaries 23.12(iii) and 25.17); (d) values on the imaginary translates in use. *Operations*:

(1) *Contour.* Find a split satisfying the node inequalities of Corollary 26.6, a linear feasibility problem with $\sum_j \sum_v 2(2^{|\mathcal{E}_{j,v}|+|G_{j,v}|} - 2)$ strict inequalities in $(2N-1)(n-1)$ unknowns; the native loads solve it, and infeasibility proves divergence.

(2) *Assemble.* The node loads of every table by Definition 26.3, the integrand of Theorem 26.13, at series-parallel nodes that of Corollary 26.14, with $\prod_j (\mathbf{x}_j^K)^{-\mathbf{a}_j} (\mathbf{x}_j^\Psi)^{-\mathbf{b}_j}$ for twists.

(3) *Pool*, for one table, disjoint pairs of marks of one series or parallel node whose twists and weights satisfy the condition of Proposition 26.15, by that proposition.

(4) *Integrate* the remaining loads on the contour; in the imaginary parts the integrand is analytic on a strip about the contour, the admissible points forming an open set, and decays exponentially there (Theorem 25.12(iii)), so the trapezoidal rule with step ς has an error of the order $e^{-2\pi d/\varsigma}$, d the half-width of the strip; or close contours on lattices (Theorem 4.5).

(5) *Recursive Mellin evaluation*, an alternative to (2) to (4) when the hinge trees of the tables are one rooted tree with the same marks $\mathcal{E}_v$ at every vertex, so that at every vertex v other than the root the subtree cells of the tables (Definition 23.15) form a cell family, the *subtree cell family* of v (Definition 23.1): from the leaves up, compute the Mellin transform of the law of each orbit of subtree cell families on an imaginary translate by Theorem 26.16(ii),

one fibre integral of dimension $(2N-1)(|\mathcal{E}_v|+|G_v|-2)$ per point, and finish at the root by Theorem 26.16(i); for one table, at series and parallel nodes with repeated subtrees, equal and with equal masses, pass to the transforms, where repetition is a power (Proposition 23.18(ii)).

Output: the period, and with the same reusable data the period at other exponents, masses and twists (Proposition 26.21 below).

Proposition 26.19 (What the network costs)**.** *In Definition 26.18:*

(i) The fibre of the loads in (1)–(4) has dimension $(2N-1)(n-1)$, for one table less one for each pooled pair; opening every prime node on the share sides of the periods of its table at the two full leans adds $2(|\mathcal{H}_{j,v}|-n_{j,v})$ for each, and series and parallel nodes add nothing. The dimension does not depend on the numbers $|\mathcal{B}_j|$ of bases of the tables, against $\sum_j 2|\mathcal{B}_j|-2N-n+1$ for the atom formula (Corollary 18.16) and $\sum_j|\mathcal{B}_j|-n+1$ after its even shares close (Theorem 20.11(iv)).

(ii) The reusable data are one function of n_v variables per orbit of nodes, the same for every node of the orbit, in every table, and for every query; a value of the period of a node at a full lean at given loads, once computed, serves every node of the orbit and every query at which those loads occur.

(iii) In the recursive Mellin evaluation the work is one Mellin transform on an imaginary translate for each orbit of subtree cell families (as in Proposition 23.18(i)), each point costing one fibre integral of dimension $(2N-1)(|\mathcal{E}_v|+|G_v|-2)$ at its top node, and at the root one of dimension $(2N-1)(|\mathcal{E}_o|+|G_o|-1)$, whose integrand needs the periods of the tables of the node at their full leans, at the loads of the fibre: closed forms at series and parallel nodes, and at a prime node an integral of its own, of dimension $|\mathcal{H}_{j,v}|-n_v$ on its share side, unless another representation of Definition 26.18 is cheaper.

In the recursive Mellin evaluation equal subtrees at a series node enter as a power of one transform (Theorems 23.14(i) and 23.9(ii)), whose growth in the number of copies Theorem 24.2 reads when the subtree is series-balanced.

26.8 Changing the query in hold form

A query about a period is a choice of exponents, of masses, of weights and of the kind of answer asked for. In the hold form each of them enters at one place: exponents and masses move the pins and the affine marker loads, twists and product weights multiply the integrand by an exponential of the loads, and a replaced node, or a general change of the weights of one node, replaces that node's two functions and nothing else. Product weights are read as twists, and the exponents at fixed masses as the Mellin variables of the relative scales of the letters.

Proposition 26.20 (Product weights are twists)**.** *For a family F on $\mathcal{E}$ and $\boldsymbol{\zeta}=(\boldsymbol{\zeta}_j)_j$, $\boldsymbol{\zeta}_j\in(0,\infty)^{\mathcal{E}}$, let $F^{\boldsymbol{\zeta}}$ be F with the weights $\theta_{j,T}\boldsymbol{\zeta}_j^T$ in table j. Then $K_{F^{\boldsymbol{\zeta}},j}(\alpha)=K_j(\boldsymbol{\zeta}_j\circ\alpha)$ and $\Psi_{F^{\boldsymbol{\zeta}},j}(\alpha)=\boldsymbol{\zeta}_j^{\mathcal{E}}\Psi_j(\alpha/\boldsymbol{\zeta}_j)$: $F^{\boldsymbol{\zeta}}$ has the letters of the twist $F[\mathbf{x}]$ with $\mathbf{x}_j^K=\boldsymbol{\zeta}_j$ and $\mathbf{x}_j^\Psi=\boldsymbol{\zeta}_j^{-1}$ (Definition 22.1), its cobasis letters multiplied by the constants $\boldsymbol{\zeta}_j^{\mathcal{E}}$, and*

$$P_{F^{\boldsymbol{\zeta}}}(\mathbf{m};\mathbf{s},\mathbf{t})=\prod_j\boldsymbol{\zeta}_j^{-t_j\mathbf{1}}\,P_{F[\mathbf{x}]}(\mathbf{m};\mathbf{s},\mathbf{t}),$$

$$P_{\mathcal{B}_j^{\boldsymbol{\zeta}_j}}(\mathbf{a};s_j,0)=\boldsymbol{\zeta}_j^{-\mathbf{a}}P_{\mathcal{B}_j}(\mathbf{a};s_j,0),\qquad P_{\mathcal{B}_j^{\boldsymbol{\zeta}_j}}(\mathbf{b};0,t_j)=\boldsymbol{\zeta}_j^{\mathbf{b}-t_j\mathbf{1}}P_{\mathcal{B}_j}(\mathbf{b};0,t_j),$$

so that the lean convolution of $F^{\boldsymbol{\zeta}}$ is that of F with the exponential $\prod_j \boldsymbol{\zeta}_j^{-t_j\mathbf{1}}\boldsymbol{\zeta}_j^{\mathbf{b}_j-\mathbf{a}_j}$ of the loads. With one $\boldsymbol{\zeta}$ for every table, $P_{F^{\boldsymbol{\zeta}}}(\mathbf{m};\mathbf{s},\mathbf{t}) = \boldsymbol{\zeta}^{-\mathbf{m}-|\mathbf{t}|\mathbf{1}}P_{F[\mathbf{x}']}(\mathbf{m};\mathbf{s},\mathbf{t})$, $\mathbf{x}'$ the twist of every cobasis letter by $\boldsymbol{\zeta}^{-2}$ and $|\mathbf{t}| = \sum_j t_j$. Weights $\zeta_{j,g}$ on the bases through one mark g, in each table j, are the twist at g with $x_j^K = \zeta_{j,g}$ and $x_j^\Psi = \zeta_{j,g}^{-1}$, up to the factor $\prod_j \zeta_{j,g}^{-t_j}$: the weight of a hinge of Theorem 24.5, at any mark.

Proposition 26.21 (Carrying a calculation through a change, in hold form)**.** *In Theorem 26.13, with its node data computed:*

(i) a change of the exponents (s_j, t_j) changes the pins $|\mathbf{a}_j| = r_j s_j$, $|\mathbf{b}_j| = r_j^* t_j$ and the marker loads of table j, which are affine in (s_j, t_j), and nothing else; the native loads of the new data are a new contour;

(ii) a change of the masses changes the load $\mathbf{a}_1 = \mathbf{m} - \sum_{j\geq 2}\mathbf{a}_j - \sum_j \mathbf{b}_j$ in the coordinates of Theorem 25.12(ii), and through it the marker loads $k_{1;v,\mathfrak{e}}$ of table 1, and in the integrand nothing else; in (i) and (ii) the contour must move when the old one is no longer admissible;

(iii) a change of twists, or of product weights on the bases of the tables, multiplies the integrand by an exponential of the loads (Proposition 26.20); product weights on the bases of one node multiply its periods at the two full leans by exponentials of its node loads;

(iv) replacing a node of a table by another table on the same marks and markers, of the same rank, one molecule with its markers neither loops nor coloops, or changing the weights of a node in any way, replaces the periods of that node at its two full leans and nothing else;

(v) in the recursive Mellin evaluation (Definition 26.18(5)), a change at one node changes the Mellin transforms of the laws of the subtree cell families on the path from it to the root only, each recomputed by Theorem 26.16(ii) from the new one of the vertex directly below it on the path and the kept ones of the other vertices directly below it, as Proposition 24.6 says of laws.

The reusable data of Chapter 23, the laws of the subtrees, depend on the exponents and on the masses below each edge (Theorem 23.17(iii)); the reusable data of the network do not, and a sweep over exponents, over masses, over twists or over product weights recomputes no node. What does change is the contour, and Corollary 26.6 decides at the nodes whether the new query has an answer.

Proposition 26.22 (The exponents are moment indices)**.** *Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$ be a family on $\mathcal{E}$, fix real masses $\mathbf{m}$, and let I be the set of exponents $(\mathbf{s},\mathbf{t}) \in (0,\infty)^{2N}$ with $\sum_j (r_j s_j + r_j^* t_j) = m_{\mathcal{E}}$ at which every proper wall of $(\mathbf{m};\mathbf{s},\mathbf{t})$ is positive: a relatively open convex subset of that hyperplane, possibly empty. In this statement write $L_1, \dots, L_{2N}$ for the letters K_j and Ψ_j of F, w_i for their exponents and g_i for their degrees, and for each i and $\boldsymbol{\lambda} \in (0,\infty)^{2N-1}$ put*

$$\mathsf{G}_i(\mathbf{m};\boldsymbol{\lambda}) = \int_{\mathbb{R}^{\mathcal{E}}_{>0}} x^{\mathbf{m}-\mathbf{1}} \exp\Big(- L_i(x) - \sum_{i'\neq i} \lambda_{i'} L_{i'}(x)\Big)\, dx,$$

the Gramma (Definition 2.1) of the concatenated configuration of all the letters, with the coefficients of L_i and $\lambda_{i'}$ times those of $L_{i'}$. For $(\mathbf{s},\mathbf{t}) \in I$ and every i,

$$\Gamma(w_i)\, P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = g_i \int_{\mathbb{R}^{\mathcal{E}}_{>0}} x^{\mathbf{m}-\mathbf{1}} e^{-L_i(x)} \prod_{i'\neq i} L_{i'}(x)^{-w_{i'}}\, dx$$

$$= \frac{g_i}{\prod_{i' \neq i} \Gamma(w_{i'})} \int_{(0,\infty)^{2N-1}} \prod_{i' \neq i} \lambda_{i'}^{w_{i'}-1} \, \mathsf{G}_i(\mathbf{m}; \boldsymbol{\lambda}) \, d\boldsymbol{\lambda}.$$

At fixed masses the numbers $\Gamma(w_i) P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})/g_i$ *on* I*, functions of the exponents of the other letters, are the integrals of* $\prod_{i' \neq i} L_{i'}^{-w_{i'}}$ *against the one positive measure* $x^{\mathbf{m}-\mathbf{1}} e^{-L_i(x)} dx$*, and* $\prod_{i'} \Gamma(w_{i'}) \, P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})/g_i$ *is the Mellin transform at* $(w_{i'})_{i' \neq i}$ *of the one function* $\mathsf{G}_i(\mathbf{m}; \cdot)$ *of the relative scales of the other letters to* L_i*, completely monotone in each of them. On* I *the period* $P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$ *is log-convex, by Proposition 8.12(iii) and Hölder's inequality.*

So the period of a family at fixed masses is one integral over the orthant with any one of its letters closed: the closed letter leaves one positive measure on the orthant, the integrand of its Gramma at the index $\mathbf{m}$, and the period is a joint moment of the other letters under it, their exponents with the sign changed being its orders.

Chapter 27

Finite interfaces and certified enclosures

A cell enters every construction through its hinge wall and its law (Theorem 23.11), and a cell with several hinges through the joint law of its channels (Theorem 21.16, Definition 21.13). A law is not a finite list of numbers. Finitely many numbers are retained for every prescribed polynomial moment, the joint moments of the channels under independent Gamma draws on the marks, up to a degree D: they compose by the bilinear map of Theorem 21.14, a repeated chain cell acts on them by one finite matrix, so that every polynomial Gamma moment of a repetition satisfies a linear recurrence with constant coefficients, and the walls turn a moment of finite degree into a certified enclosure of the period. The period is retained as well over a neighbourhood of the query: the walls give the neighbourhood explicitly, the Taylor coefficients in the weights are periods with walls at least as high, and a finite parameter bank with two explicit errors answers every query inside it. Exact representation size, arithmetic work and accuracy are separate quantities.

27.1 The joint law of the channels and its moments

Let $\mathcal{A}$ be a cell with hinges G on its marks B, or cells with the hinges G on the same marks B kept together (Definition 27.1), with channel vector $\mathrm{ch}(\mathcal{A})$ (Definition 21.13), with positive masses $\mathbf{m}$ on B; the hinges carry no mass. Its total mass m_B and the product $\prod_{e\in B}\Gamma(m_e)$ are kept as data: at a splicing the total masses add and these products multiply. For a multi-index $\mathbf{k}$ on the channels, $\mathrm{ch}(\mathcal{A})^{\mathbf{k}}$ is the product of the channels with these multiplicities, a polynomial of the degree $\deg\mathbf{k}=\sum_c k_c\deg c$, the sum over the channels c.

Definition 27.1 (The channel law; moment vectors)**.** Cells $\mathcal{A}_1,\dots,\mathcal{A}_N$ with the hinges G on the same marks B are *kept together* when their channels are read jointly: $\mathcal{A}=(\mathcal{A}_1,\dots,\mathcal{A}_N)$ has the channel vector $\mathrm{ch}(\mathcal{A})=(\mathrm{ch}(\mathcal{A}_j))_j$, listing the channels of all of them by the tags (j,letter,p), $N2^{|G|+1}$ of them, absent channels counting as zero; one cell is the case $N=1$, and the tables of a family, with $G=\varnothing$, are kept together with their letters as channels. The *channel law* of $\mathcal{A}$ is the image $\mathrm{ch}(\mathcal{A})_*\,\mathrm{Dir}_{\mathbf{m}}$ of the Dirichlet law of the shape (Definition 3.10) under the channel vector. The *Gamma draws* on the marks are $\alpha\sim\mathrm{Gamma}_{\mathbf{m}}$, independent Gamma_{m_e} variables (Proposition 8.12), and the *moments* and the *moment vector of degree* D of $\mathcal{A}$ are

$$\mathrm{Mom}_{\mathcal{A}}(\mathbf{k})=\mathbb{E}_{\alpha\sim\mathrm{Gamma}_{\mathbf{m}}}\big[\,\mathrm{ch}(\mathcal{A})(\alpha)^{\mathbf{k}}\big],\qquad \mathrm{Mom}_{\mathcal{A}}^{\le D}=\big(\mathrm{Mom}_{\mathcal{A}}(\mathbf{k})\big)_{|\mathbf{k}|\le D},$$

at most $\binom{q+D}{D}$ numbers, q the number of channels. A *polynomial Gamma moment* of degree at

most D of $\mathcal{A}$ is $\mathbb{E}_{\alpha\sim\mathrm{Gamma}_{\mathbf{m}}}\big[p(\mathrm{ch}(\mathcal{A})(\alpha))\big]$ for a polynomial p of degree at most D in the channels, and a *shape moment* is the same with $U\sim\mathrm{Dir}_{\mathbf{m}}$ in place of α. A cell without marks has constant channels, a point as its law and the products of its channels as its moments, with total mass 0 and the empty product of Gammas.

The channels must be kept jointly: the moments of the channels one at a time do not determine a product of different channels exposed to the same room.

Proposition 27.2 (The channel law composes)**.** *Let $\mathcal{A}_1$ and $\mathcal{A}_2$ be cells, or cells kept together, with disjoint marks B_1, B_2 and masses $\mathbf{m}_1$, $\mathbf{m}_2$, spliced table by table along pairs of their hinges to $\mathcal{A}_{12}$ (Theorem 21.14), both with marks. Let $U_1\sim\mathrm{Dir}_{\mathbf{m}_1}$, $U_2\sim\mathrm{Dir}_{\mathbf{m}_2}$ and $(V_1,V_2)\sim\mathrm{Dir}_{(m_{B_1},m_{B_2})}$ be independent; replace every channel c of $\mathcal{A}_1$ by $V_1^{\deg c}c(U_1)$ and every channel c of $\mathcal{A}_2$ by $V_2^{\deg c}c(U_2)$. The law of the image of the two channel vectors so replaced under the bilinear map of Theorem 21.14(iii), applied table by table, is the channel law of $\mathcal{A}_{12}$. For the tables of a family, kept together without hinges, the channels are their letters, and the period of the family is Proposition 8.12(i) read on the channel law: one Trailmoment of the channel law on its source space (Definition 5.1, Theorem 5.21). For a cell family $F=((\mathcal{A}_j,\theta_j);s_j,t_j)_{j=1}^N$ with the one hinge g (Definition 23.1), its cells kept together, with the coordinates $(x_{j,0},x_{j,1},x^*_{j,0},x^*_{j,1})$ of the channels $K_{\mathcal{A}_j\setminus g}$, $K_{\mathcal{A}_j/g}$, $\Psi_{\mathcal{A}_j\setminus g}$, $\Psi_{\mathcal{A}_j/g}$, the law of F is the weighted image*

$$(\boldsymbol{\varrho}_F)_*\phi_F=\Gamma_{\substack{|B|\\1}}\begin{bmatrix}\mathbf{m}\\ m_B\end{bmatrix}\ (R_F)_*\Big[\prod_j x_{j,1}^{-s_j}x_{j,0}^{*\,-t_j}\Big(\frac{x_{1,0}}{x_{1,1}}\Big)^{-\kappa_F}\ \mathrm{ch}(\mathcal{A})_*\,\mathrm{Dir}_{\mathbf{m}}\Big],$$

with $R_F=\big((x_{j,0}x_{1,1}/(x_{j,1}x_{1,0}))_{j\ge2},(x^*_{j,1}x_{1,1}/(x^*_{j,0}x_{1,0}))_j\big)$, an equality of positive measures, possibly infinite: the channel law, which knows nothing of the exponents, gives the law of the cell family at all exponents by a weight and an image.

Theorem 27.3 (Gamma draws close the moments)**.** *(i)* Leaves. *If $\mathrm{ch}(\mathcal{A})(x)^{\mathbf{k}}=\sum_{\mathbf{h}}c_{\mathbf{h}}x^{\mathbf{h}}$, then $\mathrm{Mom}_{\mathcal{A}}(\mathbf{k})=\sum_{\mathbf{h}}c_{\mathbf{h}}\prod_e(m_e)_{h_e}$, rational at rational masses and weights.*

(ii) Assembly. *Let $\mathrm{ch}(\mathcal{A}_{12})=\mathrm{sp}\big(\mathrm{ch}(\mathcal{A}_1),\mathrm{ch}(\mathcal{A}_2)\big)$ with the bilinear map* sp *of Theorem 21.14(iii), applied table by table to cells kept together, and write $\mathrm{sp}(c,c')^{\mathbf{k}}=\sum_{\mathbf{k}_1,\mathbf{k}_2}b_{\mathbf{k};\mathbf{k}_1,\mathbf{k}_2}c^{\mathbf{k}_1}c'^{\mathbf{k}_2}$, a sum over $|\mathbf{k}_1|=|\mathbf{k}_2|=|\mathbf{k}|$. Then*

$$\mathrm{Mom}_{\mathcal{A}_{12}}(\mathbf{k})=\sum_{\mathbf{k}_1,\mathbf{k}_2}b_{\mathbf{k};\mathbf{k}_1,\mathbf{k}_2}\,\mathrm{Mom}_{\mathcal{A}_1}(\mathbf{k}_1)\,\mathrm{Mom}_{\mathcal{A}_2}(\mathbf{k}_2),$$

and no moment of degree above $|\mathbf{k}|$ of either cell is needed; a splicing inside one cell is linear and keeps the degree.

(iii) Return to the shape. *For a cell with marks, $\mathbb{E}_{U\sim\mathrm{Dir}_{\mathbf{m}}}\big[\mathrm{ch}(\mathcal{A})(U)^{\mathbf{k}}\big]=\mathrm{Mom}_{\mathcal{A}}(\mathbf{k})/(m_B)_{\deg\mathbf{k}}$: the joint moments of the channel law through degree D are read off $\mathrm{Mom}_{\mathcal{A}}^{\le D}$, the rank, the sizes and the tags fixing the denominators.*

(iv) Sufficiency. *Two cells with the same hinges, channel tags and degrees and the same $\mathrm{Mom}^{\le D}$ give every final polynomial Gamma moment of degree at most D in the channels, in any assembly with cells on disjoint marks, the same value, even where an intermediate cell exposes more hinges than the replaced one; with the same total mass as well, they give every final shape moment of degree at most D of the channels of the root, under its Dirichlet law, the same value.*

(v) The whole law. *For a cell with marks, the* $\mathrm{Mom}_{\mathcal{A}}^{\le D}$ *for all* D*, with* m_B *and the degrees, determine its channel law, and with it the expectation of every integrable function of the channels (Proposition 27.2).*

The draws are used for nonnegative moments of the channels. A negative moment of a period integrand under the draws diverges on the balance wall: the scale contributes $\int_0^\infty S^{-1}e^{-S}dS$, the pole of $\Gamma(\kappa_{\mathcal{E}})$ in Proposition 8.12. The return to the shape, followed by Proposition 27.2 or by the peak closing (Theorem 15.13(i)) with its stopping rule (Theorem 27.7), is the change of representation that the period needs.

Corollary 27.4 (The work follows the distinct interfaces)**.** *Fix a degree* D*, an assembly that exposes at most* h *hinges at every cell it keeps, and identifications of its repeated subassemblies keeping their data and hinges. Every requested moment of the root is computed exactly by keeping at most* $\binom{2^{h+1}+D}{D}$ *numbers for each distinct cell,* $\binom{N2^{h+1}+D}{D}$ *for* N *tables kept together. The arithmetic is* $O\big(\sum_v E_v(D)\big)$ *operations once the local expansions and the leaf moments are built,* $E_v(D)$ *the number of nonzero coefficients* $b_{\mathbf{k};\mathbf{k}_1,\mathbf{k}_2}$ *at a distinct splicing* v *of two cells, at most the product of the sizes of its three moment vectors, or of two for a splicing inside one cell. Equal copies share one moment vector and remain independent draws: their moments are multiplied as in Theorem 27.3(ii), never identified.*

This counts operations. Building the local expansions, finding an assembly of small width, the bit lengths of exact coefficients and the degree a moment needs are separate parts of the cost; finding the cheapest assembly is a search, as for constructions (Section 33.1).

27.2 Repetition is a finite matrix

Theorem 27.5 (A finite matrix for every polynomial Gamma moment)**.** *Let a chain cell* $\mathcal{U}$ *(Proposition 24.4, here with several hinges) be a cell with two disjoint sets of hinges* G_{in} *and* G_{out}*, each in a fixed bijection with the hinges of a cell* $\mathcal{A}_0$*, and let* $\mathcal{A}_{l+1}$ *be* $\mathcal{U}$*, with fresh marks and the same masses and weights at every use, spliced onto* $\mathcal{A}_l$ *by pairing* G_{in} *with the hinges of* $\mathcal{A}_l$*; so* $\mathcal{A}_{l+1}$ *exposes* G_{out}*, named through the bijection as the hinges of* $\mathcal{A}_l$*, with the same channel tags, and its channel vector is the image of* $\mathrm{ch}(\mathcal{A}_l)$ *and that of the copy of* $\mathcal{U}$ *under the map* sp*. Keep one list of channel tags for every* l*, absent channels being zero. For every* D *there is a matrix* $\mathbf{T}_D$*, independent of* l *and computed from* $\mathcal{U}$ *by finite expansion and Theorem 27.3(i), with*

$$\mathrm{Mom}_{\mathcal{A}_l}^{\le D} = \mathbf{T}_D^{\,l}\ \mathrm{Mom}_{\mathcal{A}_0}^{\le D}\,.$$

Every fixed polynomial Gamma moment of degree at most D *of* $\mathcal{A}_l$*, a fixed terminal cell spliced on it included, is* $\mathbf{e}^{\mathsf{T}}\mathbf{T}_D^{\,l}\,\mathrm{Mom}_{\mathcal{A}_0}^{\le D}$ *for a fixed row* $\mathbf{e}^{\mathsf{T}}$*; so its generating series in* l *is* $\mathbf{e}^{\mathsf{T}}(I-\zeta\mathbf{T}_D)^{-1}\,\mathrm{Mom}_{\mathcal{A}_0}^{\le D}$*, rational in* ζ*, the sequence satisfies the linear recurrence with constant coefficients given by the characteristic polynomial of* $\mathbf{T}_D$*, of order at most* $\binom{q+D}{D}$*, and one length* l *costs* $O\big(\binom{q+D}{D}^3\log(l{+}1)\big)$ *operations by repeated squaring.* $\mathbf{T}_D$ *is block diagonal by the degree, and a moment of one degree uses its block alone; a repeated sequence of different chain cells is the power of the product of their matrices.*

On a cell with one hinge g, a chain cell $\mathcal{U}$ with the hinges i and o, i spliced to g, and the channels $K_{\mathcal{U},(P)}$, $\Psi_{\mathcal{U},(P)}$, $P\subseteq\{i,o\}$, acts by

$$\begin{pmatrix} K_{\mathcal{A}_{l+1},(\varnothing)} \\ K_{\mathcal{A}_{l+1},(\{o\})} \end{pmatrix} = \begin{pmatrix} K_{\mathcal{U},(\{i\})} & K_{\mathcal{U},(\varnothing)} \\ K_{\mathcal{U},(\{i,o\})} & K_{\mathcal{U},(\{o\})} \end{pmatrix} \begin{pmatrix} K_{\mathcal{A}_l,(\varnothing)} \\ K_{\mathcal{A}_l,(\{g\})} \end{pmatrix},$$

and by the same matrix of the $\Psi_{\mathcal{U},(P)}$ on the Ψ channels, which is Theorem 21.14(iii) with one pair. A moment of degree a in the K channels and b in the Ψ channels lives on $(a+1)(b+1)$ monomials, and the block of $\mathbf{T}_D$ on them is the joint expectation over the draws of $\mathcal{U}$ of the expanded actions: the two matrices share the marks of $\mathcal{U}$ and are not independent. For a family at integer exponents, the joint moments of its letters along a chain of bunches with matrix letters are the case of Theorem 22.10. An iterate of an integral operator gives no finite closing relation by itself (Theorem 22.8, Proposition 24.4); every polynomial Gamma moment of a repetition does. The period is recovered from a sequence of such moments with certified tails, in Section 27.3.

Corollary 27.6 (Shape moments have recurrences)**.** *For the repetition of Theorem 27.5 let the total masses be $m_{\mathcal{A}_l} = m_{\mathcal{A}_0} + l\, m_{\mathcal{U}}$, $m_{\mathcal{U}}$ that of $\mathcal{U}$, let p be a polynomial in the channels, the same for every l, homogeneous of degree $d_l = d_0 + lv$ in the marks, v an integer, and let M_l be the polynomial Gamma moment of $\mathcal{A}_l$ for p. The shape moment for p is $M_l/(m_{\mathcal{A}_l})_{d_l}$, and every recurrence $\sum_i c_i M_{l+i} = 0$ gives $\sum_i c_i \frac{(m_{\mathcal{A}_{l+i}})_{d_{l+i}}}{(m_{\mathcal{A}_l})_{d_l}} \frac{M_{l+i}}{(m_{\mathcal{A}_{l+i}})_{d_{l+i}}} = 0$. If the masses are rational and $h \geq 1$ is an integer with $h m_{\mathcal{U}} \in \mathbb{Z}$, then on each residue of l modulo h, with $\mathbf{T}_D^h$ for $\mathbf{T}_D$, the coefficients are rational functions of l over the field of the weights, polynomials after clearing denominators, in $\mathbb{Q}[l]$ at rational weights.*

27.3 A certified enclosure of the period

Theorem 27.7 (Explicit stopping from the walls)**.** *Let a family F on $n \geq 2$ marks have real masses on its balance wall and exponents $s_j, t_j \geq 0$, with every proper wall positive. Write its active letters, the K_j with $s_j > 0$ and the Ψ_j with $t_j > 0$, as L_i with exponents $w_i > 0$, degrees g_i and counts $d_i(S)$, as in Theorem 15.13, so that $m_{\mathcal{E}} = \sum_i g_i w_i$ and $\kappa_S = m_S - \sum_i w_i d_i(S)$. Choose references $M_i \geq \max_{\Delta_{\mathcal{E}}} L_i$, and in this statement put $Y_i = L_i/M_i \in (0,1]$ on the open simplex. For an order π of the marks let $U_{\pi,k}$ be its tails, $L_{i,\pi}$ the sector letter of L_i, the $k_{j,\pi}$ or $\psi_{j,\pi}$ of Theorem 8.5(ii), and $\underline{L}_{i,\pi} > 0$ its constant term. For integers $Q_i \geq 0$ put*

$$P^{\leq \mathbf{Q}} = \Gamma_1^n \begin{bmatrix} \mathbf{m} \\ m_{\mathcal{E}} \end{bmatrix} \prod_i M_i^{-w_i} \sum_{0 \leq k_i \leq Q_i} \prod_i \frac{(w_i)_{k_i}}{k_i!}\ \mathbb{E}_{U \sim \mathrm{Dir}_{\mathbf{m}}} \Big[\prod_i \big(1 - Y_i(U)\big)^{k_i} \Big],$$

the partial sums of the peak closing (Theorem 15.13(i)), computed exactly from the moments of the letters through the degree $\sum_i Q_i$, each monomial with its own rising factorial (Theorem 27.3(iii)). For every choice of $\epsilon_i > 0$ with

$$\kappa_S - \epsilon_i d_i(S) > 0 \qquad (\varnothing \neq S \subsetneq \mathcal{E}),$$

which is exactly $\epsilon_i < \varpi_i$, ϖ_i the least of the ratios $\kappa_S/d_i(S)$ in Theorem 15.13(ii) (any $\epsilon_i > 0$ when no proper S has $d_i(S) > 0$), put

$$C_i = M_i^{\epsilon_i}\, n^{g_i \epsilon_i} \sum_{\pi} \underline{L}_{i,\pi}^{-\epsilon_i} \prod_{i'} \underline{L}_{i',\pi}^{-w_{i'}} \prod_{k=2}^{n} \frac{1}{\kappa_{U_{\pi,k}} - \epsilon_i d_i(U_{\pi,k})}.$$

Then

$$0 \leq P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) - P^{\leq \mathbf{Q}} \leq \sum_i C_i \frac{\Gamma(w_i + \epsilon_i)\, \Gamma(w_i + Q_i + 1)}{\Gamma(w_i)\, \Gamma(w_i + Q_i + 1 + \epsilon_i)},$$

and for $\epsilon_i \leq 1$ the last factor is at most $(w_i/(w_i + Q_i + 1))^{\epsilon_i}$. So finitely many moments and finitely many walls enclose the period to any prescribed accuracy; the same moments answer every other

choice of exponents w_i with $\sum_i g_i w_i = m_{\mathcal{E}}$ at the same masses, only the coefficients of $P^{\le \mathbf{Q}}$, the walls and the certificate changing.

At rational data the constants of the certificate are positive rationals and their rational powers, and no period other than the one sought enters it; the stacked Gamma $\Gamma_1^n \begin{bmatrix} \mathbf{m} \\ m_{\mathcal{E}} \end{bmatrix}$ and the Gamma ratios stay exact products and quotients of values of the Gamma function, so the enclosure is exact without being rational. The certificate can itself be expensive, C_i being a sum over all $n!$ orders, and it is crude: it replaces every sector letter by its least value. The true tail is of the order $Q^{-\varpi}(\log Q)^{k-1}$ (Theorem 15.13(ii)); the certified decay $Q_i^{-\epsilon_i}$ tends to it as $\epsilon_i \to \varpi_i$, at the cost of the factor $\prod_k (\kappa_{U_{\pi,k}} - \epsilon_i d_i(U_{\pi,k}))^{-1}$, which grows without bound there. Sharper references and sharper sector bounds lower the degree needed without changing the moments. The degree needed can grow with the size of the assembly, so this is a terminating certified procedure, not a uniform fast approximation.

27.4 Changing the query with finite data

Proposition 27.8 (Parameters and insertions)**.** *Fix the local supports and the assembly.*

(i) For each D the leaf moments and the splicing and transfer coefficients are polynomials in the local weights and in the masses; they can be kept symbolic and specialized at any positive values.

(ii) Carrying the leaf moments, Theorem 27.3(ii) and Theorem 27.5 in the truncated ring $\mathbb{Q}(\boldsymbol{\theta}, \mathbf{m})[\boldsymbol{\zeta}]/(\boldsymbol{\zeta})^{h+1}$ of p local parameters $\boldsymbol{\zeta}$, over the field generated by the weights $\boldsymbol{\theta}$ and the masses, gives every derivative of the moments through the order h, at most $\binom{p+h}{h}$ coefficients per entry.

(iii) A further polynomial observable, a mark total for instance, can be made a channel when every local update is separately affine in each independent cell vector, a constant channel adjoined.

(iv) Raising the masses by nonnegative integers $\boldsymbol{\gamma}$ is a polynomial insertion: for every observable g,

$$\mathbb{E}_{\alpha \sim \mathrm{Gamma}_{\mathbf{m}+\boldsymbol{\gamma}}}[g(\alpha)] = \mathbb{E}_{\alpha \sim \mathrm{Gamma}_{\mathbf{m}}}\left[\alpha^{\boldsymbol{\gamma}} g(\alpha)\right] \Big/ \prod_e (m_e)_{\gamma_e}.$$

The moments do not depend on the exponents asked for: changing the exponents reuses every moment, and changing a local weight or mass changes the local data and their ancestors in the assembly only, as Proposition 24.6 says of laws. Shared parameters may appear in many copies, whose draws stay independent.

27.5 Certified parameter banks

A family F on its balance wall, its letters K_j and Ψ_j written L_i, $i = 1, \dots, \ell$, with the exponents w_i (the s_j and t_j), the degrees g_i and the counts $d_i(S) = \min\{\gamma_S : [u^\gamma] L_i > 0\}$, so that $P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \int_{\Delta_{\mathcal{E}}} u^{\mathbf{m}-\mathbf{1}} \prod_i L_i(u)^{-w_i} d\omega_{\mathcal{E}}(u)$, with $m_{\mathcal{E}} = \sum_i g_i w_i$ and the walls $\kappa_S = m_S - \sum_i w_i d_i(S) > 0$ at the starting data, is asked a neighbourhood of queries: p complex parameters $\boldsymbol{\zeta}$, and a bank of Taylor coefficients through the total order h, at most $\binom{h+p}{p}$ numbers. The order of a bank is the number of differentiations, not the degree of a polynomial moment of Section 27.1.

Theorem 27.9 (Taylor coefficients in the weights are periods with walls at least as high)**.** *Let the exponents w_i be real and change the coefficients of the letters, $L_i(\boldsymbol{\zeta}) = L_i + \sum_{j=1}^{p} \zeta_j D_{ij}$, each D_{ij} homogeneous of degree g_i with support in that of L_i and coefficients of either sign, and in this statement write $P(\boldsymbol{\zeta}) = \int_{\Delta_{\mathcal{E}}} u^{\mathbf{m}-\mathbf{1}} \prod_i L_i(\boldsymbol{\zeta})(u)^{-w_i}\, d\omega_{\mathcal{E}}(u)$, so that $P(\mathbf{0}) = P_F(\mathbf{m};\mathbf{s},\mathbf{t})$. Then, with $l_i = \sum_j l_{ij}$,*

$$[\boldsymbol{\zeta}^{\mathbf{k}}]P = \sum_{\substack{l_{ij}\geq 0 \\ \sum_i l_{ij} = k_j}} \prod_i \frac{(-1)^{l_i}(w_i)_{l_i}}{\prod_j l_{ij}!} \int_{\Delta_{\mathcal{E}}} u^{\mathbf{m}-\mathbf{1}} \prod_i \Big(L_i^{-w_i - l_i} \prod_j D_{ij}^{l_{ij}} \Big)\, d\omega_{\mathcal{E}},$$

and after the numerators are expanded every term is a convergent period of the family at masses $\mathbf{m} + \boldsymbol{\gamma}$ and exponents $w_i + l_i$, balanced, with every proper wall $\kappa'_S = \kappa_S + \gamma_S - \sum_i l_i d_i(S) \geq \kappa_S$.

Theorem 27.10 (A uniform certificate for weights)**.** *In the setting of Theorem 27.9, with $P(\boldsymbol{\zeta})$ as there, write $L_i = \sum_{\boldsymbol{\gamma}} c_{i,\boldsymbol{\gamma}} u^{\boldsymbol{\gamma}}$ with $c_{i,\boldsymbol{\gamma}} > 0$ and $D_{ij} = \sum_{\boldsymbol{\gamma}} c_{i,\boldsymbol{\gamma}} v_{i,\boldsymbol{\gamma},j} u^{\boldsymbol{\gamma}}$, $V_{ij} = \max_{\boldsymbol{\gamma}} |v_{i,\boldsymbol{\gamma},j}|$, and choose radii $R_j > 0$ with $r_i = \sum_j R_j V_{ij} < 1$. On $|\zeta_j| \leq R_j$, $|P(\boldsymbol{\zeta})| \leq P(\mathbf{0}) \prod_i \max\big((1-r_i)^{-w_i}, (1+r_i)^{-w_i}\big) =: M$, made explicit by $P(\mathbf{0}) \leq \sum_\pi \prod_i \max\big(L_{i,\pi}(\mathbf{0})^{-w_i}, L_{i,\pi}(\mathbf{1})^{-w_i}\big) \prod_{k=2}^{n} \kappa_{U_{\pi,k}}^{-1}$, with the sector letters $L_{i,\pi}$ of the letters on the sector of the order π, the $k_{j,\pi}$ or $\psi_{j,\pi}$ of Theorem 8.5(ii), or by the upper end of the enclosure of Proposition 15.12; P is holomorphic near the closed polydisc, $|[\boldsymbol{\zeta}^{\mathbf{k}}]P| \leq M\mathbf{R}^{-\mathbf{k}}$, and its Taylor polynomial $P^{[h]}$ through the order h has, on $|\zeta_j| \leq \vartheta R_j$ with $0 \leq \vartheta < 1$,*

$$|P(\boldsymbol{\zeta}) - P^{[h]}(\boldsymbol{\zeta})| \leq M \sum_{k>h} \binom{k+p-1}{p-1} \vartheta^k \leq M\, \frac{\binom{h+p}{p-1}\vartheta^{h+1}}{1 - \vartheta(h+p+1)/(h+2)},$$

the second bound when $\vartheta(h+p+1) < h+2$.

Theorem 27.11 (Wall-certified parameter banks)**.** *Keep the letters and change the masses and exponents affinely, $m_e(\boldsymbol{\zeta}) = m_e^0 + \sum_j a_{ej}\zeta_j$ and $w_i(\boldsymbol{\zeta}) = w_i^0 + \sum_j b_{ij}\zeta_j$ with real slopes and balance in every direction, so that $\kappa_S(\boldsymbol{\zeta}) = \kappa_S^0 + \sum_j c_{Sj}\zeta_j$ with $c_{Sj} = \sum_{e\in S} a_{ej} - \sum_i b_{ij} d_i(S)$, and in this statement write $P(\boldsymbol{\zeta}) = P_F(\mathbf{m}(\boldsymbol{\zeta});\mathbf{s}(\boldsymbol{\zeta}),\mathbf{t}(\boldsymbol{\zeta}))$, the exponents $w_i(\boldsymbol{\zeta})$ on the letters. Choose $R_j > 0$ with*

$$\underline{\kappa}_S := \kappa_S^0 - \sum_j |c_{Sj}| R_j > 0 \qquad (\varnothing \neq S \subsetneq \mathcal{E}).$$

On the sector of an order π every letter is its monomial times its sector letter $L_{i,\pi}$, the $k_{j,\pi}$ or $\psi_{j,\pi}$ of Theorem 8.5(ii), with nonnegative coefficients in the sector coordinates; put $\underline{L}_{i,\pi} = L_{i,\pi}(\mathbf{0})$, $\overline{L}_{i,\pi} = L_{i,\pi}(\mathbf{1})$, $\eta_{i,\pi} = \max(|\log \underline{L}_{i,\pi}|, |\log \overline{L}_{i,\pi}|)$, $\nu_i = \sum_j |b_{ij}| R_j$,

$$B_\pi = \prod_i \max\big(\underline{L}_{i,\pi}^{-w_i^0}, \overline{L}_{i,\pi}^{-w_i^0}\big) e^{\eta_{i,\pi}\nu_i}, \qquad M_{\mathbf{R}} = \sum_\pi B_\pi \prod_{k=2}^{n} \underline{\kappa}_{U_{\pi,k}}^{-1}.$$

Then P is holomorphic near $|\zeta_j| \leq R_j$ with $|P| \leq M_{\mathbf{R}}$, every $|[\boldsymbol{\zeta}^{\mathbf{k}}]P| \leq M_{\mathbf{R}}\mathbf{R}^{-\mathbf{k}}$, the bound of Theorem 27.10 holds with $M_{\mathbf{R}}$ for M, and

$$[\boldsymbol{\zeta}^{\mathbf{k}}]P = \frac{1}{\mathbf{k}!} \int_{\Delta_{\mathcal{E}}} u^{\mathbf{m}^0-\mathbf{1}} \prod_i L_i^{-w_i^0} \prod_j \Big(\sum_e a_{ej} \log u_e - \sum_i b_{ij} \log L_i \Big)^{k_j} d\omega_{\mathcal{E}},$$

absolutely integrable and of degree zero. The starting exponents may be any reals at which the proper walls are positive.

Theorem 27.12 (A finite compiler with two errors)**.** *In the setting of Theorem 27.11, with $P(\boldsymbol{\zeta})$ as there, put $y_{i,\pi} = 1 - L_{i,\pi}/\overline{L}_{i,\pi} \in [0, \lambda_\pi]$, $\lambda_\pi = \max_i(1 - \underline{L}_{i,\pi}/\overline{L}_{i,\pi}) < 1$, $\beta_i = |w_i^0| + \nu_i$ and $A_\pi = \prod_i \overline{L}_{i,\pi}^{-w_i^0} e^{|\log \overline{L}_{i,\pi}|\nu_i} \prod_{k=2}^n \underline{\kappa}_{U_{\pi,k}}^{-1}$. Expand $\prod_i L_{i,\pi}^{-w_i(\boldsymbol{\zeta})} = \prod_i \overline{L}_{i,\pi}^{-w_i(\boldsymbol{\zeta})} \sum_{\mathbf{l}} \prod_i \frac{(w_i(\boldsymbol{\zeta}))_{l_i}}{l_i!} y_{i,\pi}^{l_i}$, truncate at $|\mathbf{l}| \le Q$, and integrate the finitely many terms exactly, each $\prod_i y_{i,\pi}^{l_i} = \sum_{\boldsymbol{\gamma}} c_{\boldsymbol{\gamma}} q^{\boldsymbol{\gamma}}$ in the sector coordinates q contributing*

$$\prod_i \overline{L}_{i,\pi}^{-w_i(\boldsymbol{\zeta})} \prod_i \frac{(w_i(\boldsymbol{\zeta}))_{l_i}}{l_i!} \sum_{\boldsymbol{\gamma}} c_{\boldsymbol{\gamma}} \prod_{k=2}^n \frac{1}{\kappa_{U_{\pi,k}}(\boldsymbol{\zeta}) + \gamma_k},$$

to obtain $\widetilde{P}_Q(\boldsymbol{\zeta})$. Then on the whole polydisc

$$|P(\boldsymbol{\zeta}) - \widetilde{P}_Q(\boldsymbol{\zeta})| \le \mathrm{err}_Q := \sum_\pi A_\pi \sum_{k>Q} \frac{(|\boldsymbol{\beta}|)_k}{k!} \lambda_\pi^k \le \sum_\pi A_\pi \frac{(|\boldsymbol{\beta}|)_{Q+1} \lambda_\pi^{Q+1}}{(Q+1)!\,(1 - r_{\pi,Q})},$$

the second bound when $r_{\pi,Q} = \lambda_\pi \max\left(1, \frac{|\boldsymbol{\beta}|+Q+1}{Q+2}\right) < 1$ for every π; and the Taylor polynomial $\widetilde{P}_Q^{[h]}$ of $\widetilde{P}_Q$ through the order h, computed by finite arithmetic in a truncated ring, has on $|\zeta_j| \le \vartheta R_j$

$$|P(\boldsymbol{\zeta}) - \widetilde{P}_Q^{[h]}(\boldsymbol{\zeta})| \le \frac{\mathrm{err}_Q}{(1-\vartheta)^p} + M_{\mathbf{R}} \sum_{k>h} \binom{k+p-1}{p-1} \vartheta^k.$$

With no parameters, $p = 0$, so that $\nu_i = 0$ and $\underline{\kappa}_S = \kappa_S$, and with every $w_i^0 \ge 0$, the first bound is that of Proposition 15.12(ii): there $\overline{L}_{i,\pi} = L_i(\mathbf{1})$ for every π, $\widetilde{P}_Q = \prod_i L_i(\mathbf{1})^{-w_i^0} \sum_\pi \sum_{M \le Q} I_{\pi,M}$, and the explicit tail is $\prod_i L_i(\mathbf{1})^{-w_i^0} \sum_\pi \mathrm{err}_{\pi,Q}$, the letters being the K_j and Ψ_j with the exponents s_j and t_j.

For fixed data and $\vartheta < 1$ the orders Q and h grow like the logarithm of the inverse error, up to the polynomial factors of the scalar tails; expanding the sector polynomials still costs work that depends on the dimension and the supports. The walls also cover paths: along a segment on which every proper wall is positive, with κ_- the least proper wall at the two ends and a the largest change of a proper wall along it, every point of the segment, parametrized by $\lambda \in [0,1]$, has the disc of radius $\kappa_-/(2a)$ in the complex parameter on which every proper wall keeps a real part at least $\kappa_-/2$, the walls being affine, and a compact path has a finite cover by such discs. A bank at one point does not give the coefficients at another; what is reused everywhere is the compiled sector data, the coefficient procedure and the wall test.

27.6 Procedures

Definition 27.13 (The interface procedure)**.** *Given*: cells with their weights and masses; the pairs of hinges to splice and an assembly order with its identifications of repeated parts; a polynomial moment, a peak truncation or an accuracy, with, for an accuracy, references and a wall certificate. *Steps*: (1) read the channels of the leaves by coefficient extraction, with their degrees, the sizes, the total masses and the products $\prod_e \Gamma(m_e)$; (2) choose D, the degree of the moment or $\sum_i Q_i$ from Theorem 27.7; (3) compute the leaf moments by Theorem 27.3(i), only at the multi-indices the moment pulls back to; (4) compile every distinct splicing by Theorem 27.3(ii), and every repeated chain cell once into $\mathbf{T}_D$ and its power (Theorem 27.5), reusing a vector only when its tags and data match; (5) splice the pairs at the root, return to the shape by Theorem 27.3(iii),

and evaluate $P^{\leq \mathbf{Q}}$ with its certificate. *Output*: an exact polynomial moment, a recurrence or rational generating series for a repetition, or a certified enclosure of the period, with the vectors, the splicing coefficients, the parameter expressions and the certificate kept for the next query.

Definition 27.14 (The bank procedure)**.** *Given*: a family on its balance wall with positive walls, and affine directions of change of its masses and exponents, or of the weights of its letters. *Steps* along masses and exponents: compute the walls and a box of radii satisfying the strict inequalities of Theorem 27.11; form the sector constants and $M_{\mathbf{R}}$; choose Q and h until the bound of Theorem 27.12 is below the tolerance; compile the retained sector terms in the truncated ring. Along weights, where the sector letters move with $\boldsymbol{\zeta}$ and Theorem 27.12 does not apply: choose radii by Theorem 27.10, with its bound made explicit there; each coefficient through the order h is the finite signed sum of periods with walls at least as high of Theorem 27.9, each enclosed by Proposition 15.12, and the tail beyond h is bounded by Theorem 27.10. *Output*: the parameter bank, its domain and its certified error; every query inside the smaller box is a polynomial evaluation, and the exact coefficients remain available as the periods of Theorem 27.9 or the integrals of Theorem 27.11.

Chapter 28

Bunches of any width

A bunch of width one is one mark to its room (Theorem 19.4): its patterns fill two levels, each level is one child of the bunch against one table of the room, and what the room sees of the bunch is its wall and the law of its ratio vector, one ratio for one table (Lemma 23.2, Theorem 23.11). At every width a room sees its bunch through the wall, the widths and the joint law of the bunch letters of a level factorization (Theorem 21.16); that statement has a canonical form, and the calculus of width one carries to every width. At the width c the patterns fill $c+1$ levels, and a level between the extremes pairs several stations of patterns with several stations of room sides: which pairs meet, and with which constants, is the seam of the bunch (Definition 28.1), graded by the excess, which no description by marks or by level totals contains. The room sees the bunch through the letters of the tables it presents to it, one for each station of room sides, and the law of these letters is what the bunch retains: it suffices against every partner, and the tinkers of one partner already separate any two laws (Theorem 28.19). A bunch of width c is absorbed into its partner as one stand-in mark of degree c (Lemma 28.8), a mark of a table exactly at width one (Theorem 28.24), and a nonempty family of sets of one size is the family of bases of a table exactly when, at one bunch, its children and room children are tables, adjacent ones are quotients, the extreme ones are one, and its levels are lifts (Theorem 28.30). The circuits of the seam are the directions of the shares of the compatible pairs that neither side sees, and the period integrates over them through the Gramma of the compatible pairs (Proposition 28.14). Width one is the case of the hinge throughout: the seam of a bunch of width one is its hinge (Proposition 28.3(ii)), and its law is the law of its ratio vector read through one fixed change of scale (Proposition 28.11). Bunches compose along chains and trees (Chapter 29), the glue closes along the directions of its shares (Chapter 31), and a law has regions of equality and a reach at its ends (Chapter 32).

28.1 The seam of a bunch

Definition 28.1 (Seam)**.** Let a table $(\mathcal{B}, \theta)$ have the bunch B and the room R. A level k of B is named by its excess $i = k - d(B)$ (Definition 12.16), $0 \le i \le c(B)$: its patterns have $d(B)+i$ marks and its room sides $d(R)+c(B)-i$, the room having the width of the bunch (Definition 19.1). Fix an excess i.

(i) Two patterns of excess i lie in one station when their children (Definition 12.1) are positive multiples of one another, weights included, as at the bunches S_l of Theorem 22.9. The *room child* at a room side X is the child of the bunch R at its pattern X: the table on B with the bases $\mathcal{B}_{(X)} = \{p : \ p \sqcup X \in \mathcal{B}\}$ and the weights $\theta_{(X),p} = \theta_{p \sqcup X}$ (Lemma 12.2). Two room sides of excess i lie in one station when their room children are positive multiples of one another.

The stations of patterns of excess i form the set $\mathcal{K}_i$ and those of room sides the set $\mathcal{D}_i$: the stations of the bunch and of the room are $\mathcal{K} = \bigsqcup_i \mathcal{K}_i$ and $\mathcal{D} = \bigsqcup_i \mathcal{D}_i$, each station carrying its excess $i(C)$ or $i(D)$.

(ii) Within a station C the child at $p \in C$ is w_p times one weighted table on R, the *child of the station* C, with the bases $\mathcal{B}_{(C)}$ and the weights $\theta_{(C)}$, the *multipliers* $w_p > 0$ being normalized by $\max_{p\in C} w_p = 1$; likewise the room child at $X \in D$ is w'_X times the *room child of the station* D, a table on B with the bases $\mathcal{B}_{(D)}$ and the weights $\theta_{(D)}$, with $\max_{X\in D} w'_X = 1$. The *pair constant* of $C \in \mathcal{K}_i$ and $D \in \mathcal{D}_i$ is $h_{CD} = \theta_{p\sqcup X}/(w_p w'_X)$ for any $p \in C$ and $X \in D$ with $p \sqcup X \in \mathcal{B}$, which does not depend on the choice, and $h_{CD} = 0$ when there is none; (C, D) is *compatible* when $h_{CD} > 0$. The *seam matrix* of the excess i is $H_i = (h_{CD})_{C\in\mathcal{K}_i,\, D\in\mathcal{D}_i}$, and the *seam* of B is $(H_0, \dots, H_{c(B)})$ with its stations; a family has one seam in each table.

(iii) The *station letters* are $\mathsf{x}_C = \sum_{p\in C} w_p\, \alpha_B^p$ and $\mathsf{x}^*_C = \sum_{p\in C} w_p\, \alpha_B^{B\setminus p}$ on B, and $\mathsf{y}_D = \sum_{X\in D} w'_X\, \alpha_R^X$ and $\mathsf{y}^*_D = \sum_{X\in D} w'_X\, \alpha_R^{R\setminus X}$ on R. The *seam letters* of B are the letters $K_{(D)}$ and $\Psi_{(D)}$ of the room children of the stations $D \in \mathcal{D}$, polynomials on B; those of R are the letters $K_{(C)}$ and $\Psi_{(C)}$ of the children of the stations $C \in \mathcal{K}$, polynomials on R.

For a list every multiplier and every pair constant is 1. The normalization by the largest multiplier chooses nothing and commutes with every bijection of the marks; any other normalization multiplies x_C and y_D by positive constants and h_{CD} by their inverses, and leaves every product $h_{CD}\,\mathsf{x}_C\,\mathsf{y}_D$ unchanged. In table j of a family the stations, the letters and the constants carry the index j: $\mathcal{K}_j$, $\mathcal{D}_j = \bigsqcup_i \mathcal{D}_{j,i}$, x_{jC}, y_{jD}, $h_{j,CD}$, $K_{j,(D)}$ and so on.

Proposition 28.2 (The seam identity)**.** *In Definition 28.1:*

(i) The seam letters are the station letters through the seam:

$$K_{(D)} = \sum_C h_{CD}\,\mathsf{x}_C, \qquad \Psi_{(D)} = \sum_C h_{CD}\,\mathsf{x}^*_C,$$
$$K_{(C)} = \sum_D h_{CD}\,\mathsf{y}_D, \qquad \Psi_{(C)} = \sum_D h_{CD}\,\mathsf{y}^*_D :$$

the seam letters of a side are the letters of the tables that the other side presents to it.

(ii) If (C, D) is compatible, every $p \in C$ and $X \in D$ make a basis, with $\theta_{p\sqcup X} = h_{CD}\, w_p\, w'_X$, and the bases of excess i are the disjoint union of these rectangles $C \times D$ *over the compatible pairs.*

(iii) With x_i, x^*_i, y_i, y^*_i the vectors of the station letters of excess i,

$$K = \sum_{i=0}^{c(B)} \mathsf{x}_i^{\mathsf{T}} H_i\, \mathsf{y}_i = \sum_{D\in\mathcal{D}} K_{(D)}\,\mathsf{y}_D = \sum_{C\in\mathcal{K}} \mathsf{x}_C\, K_{(C)},$$
$$\Psi = \sum_{i=0}^{c(B)} \mathsf{x}_i^{*\mathsf{T}} H_i\, \mathsf{y}^*_i = \sum_{D\in\mathcal{D}} \Psi_{(D)}\,\mathsf{y}^*_D = \sum_{C\in\mathcal{K}} \mathsf{x}^*_C\, \Psi_{(C)},$$

and along the scale of B, $\alpha_B = \rho u$ with $u \in \Delta_B$ (Lemma 2.7),

$$K(\rho u, \alpha_R) = \rho^{d(B)} \sum_{i=0}^{c(B)} \rho^i \sum_{D\in\mathcal{D}_i} K_{(D)}(u)\,\mathsf{y}_D(\alpha_R),$$

$$\Psi(\rho u, \alpha_R) = \rho^{d^*(B)} \sum_{i=0}^{c(B)} \rho^{c(B)-i} \sum_{D \in \mathcal{D}_i} \Psi_{(D)}(u)\, \mathsf{y}^*_D(\alpha_R).$$

The writing by the stations of the room, with the bunch letters $K_{(D)}$ and the room letters y_D, is a level factorization with nonnegative terms (Definition 21.15), the room-station factorization*; the writing by the stations of the bunch is the children factorization.*

(iv) Within one excess no two stations of $\mathcal{K}_i$ have proportional rows of H_i, and no two stations of $\mathcal{D}_i$ proportional columns.

(v) At the excesses 0 and $c(B)$ every pattern meets every room side in a basis (Theorem 12.19). H_0, respectively $H_{c(B)}$, is a single positive entry exactly when the weights of that level factor along these products, as for unit weights, for weights factoring across B and R and for tables determinantal over $\mathbb{R}$ or $\mathbb{C}$; when both do, the room child of the one station of excess 0 is $\mathcal{B}/R$ and that of excess $c(B)$ is $\mathcal{B}|B$ (Proposition 12.17), these tables carrying the weights of the room children of the two stations, and the seam letters at the two extremes are $K_{\mathcal{B}/R}$, $\Psi_{\mathcal{B}/R}$ and $K_{\mathcal{B}|B}$, $\Psi_{\mathcal{B}|B}$.

(vi) Swapping B and R transposes every H_i and reverses the excesses, $i \mapsto c(B) - i$; the seam letters of R are then those of the bunch R.

A compatible pair fills its rectangle: inside it every tuple of the bunch meets every tuple of the room, with weights of rank one. What the marks do not show is the pattern of the rectangles, which stations of the bunch meet which stations of the room. At an extreme excess every station of the bunch meets every station of the room, in one rectangle when the weights of that level factor; between the extremes a station need not meet every station of the other side, and the seam matrix H_i, not the marks, says how they meet.

Proposition 28.3 (The width ladder)**.** *In Definition 28.1:*

(i) $c(B) = 0$ exactly when B is a union of molecules of the table; there is one excess, every pattern meets every room side, and $K = \mathsf{x}_0^{\mathsf{T}} H_0\, \mathsf{y}_0$, $\Psi = \mathsf{x}_0^{*\mathsf{T}} H_0\, \mathsf{y}_0^*$. The seam is one rectangle $C \times D$ exactly when the weights factor across B and R, as for lists; then $K = h_{CD}\, \mathsf{x}_C\, \mathsf{y}_D$ and $\Psi = h_{CD}\, \mathsf{x}_C^*\, \mathsf{y}_D^*$: the letters factor over the bunch and the room.

(ii) $c(B) = 1$ exactly when there are two excesses, both extreme. Each is one rectangle exactly when the weights factor across B and R; then for the stations D_0 and D_1 of the excesses 0 and 1 the seam letters are $K_{(D_0)} = K_{\mathcal{B}/R}$, $K_{(D_1)} = K_{\mathcal{B}|B}$, $\Psi_{(D_0)} = \Psi_{\mathcal{B}/R}$ and $\Psi_{(D_1)} = \Psi_{\mathcal{B}|B}$, the room station letters are $\mathsf{y}_{D_0} = K_{\mathcal{B}|R}$ and $\mathsf{y}_{D_1} = K_{\mathcal{B}/B}$, these two tables carrying the multipliers, the largest 1, and the room-station factorization is the writing

$$K = K_{\mathcal{B}/R}\, K_{\mathcal{B}|R} + K_{\mathcal{B}|B}\, K_{\mathcal{B}/B}$$

of Theorem 19.4: the letter adds over two levels, and the seam is the hinge.

(iii) For $c(B) \geq 2$ the excesses $0 < i < c(B)$ can carry several rectangles.

At every width an excess with one station on one side has one station on the other, and the children at the patterns of each excess are equal, B being in level form, exactly when every transposition of two marks of B, fixing every other mark, carries the table (Proposition 14.12); then every excess is one rectangle.

28.2 Pieces, their laws, and the glue

The seam identity writes a family as a pairing of what the bunch presents to the room and what the room presents to the bunch, station by station. The pairing uses nothing of the exchange property and holds for pieces of any kind.

Definition 28.4 (Pieces with stations; their glue)**.** Let $N \geq 1$ and $c_1, \dots, c_N \geq 0$ be integers. A set of *stations* for N tables of the widths c_j is a family $\mathcal{D} = (\mathcal{D}_j)_{j=1}^{N}$ of finite sets graded by excesses, $\mathcal{D}_j = \bigsqcup_{i=0}^{c_j} \mathcal{D}_{j,i}$, with $\mathcal{D}_{j,0}$ and $\mathcal{D}_{j,c_j}$ nonempty; a station $D \in \mathcal{D}_{j,i}$ has the excess $i(D) = i$. A *piece* with the stations $\mathcal{D}$ on a finite set B, at exponents $(s_j, t_j)_j$ with $s_j, t_j \geq 0$, carries for every j and $D \in \mathcal{D}_j$ two nonzero polynomials V_{jD} and V^*_{jD} on B with nonnegative coefficients, its *seam letters* (positive letters, Definition 25.1, where their degree is positive), homogeneous of the degrees $d_j + i(D)$ and $d^*_j + c_j - i(D)$ for integers $d_j, d^*_j \geq 0$, and masses $\mathbf{m}_B$; its *wall* and its *top wall* are

$$\kappa_B = m_B - \sum_j \big(s_j d_j + t_j d^*_j\big), \qquad \kappa_B^{\mathrm{top}} = \sum_j (s_j + t_j) c_j - \kappa_B.$$

A *partner* is a piece with the same stations on a set R disjoint from B, read with the reversed excesses $c_j - i(D)$: its letters, the *room letters* L_{jD} and L^*_{jD} (as in Definition 21.15), have the degrees $e_j + c_j - i(D)$ and $e^*_j + i(D)$, and its wall is $\kappa_R = m_R - \sum_j (s_j e_j + t_j e^*_j)$. A *family of Newton words* is a sequence $(K_j, \Psi_j; s_j, t_j)_{j=1}^{N}$ of pairs of positive letters on one set with exponents $s_j, t_j \geq 0$, carrying masses; its word is $\prod_j K_j^{-s_j} \Psi_j^{-t_j}$ and its period is the period of that word (Definition 25.1). The *glue* of the piece and the partner is the family of Newton words on $B \sqcup R$ with the letters

$$K_j = \sum_{D \in \mathcal{D}_j} V_{jD}\, L_{jD}, \qquad \Psi_j = \sum_{D \in \mathcal{D}_j} V^*_{jD}\, L^*_{jD},$$

the exponents (s_j, t_j) and the masses $(\mathbf{m}_B, \mathbf{m}_R)$; its period is written $P_{B \sqcup R}(\mathbf{m})$, and its balance wall is $\kappa_R = \kappa_B^{\mathrm{top}}$. A piece is named by its set, or by a calligraphic letter $\mathcal{X}$ when several pieces are compared, and its objects carry that name.

By Proposition 28.2(iii) a bunch of a family of tables, with its seam letters $V_{jD} = K_{j,(D)}$ and $V^*_{jD} = \Psi_{j,(D)}$, is a piece with the stations of its room, $d_j = d_j(B)$ and $d^*_j = d^*_j(B)$; its room, with the room station letters $L_{jD} = \mathsf{y}_{jD}$ and $L^*_{jD} = \mathsf{y}^*_{jD}$, is a partner, $e_j = d_j(R)$ and $e^*_j = d^*_j(R)$; and their glue is the family. By (vi) the same holds with B and R swapped, on the stations $\mathcal{K}$. The walls are the walls κ_B and κ_R of the bunch and of the room, and the top wall is the top wall κ_B^{top} of the bunch (Definition 8.1). A glue need not be a family of tables; its period converges exactly when its Newton sum has the dimension $|B \sqcup R| - 1$ and the masses lie in its relative interior (Theorem 25.2), and every statement about pieces is a statement about the period.

Definition 28.5 (The law of a piece)**.** Let a piece on B with the stations $\mathcal{D}$ have exponents with $\sum_j (s_j + t_j) c_j > 0$. Its active letters (Definition 8.1) are K_j when $s_j > 0$ and Ψ_j when $t_j > 0$; every coordinate, share, pin, product and count indexed by a letter runs over the active letters only, an inactive letter entering no period. The *excess sums* are $V_j^{(i)} = \sum_{D \in \mathcal{D}_{j,i}} V_{jD}$ and $V_j^{*(i)} = \sum_{D \in \mathcal{D}_{j,i}} V^*_{jD}$, the superscript counting excesses. On Δ_B put

$$\gamma_B^{\rho} = \prod_j \Big(\frac{V_j^{(c_j)}}{V_j^{(0)}}\Big)^{s_j/(\kappa_B + \kappa_B^{\mathrm{top}})} \Big(\frac{V_j^{*(0)}}{V_j^{*(c_j)}}\Big)^{t_j/(\kappa_B + \kappa_B^{\mathrm{top}})},$$

$$\phi_B^\rho(du) = u^{\mathbf{m}_B-\mathbf{1}} \prod_j \big(V_j^{(0)}\big)^{-s_j} \big(V_j^{*(c_j)}\big)^{-t_j} \, (\gamma_B^\rho)^{-\kappa_B} \, d\omega_B(u),$$

$$\varrho_{jD}^\rho = \frac{V_{jD}}{V_j^{(0)} \, (\gamma_B^\rho)^{i(D)}}, \qquad \varrho_{jD}^{\rho *} = \frac{V_{jD}^*}{V_j^{*(c_j)} \, (\gamma_B^\rho)^{c_j - i(D)}},$$

the *scale of the piece*, homogeneous of degree one, the *scale form*, and the coordinates of the *seam vector* $\boldsymbol{\varrho}_B^\rho = (\varrho_{jD}^\rho, \varrho_{jD}^{\rho *})_{j,D}$, homogeneous of degree zero, with a coordinate ϱ_{jD}^ρ for each active K_j and $D \in \mathcal{D}_j$ and a coordinate $\varrho_{jD}^{\rho *}$ for each active Ψ_j and $D \in \mathcal{D}_j$. Its values, the *seam points*, lie on the *seam torus*: the set of the points $\mathbf{x} = (x_{jD}, x_{jD}^*)_{j,D}$ with positive coordinates on which $\sum_{D \in \mathcal{D}_{j,0}} x_{jD} = 1$ for every active K_j, $\sum_{D \in \mathcal{D}_{j,c_j}} x_{jD}^* = 1$ for every active Ψ_j, and

$$\prod_j \Big(\sum_{D \in \mathcal{D}_{j,c_j}} x_{jD} \Big)^{s_j} \Big(\sum_{D \in \mathcal{D}_{j,0}} x_{jD}^* \Big)^{t_j} = 1,$$

of dimension $n_{\mathcal{D}}$, the number of the coordinates less the number of the active letters less one, which is $2|\mathcal{D}| - 2N - 1$, $|\mathcal{D}| = \sum_j |\mathcal{D}_j|$, when every letter is active. The *law* of the piece is the image $(\boldsymbol{\varrho}_B^\rho)_* \phi_B^\rho$, a positive measure carried by the seam torus. Its Mellin transform, at shares $(\mathbf{a}, \mathbf{b}) = (a_{jD}, b_{jD})_{j,D}$ of the active letters,

$$\int_{\Delta_B} (\boldsymbol{\varrho}_B^\rho)^{-(\mathbf{a},\mathbf{b})} \, d\phi_B^\rho = \int \mathbf{x}^{-(\mathbf{a},\mathbf{b})} \, d\big((\boldsymbol{\varrho}_B^\rho)_* \phi_B^\rho\big)(\mathbf{x}), \qquad \mathbf{x}^{-(\mathbf{a},\mathbf{b})} = \prod_{j,D} x_{jD}^{-a_{jD}} \, {x_{jD}^*}^{-b_{jD}},$$

is the *seam function*, in $[0, \infty]$ at real shares and defined at complex shares wherever it converges absolutely. A partner has its scale, scale form, seam vector, law and seam function by the same definition, with its room letters and the reversed excesses.

The scale form is projective: its orthant form has the degree $m_B - \sum_j (s_j d_j + t_j d_j^*) - \kappa_B = 0$, so it is read on any section (Lemma 16.2). The seam points lie on the seam torus: the sums at the excesses 0 and c_j are 1 by definition, and the product is $(\gamma_B^\rho)^{\kappa_B + \kappa_B^{\mathrm{top}}} (\gamma_B^\rho)^{-\sum_j (s_j + t_j) c_j} = 1$. The scale of the piece is the geometric mean of the oriented extreme ratios of the active letters, each taken to the root of its width: K_j measures the scale by $(V_j^{(c_j)} / V_j^{(0)})^{1/c_j}$ and Ψ_j by $(V_j^{*(0)} / V_j^{*(c_j)})^{1/c_j}$, in the proportions $s_j c_j$ and $t_j c_j$; a letter of width zero does not see the scale. Any other positive scale $q \, \gamma_B^\rho$ of degree one, q a positive function of the seam vector, multiplies ϕ_B^ρ by $q^{-\kappa_B}$ and the coordinates of the seam vector by powers of q: a fixed bijection of the tori with a density, so the law is determined up to it. The scale named is canonical: it uses the seam letters of the active letters alone, treats the two letters alike, and is kept at the centre by the bijections exchanging the family (Proposition 28.6(iii)). With weights factoring at the extreme levels, $V_j^{(0)} = K_{\mathcal{B}_j/R}$, $V_j^{(c_j)} = K_{\mathcal{B}_j|B}$, $V_j^{*(0)} = \Psi_{\mathcal{B}_j/R}$ and $V_j^{*(c_j)} = \Psi_{\mathcal{B}_j|B}$ (Proposition 28.2(v)); so

$$\gamma_B^\rho = \prod_j \Big(\frac{K_{\mathcal{B}_j|B}}{K_{\mathcal{B}_j/R}} \Big)^{s_j/(\kappa_B + \kappa_B^{\mathrm{top}})} \Big(\frac{\Psi_{\mathcal{B}_j/R}}{\Psi_{\mathcal{B}_j|B}} \Big)^{t_j/(\kappa_B + \kappa_B^{\mathrm{top}})},$$

$$\phi_B^\rho(du) = u^{\mathbf{m}_B-\mathbf{1}} \prod_j K_{\mathcal{B}_j/R}^{-s_j} \Psi_{\mathcal{B}_j|B}^{-t_j} \, (\gamma_B^\rho)^{-\kappa_B} \, d\omega_B(u).$$

The law is read off the measure of Theorem 21.16. For the room-station factorization the letter vector is $\mathbf{V}(u) = \big(K_{j,(D)}(u), \Psi_{j,(D)}(u)\big)_{j,D}$; the density of ϕ_B^ρ against $u^{\mathbf{m}_B-\mathbf{1}} d\omega_B$ and the seam vector are functions of $\mathbf{V}(u)$, so the law is an image of the measure $\mathbf{V}_*\big(u^{\mathbf{m}_B-\mathbf{1}} d\omega_B(u)\big)$ with

a density. The seam vector forgets the seam letters of the inactive letters and, of the others, one constant for each active letter and the scale, $V_{jD} \mapsto \lambda^{i(D)} V_{jD}$ and $V^*_{jD} \mapsto \lambda^{c_j - i(D)} V^*_{jD}$: the directions that the pins of Lemma 28.7 fix, on which the scale form changes by constant factors.

Proposition 28.6 (Symmetries of a seam)**.** *Let a bijection g of the marks $\mathcal{E}$ of a family map B onto B' and R onto R'.*

(i) If g carries table j to table j' (Definition 11.13), it maps the patterns and the room sides of B of each excess in table j onto those of B' of the same excess in table j', stations onto stations and compatible pairs onto compatible pairs, and the station letters and seam letters of the image stations are those of the stations read at $g^*\alpha$, the normalization of the multipliers commuting with g.

(ii) If g exchanges table j with table j', the windows of B and B' correspond as in Lemma 14.10, and $p \mapsto B' \setminus g(p)$, $X \mapsto R' \setminus g(X)$ map the stations of B of excess i in table j onto those of B' of excess $c(B) - i$ in table j' and compatible pairs onto compatible pairs, the station letter x_C and the seam letter $K_{(D)}$ going to the station letter $\mathsf{x}^*_{C'}$ and the seam letter $\Psi_{(D')}$ of the image stations C', D', and back.

(iii) So the bijections that keep B and carry or exchange the family permute the stations of its seams, with their station letters and seam letters, up to the bijection. Let such a bijection also keep the masses. A carrying one maps the seam torus of B onto itself, permuting the coordinates, and keeps the law $(\boldsymbol{\varrho}^\rho_B)_* \phi^\rho_B$. An exchanging one, sending table j to table j', maps the seam torus of B at the lean $\boldsymbol{\delta}$ onto the seam torus of B at the lean $-\boldsymbol{\delta}$, the coordinates ϱ^ρ_{jD} of table j going to the coordinates $\varrho^{\rho *}_{j'D'}$ of table j' and back, and maps the law of B at $\boldsymbol{\delta}$ onto the law of B at $-\boldsymbol{\delta}$; at the centre it keeps the law. At the centre the potential is kept by the carrying and the exchanging maps alike, at a lean by the carrying maps (Proposition 11.14): the centre does not tell apart stations joined by a bijection carrying or exchanging the family, nor a lean stations joined by a carrying one.

At the centre two stations can lie in one orbit through an exchange and in different orbits at every lean: the centre sees them as one, a lean separates them. These are the confusable stations of the seam, the analogue for stations of the halves C_K, C_Ψ of a class of marks (Theorem 11.17); the seam carries them down the tree with the classes of marks (Theorem 14.20).

Lemma 28.7 (The seam function is the period of the seam word)**.** *On the* pins of the seam*, the letter totals $\sum_D a_{jD} = s_j$ for every active K_j and $\sum_D b_{jD} = t_j$ for every active Ψ_j and the* scale pin

$$\sum_{j,D} \Big(i(D)\, a_{jD} + \big(c_j - i(D)\big)\, b_{jD} \Big) = \kappa_B,$$

the seam function is the period at the masses $\mathbf{m}_B$ of the seam word $W_B(\mathbf{a}, \mathbf{b}) = \prod_{j,D} V_{jD}^{-a_{jD}} {V^*_{jD}}^{-b_{jD}}$ *(Definition 25.1):*

$$\int_{\Delta_B} (\boldsymbol{\varrho}^\rho_B)^{-(\mathbf{a},\mathbf{b})}\, d\phi^\rho_B = P_{W_B(\mathbf{a},\mathbf{b})}(\mathbf{m}_B) = \int_{\Delta_B} u^{\mathbf{m}_B - \mathbf{1}} \prod_{j,D} V_{jD}(u)^{-a_{jD}} V^*_{jD}(u)^{-b_{jD}}\, d\omega_B(u).$$

For the piece of a bunch of a family the seam word is the bunch word of the room-station factorization (Theorem 22.11), and its period on the pins is the Mellin transform of one law.

Lemma 28.8 (Absorbing a piece of any width)**.** *Let a piece on B with the stations $\mathcal{D}$ carry masses $\mathbf{m}_B$ and exponents $(s_j, t_j)_j$ with $\sum_j (s_j + t_j) c_j > 0$, its wall κ_B and its seam vector $\boldsymbol{\varrho}^\rho_B$, whose*

values are written $\mathbf{x} = (x_{jD}, x^*_{jD})_{j,D}$. *Let* g *be a mark outside* B, *the* stand-in *of the piece,* Z *a finite set disjoint from* $B \sqcup \{g\}$, $\mathbf{m}_Z$ *masses on* Z, *and* $f_1, \dots, f_p$ *positive continuous functions, each assigned to one active letter of the piece,* f_l *defined on* $(0,\infty)^Z \times (0,\infty)^{\mathcal{D}_j}$ *when its letter is* K_j *or* Ψ_j *and homogeneous of degree one in its second argument,* $f_l(\alpha_Z, \lambda\mathbf{y}) = \lambda\, f_l(\alpha_Z, \mathbf{y})$ *for* $\lambda > 0$, *with real exponents* a_l *such that the exponents assigned to each letter add to its exponent. In this statement write* $\mathbf{V}_l$ *for the vector of the seam letters of the letter of* f_l, $(V_{jD})_{D\in\mathcal{D}_j}$ *for* K_j *and* $(V^*_{jD})_{D\in\mathcal{D}_j}$ *for* Ψ_j; V_l *for its extreme excess sum,* $V^{(0)}_j$ *for* K_j *and* $V^{*(c_j)}_j$ *for* Ψ_j; *and* $\mathbf{x}_l(\alpha_g)$ *for the vector* $(x_{jD}\,\alpha_g^{\,i(D)})_D$ *for* K_j *and* $(x^*_{jD}\,\alpha_g^{\,c_j - i(D)})_D$ *for* Ψ_j. *Let* $H \ge 0$ *be a Borel function on* $(0,\infty)^p$. *If the form*

$$\omega = \alpha_B^{\mathbf{m}_B - \mathbf{1}} \alpha_Z^{\mathbf{m}_Z - 1}\, H\Big(\Big(\frac{f_l\big(\alpha_Z, \mathbf{V}_l(\alpha_B)\big)}{V_l(\alpha_B)}\Big)_l\Big) \prod_{l=1}^{p} f_l\big(\alpha_Z, \mathbf{V}_l(\alpha_B)\big)^{-a_l}\, d\alpha_B\, d\alpha_Z$$

is homogeneous of degree zero on $(0,\infty)^{B\sqcup Z}$, *then, in* $[0,\infty]$,

$$\int_{\{h=1\}} \omega = \int \Big(\int_{\{h'=1\}} \omega_{\mathbf{x}} \Big)\, d\big((\boldsymbol{\varrho}^\rho_B)_* \phi^\rho_B\big)(\mathbf{x}),$$
$$\omega_{\mathbf{x}} = \alpha_Z^{\mathbf{m}_Z - \mathbf{1}} \alpha_g^{\kappa_B - 1}\, H\Big(\big(f_l(\alpha_Z, \mathbf{x}_l(\alpha_g))\big)_l\Big) \prod_l f_l\big(\alpha_Z, \mathbf{x}_l(\alpha_g)\big)^{-a_l}\, d\alpha_Z\, d\alpha_g,$$

the integrals taken over any sections of positive functions h, h' *of degree one on the two orthants.*

The piece collapses to its stand-in g, which carries the mass κ_B; a letter of table j that sees the piece sees the stand-in with the degree c_j, at its stations twisted by the seam point. At width one this is Lemma 23.2 read through Proposition 28.11.

Lemma 28.9 (The native split at the stations)**.** *Let a family of tables have real data on its balance wall, with* $s_j, t_j \ge 0$, *not all zero, and* $\mathbf{m} > 0$, *and a native gauge* $\alpha^\star$ *(Definition 8.17),* B *a bunch with* $\sum_j (s_j + t_j) c_j(B) > 0$, *and put, for the active letters,*

$$a_{jD} = s_j\, \mathbb{P}_{j,\alpha^\star}(T \cap R \in D), \qquad b_{jD} = t_j\, \mathbb{P}^*_{j,\alpha^\star}(T \cap R \in D), \qquad D \in \mathcal{D}_j,$$

the native split (Definition 12.25) aggregated to the stations of room sides. Then $(\mathbf{a}, \mathbf{b})$ *is a point of the pins of the seam with positive coordinates, at which* $\mathbf{m}_B$ *and* $\mathbf{m}_R$ *lie in the relative interiors of the Newton sums of the bunch word and of the room word (Theorem 22.11); the two words converge there exactly when these Newton sums have the full dimensions* $|B|-1$ *and* $|R|-1$ *(Theorem 25.2).*

Theorem 28.10 (The glue across a seam)**.** *Let a piece on* B *and a partner on* R *with the stations* $\mathcal{D}$ *be glued, with masses on the balance wall of the glue and* $\sum_j (s_j + t_j) c_j > 0$.

(i) The piece absorbed. *In* $[0,\infty]$,

$$P_{B\sqcup R}(\mathbf{m}) = \int P_{R^{(\mathbf{x})}}(\mathbf{m}_R, \kappa_B)\, d\big((\boldsymbol{\varrho}^\rho_B)_* \phi^\rho_B\big)(\mathbf{x}),$$

with $R^{(\mathbf{x})}$ *the* partner with its stand-in at $\mathbf{x}$*: the family of Newton words on* $R \sqcup \{g\}$ *with the letters* $\sum_D x_{jD}\, \alpha_g^{\,i(D)} L_{jD}$ *and* $\sum_D x^*_{jD}\, \alpha_g^{\,c_j - i(D)} L^*_{jD}$, *the exponents* (s_j, t_j) *and the mass* κ_B *on* g.

(ii) Both absorbed. *On the scales $\{g\}$ and one scale for each active letter let $t_{\mathcal{D}}$ be the configuration whose column at the coordinate (j,D) of K_j is $i(D)\,\mathbf{e}_g+\mathbf{e}_{K_j}$ and at that of Ψ_j is $(c_j-i(D))\,\mathbf{e}_g+\mathbf{e}_{\Psi_j}$. In $[0,\infty]$,*

$$P_{B\sqcup R}(\mathbf{m})=\iint \Gamma(\kappa_B)\,\mathsf{Z}_{(\kappa_B,\mathbf{s},\mathbf{t});t_{\mathcal{D}}}(\mathbf{x}\circ\mathbf{x}')\,d\big((\boldsymbol{\varrho}_B^{\rho})_*\phi_B^{\rho}\big)(\mathbf{x})\,d\big((\boldsymbol{\varrho}_R^{\rho})_*\phi_R^{\rho}\big)(\mathbf{x}'),$$

$\mathbf{x}\circ\mathbf{x}'$ the coordinatewise product and the index $(\kappa_B,\mathbf{s},\mathbf{t})$ read on the active letters (Definition 2.12). The kernel is the period of the stand-in pair*, the marks g and g' with the masses κ_B and κ_R and the letters $\sum_D x_{jD}x'_{jD}\,\alpha_g^{i(D)}\alpha_{g'}^{c_j-i(D)}$ and $\sum_D x^*_{jD}x'^*_{jD}\,\alpha_g^{c_j-i(D)}\alpha_{g'}^{i(D)}$, read on one scale:*

$$\Gamma(\kappa)\,\mathsf{Z}_{(\kappa,\mathbf{s},\mathbf{t});t_{\mathcal{D}}}(\mathbf{x}\circ\mathbf{x}')=\int_0^{\infty}v^{\kappa-1}\prod_j\Big(\sum_{D\in\mathcal{D}_j}x_{jD}x'_{jD}\,v^{i(D)}\Big)^{-s_j}\Big(\sum_{D\in\mathcal{D}_j}x^*_{jD}x'^*_{jD}\,v^{c_j-i(D)}\Big)^{-t_j}dv.$$

(iii) One share per station. *On every contour of shares a_{jD}, b_{jD} of the active letters with positive real parts, on the pins of the seam (Lemma 28.7), which on the balance wall are the pins of the partner as well, at which the seam functions of the piece and of the partner converge,*

$$P_{B\sqcup R}(\mathbf{m})=\int_{pins}\prod_{j:\,s_j>0}\Gamma_{|\mathcal{D}_j|}\begin{bmatrix}\mathbf{a}_j\\ s_j\end{bmatrix}\prod_{j:\,t_j>0}\Gamma_{|\mathcal{D}_j|}\begin{bmatrix}\mathbf{b}_j\\ t_j\end{bmatrix}\int_{\Delta_B}(\boldsymbol{\varrho}_B^{\rho})^{-(\mathbf{a},\mathbf{b})}\,d\phi_B^{\rho}\int_{\Delta_R}(\boldsymbol{\varrho}_R^{\rho})^{-(\mathbf{a},\mathbf{b})}\,d\phi_R^{\rho},$$

a fibre integral of the dimension $n_{\mathcal{D}}$ of the seam torus: the two seam functions are evaluated at the same shares, one per station and letter.

Parts (i) and (ii) hold in every case; (iii) needs a point of the pins at which both seam functions are finite. Full dimension of the Newton sums of the seam word and of the room word is necessary for it (Theorem 25.2), and when the glue is a family of tables with a native gauge, every proper wall positive, it is sufficient, the native split at the stations being such a point (Lemma 28.9); without it the share side carries one pin more for each direction that a side does not see (Theorem 28.12 below).

The glue is one pairing at every width: the bunch is a law on its seam torus, the room another, and the kernel is the period of two stand-in marks whose letters pair the stations. At width one the seam torus has one dimension less than the number of active letters, a half-line for one table with $s,t>0$ and $(0,\infty)^{2N-1}$ when every letter is active (Proposition 28.11), and the kernel is the period of two marks in every table (Lemma 23.7, Theorem 23.6(i)); at the width c the seam torus has the dimension $n_{\mathcal{D}}$ and the kernel is one scale with at most c_j+1 levels in the letters of table j, exactly c_j+1 for a table. Opened on its shares, the glue is the product of the two seam functions against the share kernels of Corollary 4.4, one for each active letter.

Proposition 28.11 (Width one is the hinge)**.** *Let B have width one in every table of a family with exponents $s_j,t_j>0$, the weights factoring across B and R, $\theta_{j,T}=\theta'_{j,T\cap B}\,\theta''_{j,T\cap R}$, with θ''_j of largest value 1 on the room sides of each excess, so that θ''_j gives the multipliers of the room sides (Definition 28.1), with the stations D_0 and D_1 of the excesses 0 and 1 in every table (Proposition 28.3(ii)), the hinge values $\gamma^K_{j,B}$, $\gamma^{\Psi}_{j,B}$ of Definition 19.2, and the cell family $F_B^+=((\mathcal{B}^+_{j,B},\theta'_j);s_j,t_j)_j$ of the bunch (Definition 23.1), with its hinge wall κ_B, base form $\phi_{F_B^+}$ and ratio vector $\boldsymbol{\varrho}_{F_B^+}$, whose values are written $\mathbf{x}=(x_{j,K},x_{j,\Psi})_j$, $x_{1,K}=1$. In this statement write $\psi(\mathbf{x})=\prod_j x_{j,K}^{s_j/(2\sigma)}x_{j,\Psi}^{t_j/(2\sigma)}$, $\sigma=\sum_j\sigma_j$ the total strength (Definition 8.1).*

(i) $\gamma^{\rho}_{B} = \prod_j (\gamma^{K}_{j,B})^{s_j/(2\sigma)} (\gamma^{\Psi}_{j,B})^{t_j/(2\sigma)} = \gamma^{K}_{1,B}\,\psi(\boldsymbol{\varrho}_{F^+_B})$ *and* $\phi^{\rho}_{B} = \psi(\boldsymbol{\varrho}_{F^+_B})^{-\kappa_B}\,\phi_{F^+_B}$.

(ii) The seam vector of the piece has $\varrho^{\rho}_{jD_0} = \varrho^{\rho*}_{jD_1} = 1$, $\varrho^{\rho}_{jD_1} = x_{j,K}/\psi(\mathbf{x})$ *and* $\varrho^{\rho*}_{jD_0} = x_{j,\Psi}/\psi(\mathbf{x})$ *at* $\mathbf{x} = \boldsymbol{\varrho}_{F^+_B}$*; the map* $\mathbf{x} \mapsto \big(x_{j,K}/\psi(\mathbf{x}),\, x_{j,\Psi}/\psi(\mathbf{x})\big)_j$ *is a bijection of* $(0,\infty)^{2N-1}$ *onto the seam torus, and under it the law* $(\boldsymbol{\varrho}^{\rho}_{B})_*\phi^{\rho}_{B}$ *is the image of* $\psi^{-\kappa_B}$ *times the law* $(\boldsymbol{\varrho}_{F^+_B})_*\phi_{F^+_B}$ *of the cell family.*

(iii) The partner with its stand-in at the seam point of $\mathbf{x}$ *is, after* $\alpha_g \mapsto \psi(\mathbf{x})\,\alpha_g$*, the family* $((\mathcal{B}^{+}_{j,R}, \theta''_j); s_j, t_j)_j$ *of the cells of the room twisted at* g *by* $\mathbf{x}$*,* $x_{j,K}$ *in* K_j *and* $x_{j,\Psi}$ *in* Ψ_j *(Definition 22.1); the change of variable multiplies* $\alpha_g^{\kappa_B - 1} d\alpha_g$ *by* $\psi(\mathbf{x})^{\kappa_B}$*, which cancels the density of (ii), and Lemma 28.8 is Lemma 23.2 for the cell family* F^{+}_{B}.

(iv) The room, read as the partner, has the same description through the cell family $F^{+}_{R} = ((\mathcal{B}^{+}_{j,R}, \theta''_j); s_j, t_j)_j$ *of the room, with its hinge wall* κ_R *and ratio vector* $\boldsymbol{\varrho}_{F^+_R}$*, whose values are written* $\mathbf{x}'$*,* $x'_{1,K} = 1$*: its scale is* $\gamma^{K}_{1,R}\,\psi(\boldsymbol{\varrho}_{F^+_R})$*, its scale form* $\psi(\boldsymbol{\varrho}_{F^+_R})^{-\kappa_R}\phi_{F^+_R}$*, its seam vector has* $\varrho^{\rho}_{jD_1} = \varrho^{\rho*}_{jD_0} = 1$, $\varrho^{\rho}_{jD_0} = x'_{j,K}/\psi(\mathbf{x}')$ *and* $\varrho^{\rho*}_{jD_1} = x'_{j,\Psi}/\psi(\mathbf{x}')$ *at* $\mathbf{x}' = \boldsymbol{\varrho}_{F^+_R}$*, and its law is the image of* $\psi^{-\kappa_R}$ *times the law* $(\boldsymbol{\varrho}_{F^+_R})_*\phi_{F^+_R}$ *under the bijection of (ii). At the seam points the coordinate ratios* $\varrho^{\rho*}_{jD_0}/\varrho^{\rho}_{jD_1}$ *of the piece and* $\varrho^{\rho*}_{jD_1}/\varrho^{\rho}_{jD_0}$ *of the partner are the ratios* $\varrho_{j,B}$ *and* $\varrho_{j,R}$ *of Definition 19.2. At the seam points* $\mathbf{p}$ *of the piece and* $\mathbf{p}'$ *of the partner that are the images of* $\mathbf{x}$ *and* $\mathbf{x}'$*,*

$$\begin{aligned}\Gamma(\kappa_B)\,\mathsf{Z}_{(\kappa_B,\mathbf{s},\mathbf{t});t_{\mathcal{D}}}(\mathbf{p}\circ\mathbf{p}') &= \int_0^{\infty} v^{\kappa_B-1} \prod_j \Big(\frac{x_{j,K}\,v}{\psi(\mathbf{x})} + \frac{x'_{j,K}}{\psi(\mathbf{x}')}\Big)^{-s_j} \Big(\frac{x_{j,\Psi}\,v}{\psi(\mathbf{x})} + \frac{x'_{j,\Psi}}{\psi(\mathbf{x}')}\Big)^{-t_j} dv \\ &= \psi(\mathbf{x})^{\kappa_B}\psi(\mathbf{x}')^{\kappa_R}\,P_{F_{\mathcal{H}}[(\mathbf{x},\mathbf{x}')]}\big((\kappa_B,\kappa_R);\mathbf{s},\mathbf{t}\big),\end{aligned}$$

$F_{\mathcal{H}}[(\mathbf{x},\mathbf{x}')]$ the core $\binom{\{g,g'\}}{1}$ *in every table twisted at g by $\mathbf{x}$ and at g' by $\mathbf{x}'$, with the masses κ_B and κ_R (Theorem 23.6(i)). So Theorem 28.10(i) is Lemma 23.2 at the hinge, by part (iii); Theorem 28.10(ii) is Theorem 23.6(i) with that core and the cell families F^{+}_{B} at g and F^{+}_{R} at g', the factor $\psi(\mathbf{x})^{\kappa_B}\psi(\mathbf{x}')^{\kappa_R}$ cancelling the densities of the two laws; and Theorem 28.10(iii) is Theorem 19.13.*

At width one the scale of the piece is the geometric mean of the hinge values in the proportions of the exponents, and the general law is the law of the cell family of the bunch with a fixed power of its ratio vector as density. Every statement about pieces therefore specializes to its statement about cells through this one fixed change, and the calculus of cells (Chapter 23) is the case of width one of the calculus of pieces.

Theorem 28.12 (The share side with transverse pins)**.** *In Theorem 28.10(iii), the period of the glue converging, so that its Newton sum has full dimension (Theorem 25.2), let* $\vec{\mathcal{N}}_B \subseteq \mathbb{R}^B$ *and* $\vec{\mathcal{N}}_R \subseteq \mathbb{R}^R$ *be the spaces of the directions of the Newton sums of the seam word of the piece and of the room word of the partner at shares with positive real parts, which do not depend on the shares, and* $M = \vec{\mathcal{N}}_B^{\perp} \oplus \vec{\mathcal{N}}_R^{\perp} \subseteq \mathbb{R}^{B \sqcup R}$*, which contains* $\mathbf{1}$*; let* $\mathbf{v}_1, \ldots, \mathbf{v}_q$ *complete* $\mathbf{1}$ *to a basis of the lattice* $M \cap \mathbb{Z}^{B\sqcup R}$*. For every active letter and station fix the exponents* $\mathbf{n}_{jD}$*,* $\mathbf{n}^{*}_{jD}$*,* $\mathbf{n}'_{jD}$ *and* $\mathbf{n}'^{*}_{jD}$ *of one monomial of each of* V_{jD}*,* V^{*}_{jD}*,* L_{jD} *and* L^{*}_{jD}*, and in this statement write*

$$\mathbf{n}(\mathbf{a},\mathbf{b}) = \sum_{j,D} \Big(a_{jD}\big(\mathbf{n}_{jD} + \mathbf{n}'_{jD}\big) + b_{jD}\big(\mathbf{n}^{*}_{jD} + \mathbf{n}'^{*}_{jD}\big)\Big),$$

which modulo $\vec{\mathcal{N}}_B \oplus \vec{\mathcal{N}}_R$ *does not depend on the monomials fixed. For a word* W *on* B *whose Newton sum has the space of directions* $\vec{\mathcal{N}}_B$*, its* reduced period *is*

$$P^\flat_W(\mathbf{m}_B) = \int_{\mathbb{R}^B/\vec{\mathcal{N}}_B^\perp} e^{\langle \mathbf{m}_B, y\rangle}\, W(e^y)\, dy,$$

dy the quotient of Lebesgue measure by the measure on $\vec{\mathcal{N}}_B^\perp$ *that gives its integer lattice the covolume one; likewise on* R*. On every contour of shares of the active letters with positive real parts, pinned by the letter totals and by* $\langle \mathbf{n}(\mathbf{a},\mathbf{b}), \mathbf{v}_l\rangle = \langle \mathbf{m}, \mathbf{v}_l\rangle$*,* $l \le q$*, pins that are independent by the full dimension, at which the reduced periods of the two words converge,*

$$P_{B\sqcup R}(\mathbf{m}) = \int_{pins} \prod_{j:\, s_j>0} \Gamma_{|\mathcal{D}_j|}\begin{bmatrix}\mathbf{a}_j\\ s_j\end{bmatrix} \prod_{j:\, t_j>0} \Gamma_{|\mathcal{D}_j|}\begin{bmatrix}\mathbf{b}_j\\ t_j\end{bmatrix}\; P^\flat_{W_B(\mathbf{a},\mathbf{b})}(\mathbf{m}_B)\, P^\flat_{W_R(\mathbf{a},\mathbf{b})}(\mathbf{m}_R),$$

$W_R(\mathbf{a},\mathbf{b}) = \prod_{j,D} L_{jD}^{-a_{jD}} {L^*_{jD}}^{-b_{jD}}$ *the room word of the partner; on the pins the integrands of the reduced periods are invariant under* $\vec{\mathcal{N}}_B^\perp$ *and* $\vec{\mathcal{N}}_R^\perp$*. When* $\vec{\mathcal{N}}_B$ *and* $\vec{\mathcal{N}}_R$ *are the hyperplanes of sum zero,* $q = 1$*, the pin is the scale pin, the reduced periods are the periods, and this is Theorem 28.10(iii). When every room letter of the partner is a monomial, as for the room of a table whose stations of room sides are single room sides, with the coefficients* 1*,* $\vec{\mathcal{N}}_R = 0$*, the pins on* R *say that the exponent of the partner's monomials is* $\mathbf{m}_R$*, and the reduced period of the partner is the product of the coefficients of these monomials raised to minus the shares.*

So a degenerate seam word or room word costs pins, not convergence: the directions that a side does not see are fixed by the masses, one pin each, and the integral over them is gone.

28.3 The Gramma of a set of pairs

The station letters are what the bunch is; the seam letters are what the room sees. The seam joins the two, and its compatible pairs enter the period through one Gramma.

Definition 28.13 (The Gramma of a set of pairs)**.** Let $\mathfrak{R} \subseteq \mathcal{K}\times\mathcal{D}$ be a set of pairs of stations of two finite sets, every station in some pair, with coefficients $h_{CD} > 0$ on its pairs. Its *station map* sends $\mathbf{e} = (e_{CD}) \in \mathbb{C}^{\mathfrak{R}}$ to $\partial\mathbf{e}$, with $(\partial\mathbf{e})_C = \sum_D e_{CD}$ and $(\partial\mathbf{e})_D = \sum_C e_{CD}$. Two pairs lie in one *part* when a chain of pairs, each sharing a station with the next, joins them; a *circuit* is a minimal set of pairs whose columns $\mathbf{e}_C + \mathbf{e}_D$ are linearly dependent, which is the set of pairs of a closed chain $C_1D_1C_2D_2\cdots C_mD_mC_1$, $m \ge 2$, of distinct stations with (C_l, D_l) and (C_{l+1}, D_l) in $\mathfrak{R}$. Choose one station of $\mathcal{D}$ in each part, and call the other stations *kept*. For *loads* $(\mathbf{a},\mathbf{a}') \in \mathbb{C}^{\mathcal{K}}\oplus\mathbb{C}^{\mathcal{D}}$ whose totals on the two sides of every part agree, the *Gramma of* $\mathfrak{R}$ is the Gramma $\mathsf{G}_{(\mathbf{a},\mathbf{a}');\partial\mathfrak{R}}(\mathbf{h})$ (Definition 2.1) on the scales of the kept stations whose configuration $\partial\mathfrak{R}$ has at the pair (C,D) the column $\mathbf{e}_C + \mathbf{e}_D$, a station that is not kept read as 0, whose index is the loads of the kept stations, and whose coefficients are the h_{CD}. By Proposition 4.2 it is the fibre integral

$$\mathsf{G}_{(\mathbf{a},\mathbf{a}');\partial\mathfrak{R}}(\mathbf{h}) = \int_{\partial\mathbf{e}=(\mathbf{a},\mathbf{a}')} \prod_{(C,D)\in\mathfrak{R}} \Gamma(e_{CD})\, h_{CD}^{-e_{CD}},$$

pinned by the sums at the kept stations, which imply the others. Another choice of the stations not kept changes the pins by an integer matrix of determinant ±1, which leaves the fibre integral unchanged; its dimension is $|\mathfrak{R}| - |\mathcal{K}| - |\mathcal{D}|$ plus the number of parts. The *seam Gramma* of the excess i is the Gramma of the set $\mathfrak{R}_i$ of the compatible pairs of H_i, with the pair constants as its coefficients.

Proposition 28.14 (The seam transfers the station loads of the bunch to those of the room)**.** *For a bunch of a family let the* station word *of the bunch be* $\prod_{j,C} \mathsf{x}_{jC}^{-a_{jC}} {\mathsf{x}^*_{jC}}^{-b_{jC}}$*, with the station loads* a_{jC} *of the active* K_j *and* b_{jC} *of the active* Ψ_j *on the pins* $\sum_C a_{jC} = s_j$*,* $\sum_C b_{jC} = t_j$ *and* $\sum_{j,C} \big(i(C)a_{jC} + (c_j - i(C))b_{jC}\big) = \kappa_B$*, and let the station loads* a_{jD} *and* b_{jD} *of the room be shares on the pins of the seam (Lemma 28.7). On contours of positive real parts at which the station word of the bunch converges,*

$$\prod_{j:\, s_j>0} \prod_{D\in\mathcal{D}_j} \Gamma(a_{jD}) \prod_{j:\, t_j>0} \prod_{D\in\mathcal{D}_j} \Gamma(b_{jD})\; P_{W_B(\mathbf{a},\mathbf{b})}(\mathbf{m}_B)$$
$$= \int \prod_{j:\, s_j>0} \prod_{i=0}^{c_j} \mathsf{G}_{(\mathbf{a}_{j,\mathcal{K}_i},\mathbf{a}_{j,\mathcal{D}_i});\partial\mathfrak{R}_{j,i}}(\mathbf{h}_j) \prod_{j:\, t_j>0} \prod_{i=0}^{c_j} \mathsf{G}_{(\mathbf{b}_{j,\mathcal{K}_i},\mathbf{b}_{j,\mathcal{D}_i});\partial\mathfrak{R}_{j,i}}(\mathbf{h}_j)\; P_{\prod_{j,C} \mathsf{x}_{jC}^{-a_{jC}} {\mathsf{x}^*_{jC}}^{-b_{jC}}}(\mathbf{m}_B),$$

the integral over the station loads of the bunch with equal totals on the two sides of every part of every set $\mathfrak{R}_{j,i}$ *of the compatible pairs of table* j *at the excess* i*,* $\mathbf{h}_j$ *its pair constants.*

Along a circuit the pair terms $h_{CD}\,\mathsf{x}_C\,\mathsf{y}_D$ of a level have the alternating product $\prod_l h_{C_lD_l}/h_{C_{l+1}D_l}$, a constant: a direction $\mathbf{e}$ of the pair shares with $\partial\mathbf{e} = 0$ moves neither the station loads of the bunch, which the bunch sees, nor those of the room, which the room sees, and the period integrates over it through the seam Gramma alone. A part without circuits has a fibre of dimension zero, and its Gramma is the product $\prod \Gamma(e_{CD}) h_{CD}^{-e_{CD}}$ at the one solution of $\partial\mathbf{e} = (\mathbf{a}, \mathbf{a}')$ (Corollary 2.6).

Proposition 28.15 (The Gramma of a set of pairs in the Foreman's order)**.** *Let* $\mathfrak{R}$ *have the parts* $\mathfrak{R}_1, \dots, \mathfrak{R}_\nu$*, the part* $\mathfrak{R}_l$ *on the stations* $\mathcal{K}_l \sqcup \mathcal{D}_l$*, and loads with* $|\mathbf{a}_{\mathcal{K}_l}| = |\mathbf{a}'_{\mathcal{D}_l}|$ *for every* l*; in this statement write* $L_C(v) = \sum_{D:\,(C,D)\in\mathfrak{R}} h_{CD}\, v_D$ *for* $C \in \mathcal{K}_l$ *and* $v \in \Delta_{\mathcal{D}_l}$*. Then*

$$\mathsf{G}_{(\mathbf{a},\mathbf{a}');\partial\mathfrak{R}}(\mathbf{h}) = \prod_{C\in\mathcal{K}} \Gamma(a_C) \prod_{l=1}^{\nu} \int_{\Delta_{\mathcal{D}_l}} v^{\mathbf{a}'_{\mathcal{D}_l}-\mathbf{1}} \prod_{C\in\mathcal{K}_l} L_C(v)^{-a_C}\, d\omega_{\mathcal{D}_l}(v)$$
$$= \prod_{C\in\mathcal{K}} \Gamma(a_C) \prod_{l=1}^{\nu} P_{\prod_{C\in\mathcal{K}_l} L_C^{-a_C}}(\mathbf{a}'_{\mathcal{D}_l}),$$

both sides converging together, the period of the part l *being that of the word* $\prod_{C\in\mathcal{K}_l} L_C^{-a_C}$ *on* $\mathcal{D}_l$ *at the masses* $\mathbf{a}'_{\mathcal{D}_l}$*; with* $\operatorname{Re} a_C > 0$ *it converges exactly when, for every* l*,* $\operatorname{Re}\mathbf{a}'_{\mathcal{D}_l}$ *lies in the relative interior of* $\sum_{C\in\mathcal{K}_l} \operatorname{Re} a_C \operatorname{conv}\{\mathbf{e}_D :\ (C,D)\in\mathfrak{R}\}$ *(Theorem 25.2).*

The stations of the bunch are integrated first, each on its half-line, and those of the room last, on the simplex of each part: the Foreman's order of Definition 16.14, the bunch inside the integral over its room. For a seam the inner step returns, at each station C of the bunch, its child letter $K_{(C)} = \sum_D h_{CD}\,\mathsf{y}_D$ with every room station letter y_D replaced by a scale v_D. No station is singled out and no order is chosen.

Proposition 28.16 (Closing the Gramma of a set of pairs)**.** *In Proposition 28.15 let the loads be real and positive in the domain for (i) and (iii); in this statement write, for a part* $\mathfrak{R}_l$*,* $L_C(v) = \sum_{D:\,(C,D)\in\mathfrak{R}} h_{CD}\, v_D$ *for* $C \in \mathcal{K}_l$ *and* $v \in \Delta_{\mathcal{D}_l}$*,* $M_C = \max_D h_{CD}$ *for its largest coefficient, its largest value on the simplex, and* $\mathsf{G}_{(\mathbf{a},\mathbf{a}')}$ *for* $\mathsf{G}_{(\mathbf{a},\mathbf{a}');\partial\mathfrak{R}}(\mathbf{h})$*.*

(i) Peak closing. *For every part* $\mathfrak{R}_l$*, with* $\bar{L}_C = 1 - L_C/M_C \geq 0$ *on* $\Delta_{\mathcal{D}_l}$*,*

$$\int_{\Delta_{\mathcal{D}_l}} v^{\mathbf{a}'_{\mathcal{D}_l}-\mathbf{1}} \prod_{C\in\mathcal{K}_l} L_C(v)^{-a_C}\, d\omega_{\mathcal{D}_l}(v)$$
$$= \prod_{C\in\mathcal{K}_l} M_C^{-a_C}\, \Gamma_{\substack{|\mathcal{D}_l|\\1}}\!\begin{bmatrix}\mathbf{a}'_{\mathcal{D}_l}\\ |\mathbf{a}'_{\mathcal{D}_l}|\end{bmatrix} \sum_{\mathbf{n}\in\mathbb{N}^{\mathcal{K}_l}} \prod_{C\in\mathcal{K}_l} \frac{(a_C)_{n_C}}{n_C!}\; \mathbb{E}_{V\sim \mathrm{Dir}_{\mathbf{a}'_{\mathcal{D}_l}}}\Big[\prod_{C\in\mathcal{K}_l} \bar{L}_C(V)^{n_C}\Big],$$

a series of nonnegative terms, each a finite nonnegative combination of Dirichlet moments (Theorem 3.11), rational at rational loads and coefficients; it is Theorem 15.13(i) with the sharp references M_C, and $\mathsf{G}_{(\mathbf{a},\mathbf{a}')}$ is $\prod_C \Gamma(a_C)$ times the product of these right sides over the parts.

(ii) Relations at shifted loads. *At all loads in the domain, real or complex, for every C and D,*

$$a_C\, \mathsf{G}_{(\mathbf{a},\mathbf{a}')} = \sum_{D'\colon (C,D')\in\mathfrak{R}} h_{CD'}\, \mathsf{G}_{(\mathbf{a}+\mathbf{e}_C,\, \mathbf{a}'+\mathbf{e}_{D'})},$$
$$a'_D\, \mathsf{G}_{(\mathbf{a},\mathbf{a}')} = \sum_{C'\colon (C',D)\in\mathfrak{R}} h_{C'D}\, \mathsf{G}_{(\mathbf{a}+\mathbf{e}_{C'},\, \mathbf{a}'+\mathbf{e}_D)}.$$

(iii) Residues. *A part that is one circuit $C_1D_1\cdots C_mD_m$ has one share z moving round the circuit with alternating signs: for a real point $\mathbf{q}$ of the fibre the pairs (C_l, D_l) carry $q_l + z$ and the pairs (C_{l+1}, D_l) carry $q'_l - z$. With $x = \prod_l h_{C_lD_l}/h_{C_{l+1}D_l}$ and $\Sigma = \sum_l (q_l + q'_l)$, the total load of the part, its Gramma is a constant times*

$$\frac{1}{2\pi i}\int_{(0)} x^{-z} \prod_{l=1}^{m} \Gamma(q_l + z)\, \Gamma(q'_l - z)\, dz.$$

If $x < 1$, or $x = 1$ and $\Sigma < m$, the contour moves to the left across the poles of the $\Gamma(q_l + z)$, and if $x > 1$, or $x = 1$ and $\Sigma < m$, to the right across those of the $\Gamma(q'_l - z)$ (Theorem 4.5): the Gramma is the limit of the sums of the residues at the poles crossed, a series over m lattices, absolutely convergent when $x \neq 1$ or $\Sigma < m - 1$. The residue at a simple pole is a product of the other Gammas at the shifted point, and where poles of several factors meet, the q_l being congruent modulo $\mathbb{Z}$, it is a Laurent coefficient. At $x = 1$ with $\Sigma \geq m$ the shifted contours need not tend to zero and the residues need not sum.

Theorem 28.17 (Shares inside the rectangles close)**.** *Fix a table and an excess i, and give every basis T of excess i a share a_T. For pattern loads $\mathbf{a}^B = (a^B_p)_p$ and room-side loads $\mathbf{a}^R = (a^R_X)_X$ whose station loads $a^B_C = \sum_{p\in C} a^B_p$ and $a^R_D = \sum_{X\in D} a^R_X$ have equal totals on every part of $\mathfrak{R}_i$, on contours of positive real parts,*

$$\int_{\sum_X a_{p\sqcup X}=a^B_p,\ \sum_p a_{p\sqcup X}=a^R_X} \prod_T \Gamma(a_T)\, \theta_T^{-a_T}$$
$$= \prod_{C\in\mathcal{K}_i} \Gamma_{\substack{|C|\\1}}\!\begin{bmatrix}\mathbf{a}^B|_C\\ a^B_C\end{bmatrix} \prod_p w_p^{-a^B_p} \prod_{D\in\mathcal{D}_i} \Gamma_{\substack{|D|\\1}}\!\begin{bmatrix}\mathbf{a}^R|_D\\ a^R_D\end{bmatrix} \prod_X {w'_X}^{-a^R_X}\; \mathsf{G}_{(\mathbf{a}^B_{\mathcal{K}_i},\mathbf{a}^R_{\mathcal{D}_i});\partial\mathfrak{R}_i}(\mathbf{h}),$$

$\mathbf{a}^B_{\mathcal{K}_i}$ and $\mathbf{a}^R_{\mathcal{D}_i}$ the vectors of the station loads, the fibre on the left pinned by these sums at all patterns and at all room sides but one in each part of $\mathfrak{R}_i$, which imply the others.

Inside the rectangle of a compatible pair the shares spread freely and close to stacked Gammas, one for each station; what does not close is how the stations share one another, the seam Gramma.

28.4 What a piece retains

Definition 28.18 (Tinkers)**.** A *tinker* of a partner $\mathcal{Y}$ with the stations $\mathcal{D}$ is a vector $\mathbf{v} = (v_{jD}, v^*_{jD})_{j,D}$ of positive numbers, one for each coordinate of the seam vector; the *tinkered partner* $\mathcal{Y}_{\mathbf{v}}$ has the room letters $v_{jD}L_{jD}$ and $v^*_{jD}L^*_{jD}$. A tinker is *plain* when $v_{jD} = v^*_{jD}$ for every coordinate. On the room of a table a plain tinker multiplies the weights of the room sides of each station by one constant, which keeps the bases and gives a table (Proposition 12.9, read for the bunch R); a tinker that is not plain gives the room two systems of weights, one for each letter, as a cell may carry (Definition 21.1).

Theorem 28.19 (The law is what a piece retains, at every width)**.** *Let $\mathcal{X}$ and $\mathcal{X}'$ be pieces with the stations $\mathcal{D}$, on sets B and B' of any sizes, with the exponents $(s_j, t_j)_j$, $\sum_j (s_j + t_j)c_j > 0$, and one wall κ. Let $\mathcal{Y}_0$ be a partner of both with the wall $\sum_j (s_j + t_j)c_j - \kappa$, and let some real point $\mathbf{c}$ of the pins of the seam, with positive coordinates, lie in the interior, relative to the pins, of the domains of the seam functions of $\mathcal{X}$, $\mathcal{X}'$ and $\mathcal{Y}_0$. The following are equivalent.*

(a) $(\boldsymbol{\varrho}^{\rho}_{\mathcal{X}})_* \phi^{\rho}_{\mathcal{X}} = (\boldsymbol{\varrho}^{\rho}_{\mathcal{X}'})_* \phi^{\rho}_{\mathcal{X}'}$.

(b) $P_{\mathcal{X} \sqcup \mathcal{Y}} = P_{\mathcal{X}' \sqcup \mathcal{Y}}$, *in* $[0, \infty]$, *for every partner* $\mathcal{Y}$ *with the wall* $\sum_j (s_j + t_j)c_j - \kappa$.

(c) $P_{\mathcal{X} \sqcup \mathcal{Y}_{0,\mathbf{v}}} = P_{\mathcal{X}' \sqcup \mathcal{Y}_{0,\mathbf{v}}}$ *for every tinker* $\mathbf{v}$ *of* $\mathcal{Y}_0$.

(d) The seam functions of $\mathcal{X}$ and $\mathcal{X}'$ agree on the contour of the pins through $\mathbf{c}$.

When every table j with both letters active has $|\mathcal{D}_j| = 1$, except at most one, which has $c_j \geq 1$ and $|\mathcal{D}_j| = 2$, the plain tinkers suffice in (c). For one table at width one with factoring weights, $|\mathcal{D}| = 2$, and the theorem is Theorem 23.11 read through Proposition 28.11: the one-mark cell of ratio 1 (Definition 23.10), glued at the hinge, is a partner whose plain tinkers $(1, q^{1/2})$ are the one-mark cells of ratio q.

So the wall and the law are the whole of what a piece contributes to the families glued on it, and the tinkers of one partner already separate any two laws. A plain tinker multiplies the two room letters of a station by one constant, so with every letter active, and some table of positive width, the plain tinkers of one partner move only $|\mathcal{D}| - N$ of the $2|\mathcal{D}| - 2N - 1$ directions of the seam torus. The other directions are reached by partners with one system of weights whose weights and masses vary.

Definition 28.20 (Plain partners)**.** A partner on R with the stations $\mathcal{D}$ is *plain* when for every table j with an active letter and every $D \in \mathcal{D}_j$ there are a nonempty family $\mathcal{S}_{jD}$ of subsets of R of $e_j + c_j - i(D)$ marks, its *room sides*, and positive weights $w'_{jD,X}$, $X \in \mathcal{S}_{jD}$, with

$$L_{jD} = \sum_{X \in \mathcal{S}_{jD}} w'_{jD,X}\, \alpha^X_R, \qquad L^*_{jD} = \sum_{X \in \mathcal{S}_{jD}} w'_{jD,X}\, \alpha^{R \setminus X}_R,$$

one system of weights for the two letters of a station; then $e^*_j = |R| - e_j - c_j$. The room of a family of tables is plain (Proposition 28.2(iii)), its stations of room sides being disjoint, with $w'_{jD,X}$ the multiplier of X in table j (Definition 28.1).

Definition 28.21 (The station transform of a piece)**.** For a piece $\mathcal{X}$ on B with the stations $\mathcal{D}$, $\sum_j (s_j + t_j)c_j > 0$, the wall $\kappa_{\mathcal{X}}$ and the masses $\mathbf{m}_B$, and for $\mathbf{p} = (p_{jD}, p^*_{jD})_{j,D}$ with positive coordinates, one for each coordinate of the seam vector, the *station transform* is

$$\mathcal{I}_{\mathcal{X}}(\mathbf{p}) = \int \Gamma(\kappa_{\mathcal{X}})\, \mathsf{Z}_{(\kappa_{\mathcal{X}}, \mathbf{s}, \mathbf{t}); t_{\mathcal{D}}}(\mathbf{x} \circ \mathbf{p})\, d\big((\boldsymbol{\varrho}^{\rho}_{\mathcal{X}})_* \phi^{\rho}_{\mathcal{X}}\big)(\mathbf{x})$$

$$= \int_{(0,\infty)^B} \alpha^{\mathbf{m}_B - \mathbf{1}} \prod_j \Big(\sum_D p_{jD} V_{jD} \Big)^{-s_j} \Big(\sum_D p^*_{jD} V^*_{jD} \Big)^{-t_j} d\alpha,$$

in $[0,\infty]$: the kernel of Theorem 28.10(ii) read against the law, the period of the piece against the constant room letters $\mathbf{p}$, the second expression by the computation of Lemma 28.8 with $\alpha = \rho u$ and $v = \rho\, \gamma^\rho_{\mathcal{X}}(u)$.

Theorem 28.22 (Plain partners separate laws)**.** *Let $\mathcal{X}$ and $\mathcal{X}'$ be pieces as in Theorem 28.19, with a real point $\mathbf{c}$ of the pins, with positive coordinates, in the interior of the domains of their seam functions on the pins. Fix room sides $\mathcal{S}_{jD}$ on a set R, every family with at least two members, such that the room word of the plain partners with these room sides has at $\mathbf{c}$ a Newton sum of the dimension $|R|-1$, as when one family of an active letter has a Newton polytope of that dimension, and masses $\mathbf{m}^0_R$ in its relative interior, with $\kappa_R = \sum_j (s_j + t_j) c_j - \kappa$. Then $(\boldsymbol{\varrho}^\rho_{\mathcal{X}})_* \phi^\rho_{\mathcal{X}} = (\boldsymbol{\varrho}^\rho_{\mathcal{X}'})_* \phi^\rho_{\mathcal{X}'}$ exactly when $P_{\mathcal{X} \sqcup \mathcal{Y}} = P_{\mathcal{X}' \sqcup \mathcal{Y}}$ for every plain partner $\mathcal{Y}$ with these room sides, at every positive weights and every masses in a neighbourhood of $\mathbf{m}^0_R$ on the hyperplane $\kappa_R = \sum_j (s_j + t_j) c_j - \kappa$. Such room sides exist for all stations and degrees: $e_j = 1$, $|R| \geq \max_j c_j + 2$, and every $\mathcal{S}_{jD}$ all the subsets of $1 + c_j - i(D)$ marks.*

The room of a family of tables is a plain partner, and multiplying the weights of the bases of each table by positive numbers that depend on the room side alone keeps the bases and the stations, and multiplies the members of each station of room sides by these numbers. So when a bunch of a family has at least two room sides in every station of every table with an active letter and the room word of its room has a Newton sum of full dimension, these families, with the masses of the room near the family's and those of the bunch kept, separate its law from every other law whose seam function converges, as its own does, at the native split (Lemma 28.9, which puts the masses of the room in the relative interior there).

Lemma 28.23 (Partners on one mark see a point mass)**.** *Let $\mathcal{X}$ be a piece on B with the stations $\mathcal{D}$ (Definition 28.4), the exponents $(s_j, t_j)_j$ with $w = \sum_j (s_j + t_j) c_j > 0$, the masses $\mathbf{m}_B$ and the wall $\kappa = \kappa_{\mathcal{X}}$ with $0 < \kappa < w$. For a point $\mathbf{x}$ of its seam torus (Definition 28.5), the* one-mark piece at $\mathbf{x}$ *is the piece on one mark g with the seam letters $x_{jD} \alpha_g^{i(D)}$ and $x^*_{jD} \alpha_g^{c_j - i(D)}$ and the mass κ; its scale is α_g, its seam vector is $\mathbf{x}$, its law is $\delta_{\mathbf{x}}$, and its station transform (Definition 28.21) is $\Gamma(\kappa) \mathsf{Z}_{(\kappa,\mathbf{s},\mathbf{t});t_{\mathcal{D}}}(\mathbf{x} \circ \mathbf{p})$. If for some $c > 0$ and $\mathbf{x}_0$ on the seam torus*

$$\mathcal{I}_{\mathcal{X}}(\mathbf{p}) = c\, \Gamma(\kappa)\, \mathsf{Z}_{(\kappa,\mathbf{s},\mathbf{t});t_{\mathcal{D}}}(\mathbf{x}_0 \circ \mathbf{p}) \qquad \text{for every } \mathbf{p},$$

then the law of $\mathcal{X}$ is $c\, \delta_{\mathbf{x}_0}$. The station transform at $\mathbf{p}$ is the period of the glue of $\mathcal{X}$ with the partner on one mark b with the room letters $p_{jD} \alpha_b^{c_j - i(D)}$ and $p^*_{jD} \alpha_b^{i(D)}$ and the mass $w - \kappa$, the tinker $\mathbf{p}$ of one partner on one mark (Definition 28.18). So a piece that acts on these partners as c times one mark has the law of c times one mark, with no condition on the domains of the seam functions as in Theorem 28.19.

28.5 Storage, and what replaces it

Theorem 28.24 (A bunch is stored on one mark exactly at width one)**.** *In Theorem 28.10(i) let the partner be the room of a family of tables. The partner with its stand-in at $\mathbf{x}$, $R^{(\mathbf{x})}$, is a family of tables on $R \sqcup \{g\}$, with a system of weights for each letter as a cell may carry (Definition 21.1), at every point of the seam torus exactly when every table with an active letter has $c_j \leq 1$, and $c_j = 1$ when both of its letters are active. At width one with factoring weights, normalized as*

in Proposition 28.11, it is the family of the cells $\mathcal{B}^{+}_{j,R}$ of the room with g twisted in both letters, which the change of variable of Proposition 28.11(iii) turns into the twist of Definition 22.1, and Lemma 28.8 is Lemma 23.2 with the scale changed from $\gamma^{K}_{1,B}$ to γ^{ρ}_{B}, a fixed bijection of the tori with a density (Proposition 28.11). A table with $c_j = 0$ does not see the stand-in, in either letter, and at the width $c_j \geq 2$ the stand-in enters the letters of table j with the degree c_j, the coefficient of $\alpha_g^{c_j}$ in K_j being $\sum_{D \in \mathcal{D}_{j,c_j}} x_{jD} L_{jD} \neq 0$: the partner with its stand-in is a family of Newton words, whose period converges exactly when its Newton sum has the dimension $|R|$ and the masses lie in its relative interior (Theorem 25.2).

So the single mark of width one is the case $c = 1$ of a stand-in of degree c. What replaces storage at every width is the stand-in itself, the station-wise pairing of Theorem 28.10: every statement about pieces is made on pieces with stations, whose glue is a family of Newton words, and table structure is never used to compose.

Theorem 28.25 (A point mass is a pinned set)**.** *Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^{N}$ be a family on $\mathcal{E}$ with real exponents $s_j, t_j \geq 0$ and masses on its balance wall with every proper wall positive, and let $\varnothing \neq S \subsetneq \mathcal{E}$, with the room $S' = \mathcal{E} \setminus S$, be read as a piece with the stations of its room and S' as a partner (Definition 28.4). Call S* pinned *when every active table has width at most one at S, with its weights factoring across S and S', and the active letters of the tables of width one read S alike (Theorem 22.5): there are a function γ on Δ_S and constants $c_j, c_j^* > 0$ with $\gamma^{K}_{j,S} = c_j \gamma$ whenever $s_j > 0$ and $\gamma^{\Psi}_{j,S} = c_j^* \gamma$ whenever $t_j > 0$ (Definition 19.2). Then $w = \sum_j (s_j + t_j) c_j(S) > 0$ and $0 < \kappa_S < w$, and the following are equivalent.*

- *(i) The law of S is carried by one point: $(\boldsymbol{\varrho}^{\rho}_{S})_* \phi^{\rho}_{S} = c\, \delta_{\mathbf{x}_0}$ (Definition 28.5) with $c > 0$ and $\mathbf{x}_0$ on the seam torus.*
- *(ii) S is pinned.*
- *(iii) S* splits off*: there are $c > 0$ and $\mathbf{x}_0$ on the seam torus such that every partner $\mathcal{Y}$ of S with the wall $w - \kappa_S$ has $P_{S \sqcup \mathcal{Y}} = c\, P_{\mathcal{Y}^{(\mathbf{x}_0)}}$ in $[0, \infty]$, $\mathcal{Y}^{(\mathbf{x}_0)}$ the partner with its stand-in at $\mathbf{x}_0$ carrying the mass κ_S (Theorem 28.10(i)).*
- *(iv) S splits off against the partners on one mark: its station transform is c times that of the one-mark piece at $\mathbf{x}_0$ with the mass κ_S (Lemma 28.23).*

When they hold, the seam vector is the constant $\mathbf{x}_0$, $c = \int_{\Delta_S} \phi^{\rho}_{S}$, and $P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = c\, P_{S'^{(\mathbf{x}_0)}}$. For a family of lists, read at the factorization with the weights 1, the active letters of the tables of width one read S alike exactly when their hinge values are equal, $c_j = c_j^* = 1$, and then $\mathbf{x}_0 = \mathbf{1}$. For one list $\mathcal{B}$ with $s, t > 0$ and $|S| \geq 2$, S is pinned exactly when it has width one and $\varrho_S = 1$, that is $\mathbf{E}_{\mathcal{B}|S} = \mathbf{E}_{\mathcal{B}/S'}$.

When $\mathcal{B}|S$ and $\mathcal{B}/S'$ are connected, Chapter 30 reads the last condition as a dual pair (Corollary 30.18).

Corollary 28.26 (Which sets split off)**.** *Let F and S be as in Theorem 28.25.*

- *(i) If some active table has width two or more at S, then S does not split off, and its law is carried by no point.*
- *(ii) If $F = ((\mathcal{B}, \theta); s, t)$ is one prime table (Theorem 23.16) with $s + t > 0$, no set with at least two marks on each side splits off.*

(iii) If $F = (\mathcal{B}; s, 0)$ is one list with $s > 0$ and e is a mark that is neither a loop nor a coloop, then $\mathcal{E} \setminus \{e\}$ splits off, and

$$P_F(\mathbf{m}; s, 0) = \Gamma_{\substack{2\\1}}\begin{bmatrix} s - m_e, & m_e \\ & s \end{bmatrix} P_{((\mathcal{B}/e;\, m_e, 0),\, (\mathcal{B}\setminus e;\, s-m_e, 0))}\big(\mathbf{m}|_{\mathcal{E}\setminus\{e\}}\big),$$

the period of the bunch family of Corollary 19.14; at $(0, t)$, $t > 0$, the same holds with $\Gamma_{\substack{2\\1}}\begin{bmatrix} t - m_e, & m_e \\ & t \end{bmatrix}$ and the family $((\mathcal{B}/e;\, 0, t - m_e), (\mathcal{B} \setminus e;\, 0, m_e))$.

(iv) If $F = (\mathcal{B}; s, t)$ is one list on at least three marks with $s, t > 0$ and e is neither a loop nor a coloop, then $\mathcal{E} \setminus \{e\}$ splits off exactly when $\mathbf{E}_{\mathcal{B}\setminus e} = \mathbf{E}_{\mathcal{B}/e}$.

Lemma 28.27 (The level cell of a bunch)**.** *Let B have the width $c = c(B) \geq 1$ in a table, and let G be a set of c new marks. The sets $p \sqcup F$, $F \subseteq G$ and p a pattern of excess $c - |F|$, are the bases of a table $\mathcal{B}_B^\natural$ on $B \sqcup G$ of rank $r(B)$, the* level cell *of B, with any positive weights; $\mathcal{B}_B^\natural \setminus G = \mathcal{B}|B$ and $\mathcal{B}_B^\natural/G = \mathcal{B}/R$. At width one $\mathcal{B}_B^\natural$ is the cell of the bunch $\mathcal{B}_B^+$ of Theorem 19.4.*

Theorem 28.28 (The level envelope)**.** *Let the weights of a table factor across B and R, $\theta_T = \theta'_{T\cap B}\,\theta''_{T\cap R}$, with $c = c(B) \geq 1$, and let $\mathcal{B}_B^\natural$ on $B \sqcup G$ and $\mathcal{B}_R^\natural$ on $R \sqcup G'$ be the level cells of the bunch and of the room, G' a copy of G, with the weights θ'_p on $p \sqcup F$ and $\theta''_X\binom{c}{|F'|}^{-1}$ on $X \sqcup F'$. Splicing the c pairs of a mark of G and its copy (Theorem 21.14) gives the table $\mathcal{B}^{\mathrm{env}}$ on $\mathcal{E}$, the* level envelope *of the bunch, whose bases are the sets $p \sqcup X$ of a pattern p and a room side X of one excess, with the weights $\theta'_p\,\theta''_X$. It has the patterns and the room sides of the table at every excess, its seam has one rectangle at every excess, and $\mathcal{B} \subseteq \mathcal{B}^{\mathrm{env}}$, with equality exactly when every excess of the seam of B is one rectangle.*

A bunch in level form is therefore stored on $c(B)$ pairs of hinges, the table being the splicing of its two level cells, and every bunch is read off its envelope by its seam: the table keeps, at each excess, the rectangles of the compatible pairs.

Proposition 28.29 (When a glue of seamed pieces is a table: what is necessary)**.** *Let $\mathcal{B}$ be a nonempty family of r-sets of $B \sqcup R$, with children and room children as in Definition 28.1. If $\mathcal{B}$ is the family of bases of a table, then:*

(a) every child and every room child is a table;

(b) the children at adjacent patterns p and $p + b$ are quotients, the child at $p + b$ of the child at p, and likewise the room children at adjacent room sides;

(c) at the least and at the largest number of marks of a pattern all the children are one table, and likewise all the room children;

(d) with d and $d + c$ the least and the largest numbers of marks of a pattern, for every k with $d \leq k \leq d + c$ the patterns of k marks are the k-sets independent in the table of the patterns of $d + c$ marks that span the table of the patterns of d marks, the bases of the $(k - d)$-th lift of the latter toward the former (Proposition 12.17); and likewise for the room sides.

Theorem 28.30 (The gluing criterion)**.** *Conditions (a)–(d) of Proposition 28.29 suffice: a nonempty family of r-sets of $B \sqcup R$ satisfying them is the family of bases of a table. So a nonempty family of sets of one size is the family of bases of a table exactly when, at one bunch, its children and room children are tables, adjacent ones are quotients, the extreme ones are one, and its levels are lifts (Proposition 12.17).*

Each of (c) and (d) is needed, and (d) on each side. The criterion is what storage of a bunch on new marks of a table asks, and nothing in the periods depends on it: the glue of Theorem 28.10 composes pieces whether or not their glue is a table.

Chapter 29

Composing bunches

The pieces of Chapter 28 compose. A family with several bunches is read through a core in which every bunch is replaced by its stand-in at its seam point, and its period is the mixture of the periods of these cores over the laws of the bunches (Theorem 29.1); a bunch inside a bunch makes the law of the larger one a mixture of the laws of its nodes (Theorem 29.2); and along a chain of bunches the letters are products of transfer matrices indexed by the stations of room sides, the laws are carried from bunch to bunch by one transfer each, and the period opens as a flow of shares through the stations (Theorem 29.3, Corollary 29.5). Every operation is a rule on the seam functions on contours or on the station transforms (Theorem 29.6), a closed chain of cells is read the same way (Theorem 29.8), and the Foreman tree with nodes of any width is evaluated by one procedure whose reusable data are the laws on its bunches (Definition 29.9). Read backward, the period as a function of the masses determines the potential, so the classes of marks and the tree are read off the periods, and with retention at every node this is the correspondence between a realization and its word (Theorems 29.11 and 29.12).

29.1 Cores, nested pieces and chains of bunches

Theorem 29.1 (The core reads its pieces, at any width)**.** *Let $B_1, \dots, B_q$ be disjoint bunches of a family F on its balance wall, each with $\sum_j (s_j + t_j) c_j(B_l) > 0$, with their scales $\gamma^\rho_{B_l}$, scale forms $\phi^\rho_{B_l}$ and seam vectors $\boldsymbol{\varrho}^\rho_{B_l}$ (Definition 28.5), and let Z be the marks outside them. For $u = (u_l)_l \in \prod_l \Delta_{B_l}$ read the letters of F at $\alpha_{B_l} = \alpha_{g_l} u_l / \gamma^\rho_{B_l}(u_l)$, for new marks g_l, and divide each letter of table j by the product over l of the extreme excess sums of the bunches B_l in that letter (Definition 28.5), $V_j^{(0)}$ for K_j and $V_j^{*(c_j(B_l))}$ for Ψ_j, read at the same point. The letters obtained depend on u only through the seam points $\mathbf{x}_l = \boldsymbol{\varrho}^\rho_{B_l}(u_l)$; with them, the exponents of F and the masses κ_{B_l} on g_l and $\mathbf{m}_Z$ on Z they form the* stand-in core $F^{(\mathbf{x}_1, \dots, \mathbf{x}_q)}$*, a family of Newton words on $Z \sqcup \{g_1, \dots, g_q\}$ (Definition 28.4) in which the stand-in g_l enters the letters K_j and Ψ_j with the degree $c_j(B_l)$. In $[0, \infty]$,*

$$P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \int_{\prod_l \Delta_{B_l}} \prod_l \phi^\rho_{B_l}(du_l)\ P_{F^{(\boldsymbol{\varrho}^\rho_{B_1}(u_1), \dots, \boldsymbol{\varrho}^\rho_{B_q}(u_q))}}\big(\mathbf{m}_Z, \kappa_{B_1}, \dots, \kappa_{B_q}\big)$$
$$= \int P_{F^{(\mathbf{x}_1, \dots, \mathbf{x}_q)}}\big(\mathbf{m}_Z, \kappa_{B_1}, \dots, \kappa_{B_q}\big) \prod_l d\big((\boldsymbol{\varrho}^\rho_{B_l})_* \phi^\rho_{B_l}\big)(\mathbf{x}_l).$$

At width one with factoring weights the stand-in core is the twisted family $F_{\mathcal{H}}[\mathbf{x}]$ of Theorem 23.6(i), up to the change of scale of Proposition 28.11, and this is Theorem 23.6(i); before the laws are

formed it is Theorem 22.3 with the scale of every marker divided by the scale $\gamma^{\rho}_{B_l}$ of its piece.

The core meets its pieces only through their seam points: every bunch collapses to one stand-in mark carrying the mass of its wall, and enters each letter with the degree of its width, at its stations twisted by its seam point. The cores of Chapter 22 are the case in which every piece is a cell.

Theorem 29.2 (The law of a piece from its sub-pieces)**.** *Let S be a bunch of a family with $\sum_j (s_j + t_j) c_j(S) > 0$, and $S_1, \dots, S_k \subseteq S$ disjoint bunches with $\sum_j (s_j + t_j) c_j(S_l) > 0$.*

(i) The seam letters of S are linear in those of each S_l, with nonnegative coefficients: in each table, for S_1, every station D of room sides of S and any member $X \in D$,

$$K_{(D)} = \sum_q \frac{w'_{q \sqcup X}}{w'_X}\, \alpha^{\,q}\, K_{(D_1(q))}, \qquad \Psi_{(D)} = \sum_q \frac{w'_{q \sqcup X}}{w'_X}\, \alpha^{(S \setminus S_1) \setminus q}\, \Psi_{(D_1(q))},$$

the sums over the sets $q \subseteq S \setminus S_1$ for which $q \sqcup X$ is a room side of S_1, $D_1(q)$ its station, $w'_{q \sqcup X}$ its multiplier there and w'_X that of X at S; the coefficients and the stations $D_1(q)$ do not depend on the member X.

(ii) Let the node $S^{(\mathbf{x}_1, \dots, \mathbf{x}_k)}$*, the node at S of the tree of the bunches $S \supseteq S_1, \dots, S_k$, be the piece on $(S \setminus \bigcup_l S_l) \sqcup \{g_1, \dots, g_k\}$ whose seam letters are those of S with each S_l replaced by its stand-in at $\mathbf{x}_l$, as in Theorem 29.1, with the masses κ_{S_l} on g_l. The node has the wall of S, and, in this statement writing λ_S, λ_{S_l} and $\lambda_{\mathbf{x}}$ for the laws of S, of S_l and of the node at $\mathbf{x} = (\mathbf{x}_l)_l$, the law of S is the mixture of the laws of its nodes:*

$$\int H \, d\lambda_S = \int \Big(\int H \, d\lambda_{\mathbf{x}} \Big) \prod_l d\lambda_{S_l}(\mathbf{x}_l) \qquad \text{for every Borel } H \geq 0,$$

and so are the seam functions, $\int \mathbf{z}^{-(\mathbf{a},\mathbf{b})}\, d\lambda_S(\mathbf{z}) = \int \big(\int \mathbf{z}^{-(\mathbf{a},\mathbf{b})}\, d\lambda_{\mathbf{x}}(\mathbf{z}) \big) \prod_l d\lambda_{S_l}(\mathbf{x}_l)$ at all shares $(\mathbf{a}, \mathbf{b})$.

At width one, with factoring weights, this is Theorem 23.6(ii), up to the change of scale of Proposition 28.11.

Theorem 29.3 (A chain of bunches)**.** *Let $\varnothing = S_0 \subset S_1 \subset \cdots \subset S_L = \mathcal{E}$, $L \geq 2$, be a chain of bunches of a family with the steps $B_{l-1} = S_l \setminus S_{l-1}$, and for $0 < l < L$ let $\mathcal{D}(S_l)$ be the stations of room sides of the bunch S_l, in each table, the index j dropped.*

(i) Letters. *For $2 \leq l \leq L-1$, $D' \in \mathcal{D}(S_{l-1})$ and $D \in \mathcal{D}(S_l)$ put, for any $X \in D$,*

$$\mathbf{N}^K_l(D', D) = \sum_q \frac{w'_{q \sqcup X}}{w'_X}\, \alpha^{\,q}_{B_{l-1}}, \qquad \mathbf{N}^{\Psi}_l(D', D) = \sum_q \frac{w'_{q \sqcup X}}{w'_X}\, \alpha^{B_{l-1} \setminus q}_{B_{l-1}},$$

the sums over the $q \subseteq B_{l-1}$ for which $q \sqcup X$ is a room side of S_{l-1} in the station D'. With $\mathbf{k} = (K_{(D)})_{D \in \mathcal{D}(S_1)}$ and $\mathbf{k}^* = (\Psi_{(D)})_{D \in \mathcal{D}(S_1)}$ the seam letters of S_1 and $\mathsf{y} = (\mathsf{y}_D)_{D \in \mathcal{D}(S_{L-1})}$ and $\mathsf{y}^* = (\mathsf{y}^*_D)_{D \in \mathcal{D}(S_{L-1})}$ the room station letters of S_{L-1},

$$K = \mathbf{k}^{\mathsf{T}} \mathbf{N}^K_2 \cdots \mathbf{N}^K_{L-1}\, \mathsf{y}, \qquad \Psi = \mathbf{k}^{*\mathsf{T}} \mathbf{N}^{\Psi}_2 \cdots \mathbf{N}^{\Psi}_{L-1}\, \mathsf{y}^*,$$

products of matrices of polynomials with nonnegative coefficients, indexed by the stations of room sides of the bunches S_l: Theorem 22.9 with these stations as the states.

(ii) Laws. *Let $\sum_j (s_j + t_j) c_j(S_l) > 0$ for every $0 < l < L$, and in this statement write λ_l for the law of S_l. For $2 \le l \le L-1$ let $S_l^{(\mathbf{x})}$ be the node of S_l with its sub-bunch S_{l-1} at $\mathbf{x}$ (Theorem 29.2(ii)), the piece on $B_{l-1} \sqcup \{g\}$ with the seam letters $\sum_{D'} x_{D'}\, \alpha_g^{i(D')} \mathbf{N}_l^K(D', D)$ and $\sum_{D'} x^*_{D'}\, \alpha_g^{c(S_{l-1}) - i(D')} \mathbf{N}_l^\Psi(D', D)$, $D \in \mathcal{D}(S_l)$, and the mass $\kappa_{S_{l-1}}$ on g, and let $\lambda_{\mathbf{x}}^{(l)}$ be its law. Then λ_l is the image of λ_{l-1} under the* transfer $\mathcal{Q}_l$,

$$\lambda_l = \mathcal{Q}_l \lambda_{l-1} = \int \lambda_{\mathbf{x}}^{(l)}\, d\lambda_{l-1}(\mathbf{x}),$$

and $P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \int P_{B_{L-1}^{(\mathbf{x})}}(\mathbf{m}_{B_{L-1}}, \kappa_{S_{L-1}})\, d\lambda_{L-1}(\mathbf{x})$, the room B_{L-1} of the last bunch S_{L-1} with its stand-in at $\mathbf{x}$ (Theorem 28.10(i)).

(iii) Repetition. *If the nodes $S_l^{(\cdot)}$, $2 \le l \le L-1$, are one piece up to bijections of marks keeping seam letters and masses, the transfers are one operator $\mathcal{Q}$ and $\lambda_l = \mathcal{Q}^{l-1} \lambda_1$: the chain is the power of one operator, whatever the widths of its bunches. At width one with factoring weights this is Theorem 22.8 and Proposition 24.4, the seam point being the twist up to the change of scale of Proposition 28.11.*

Lemma 29.4 (The native split along a chain)**.** *Let a family of tables have real data on its balance wall, with $s_j, t_j \ge 0$, not all zero, and $\mathbf{m} > 0$, and a native gauge $\alpha^\star$ (Definition 8.17), and let $\varnothing = S_0 \subset S_1 \subset \cdots \subset S_L = \mathcal{E}$ be a chain of bunches as in Theorem 29.3, with the steps $B_{l-1} = S_l \setminus S_{l-1}$. For the active letters put*

$$e^{(l)}_{jD'D} = s_j\, \mathbb{P}_{j,\alpha^\star}\big(T \setminus S_{l-1} \in D',\ T \setminus S_l \in D\big), \qquad f^{(l)}_{jD'D} = t_j\, \mathbb{P}^*_{j,\alpha^\star}\big(T \setminus S_{l-1} \in D',\ T \setminus S_l \in D\big),$$

and $a^{(l)}_{jD} = s_j\, \mathbb{P}_{j,\alpha^\star}(T \setminus S_l \in D)$, $b^{(l)}_{jD} = t_j\, \mathbb{P}^*_{j,\alpha^\star}(T \setminus S_l \in D)$, the native split at the stations of the bunch S_l (Lemma 28.9). Then the entry shares conserve the loads, $\sum_{D'} e^{(l)}_{jD'D} = a^{(l)}_{jD} = \sum_{D''} e^{(l+1)}_{jDD''}$, and likewise with f and b; and $\mathbf{m}_{B_{l-1}}$ lies in the relative interior of the Newton sum of the word of the node l at its shares, which converges there exactly when that Newton sum has the dimension $|B_{l-1}| - 1$.

Corollary 29.5 (The word of a chain of bunches)**.** *In Theorem 29.3 read the room B_{L-1} of the last bunch S_{L-1} as a last node whose transfer matrix from $\mathcal{D}(S_{L-1})$ to one terminal station is the column y, and y^* for Ψ, and open every active letter with one share per nonzero entry of every transfer matrix: $e^{(l)}_{jD'D}$ for the entry (D', D) of $\mathbf{N}_l^K$ and $f^{(l)}_{jD'D}$ for that of $\mathbf{N}_l^\Psi$, $2 \le l \le L$. A station D of a bunch S_l, $2 \le l \le L-1$, carries the load $a^{(l)}_{jD} = \sum_{D'} e^{(l)}_{jD'D}$ in and $\sum_{D''} e^{(l+1)}_{jDD''}$ out, and a station D of the first bunch S_1 the load $a^{(1)}_{jD} = \sum_{D''} e^{(2)}_{jDD''}$; likewise b with f. In this statement write $W_l(\mathbf{e}, \mathbf{f}) = \prod_{D',D} \mathbf{N}_l^K(D', D)^{-e_{D'D}}\, \mathbf{N}_l^\Psi(D', D)^{-f_{D'D}}$ for the word of the node l on B_{l-1}, the products over the active letters of every table understood. On contours of positive real parts at which the seam function of S_1 and the words of the nodes converge, which needs their Newton sums to have full dimension and, for a family with a native gauge, holds as soon as they do (Lemmas 28.9 and 29.4),*

$$P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \int \prod_{j:\, s_j > 0} \frac{\prod_{l=2}^{L} \prod_{D',D} \Gamma(e^{(l)}_{jD'D})}{\Gamma(s_j) \prod_{l=2}^{L-1} \prod_D \Gamma(a^{(l)}_{jD})} \prod_{j:\, t_j > 0} \frac{\prod_{l=2}^{L} \prod_{D',D} \Gamma(f^{(l)}_{jD'D})}{\Gamma(t_j) \prod_{l=2}^{L-1} \prod_D \Gamma(b^{(l)}_{jD})}$$
$$\times P_{W_{S_1}(\mathbf{a}^{(1)}, \mathbf{b}^{(1)})}(\mathbf{m}_{B_0}) \prod_{l=2}^{L} P_{W_l(\mathbf{e}^{(l)}, \mathbf{f}^{(l)})}(\mathbf{m}_{B_{l-1}}),$$

W_{S_1} the seam word of the first bunch S_1 (Lemma 28.7), the fibre pinned by the letter totals, the equality of the loads in and out at every station of the bunches $S_2, \dots, S_{L-1}$, and the homogeneity of the first bunch and of every node but one. At a bunch or a node whose Newton sum is degenerate the pins and the reduced period of Theorem 28.12 take the place of the period. At $L = 2$ this is Theorem 28.10(iii).

The word of a chain of bunches is a flow: one share per transfer entry, conserved at every station, each node contributing the period of its own word at the loads of its entries. Read with insertions, the same flow carries the module of the family: every value of every insertion is this word with the periods of the nodes replaced by the values of the masters of their modules, and the chance of a basis is the probability of its path under the flow times the chances of its pieces in the entries (Theorem 48.7). Every station through which the flow passes is paid once by a Gamma in the denominator, except at the first bunch, where the seam function of the piece takes the loads. At width one with factoring weights every bunch S_l has two stations, and this is the word of the tree (Corollary 20.10) grouped by the two stations of each bunch.

Theorem 29.6 (Two transforms of a law, and their rules)**.** *Let a piece $\mathcal{X}$ on B with the stations $\mathcal{D}$ have $\sum_j (s_j + t_j)c_j > 0$, and a real point $\mathbf{c}$ of the pins of the seam, with positive coordinates, in the interior of the domain of its seam function on the pins.*

(i) Two transforms. *The law $(\boldsymbol{\varrho}^{\rho}_{\mathcal{X}})_* \phi^{\rho}_{\mathcal{X}}$ is determined by its seam function on the contour through $\mathbf{c}$, and by its station transform $\mathcal{I}_{\mathcal{X}}$ (Definition 28.21) on any nonempty open set of points $\mathbf{p}$; the two are related by*

$$\mathcal{I}_{\mathcal{X}}(\mathbf{p}) = \int_{pins} \prod_{j:\, s_j > 0} \Gamma_{|\mathcal{D}_j|}\begin{bmatrix} \mathbf{a}_j \\ s_j \end{bmatrix} \prod_{j:\, t_j > 0} \Gamma_{|\mathcal{D}_j|}\begin{bmatrix} \mathbf{b}_j \\ t_j \end{bmatrix} \; \mathbf{p}^{-(\mathbf{a},\mathbf{b})} \int_{\Delta_B} (\boldsymbol{\varrho}^{\rho}_{\mathcal{X}})^{-(\mathbf{a},\mathbf{b})} \, d\phi^{\rho}_{\mathcal{X}},$$

$\mathbf{p}^{-(\mathbf{a},\mathbf{b})} = \prod_{j,D} p_{jD}^{-a_{jD}} {p^*_{jD}}^{-b_{jD}}$.

(ii) The glue. *For a partner $\mathcal{Y}$ with the wall $\sum_j (s_j + t_j)c_j - \kappa_{\mathcal{X}}$, $P_{\mathcal{X} \sqcup \mathcal{Y}} = \int \mathcal{I}_{\mathcal{X}}(\mathbf{x}') \, d\big((\boldsymbol{\varrho}^{\rho}_{\mathcal{Y}})_* \phi^{\rho}_{\mathcal{Y}}\big)(\mathbf{x}')$, the station transform read against the law of the partner; on the pins, at a point where the seam function of the partner converges too, it is the share side of Theorem 28.10(iii). It extends the node of width one in one scale (Theorem 20.26) to any width.*

(iii) Nesting. *In Theorem 29.2, $\mathcal{I}_S(\mathbf{p}) = \int \mathcal{I}_{S(\mathbf{x}_1, \dots, \mathbf{x}_k)}(\mathbf{p}) \prod_l d\big((\boldsymbol{\varrho}^{\rho}_{S_l})_* \phi^{\rho}_{S_l}\big)(\mathbf{x}_l)$. With one sub-piece S_1, in this statement write $\mathbf{N}^K_{2,j}(\alpha)$ and $\mathbf{N}^{\Psi}_{2,j}(\alpha)$, $\alpha = \alpha_{S \setminus S_1}$, for the matrices $\mathbf{N}^K_2$ and $\mathbf{N}^{\Psi}_2$ in table j of the chain $\varnothing \subset S_1 \subset S \subset \mathcal{E}$ (Theorem 29.3(i)), the transfer matrices from the bunch S_1 to the bunch S. Then*

$$\mathcal{I}_S(\mathbf{p}) = \int_{(0,\infty)^{S \setminus S_1}} \alpha^{\mathbf{m}_{S \setminus S_1} - \mathbf{1}} \, \mathcal{I}_{S_1}\big(\big(\mathbf{N}^K_{2,j}(\alpha)\, \mathbf{p}_j\big)_j, \big(\mathbf{N}^{\Psi}_{2,j}(\alpha)\, \mathbf{p}^*_j\big)_j\big) \, d\alpha,$$

$\mathbf{p}_j = (p_{jD})_D$ *and* $\mathbf{p}^*_j = (p^*_{jD})_D$*; and at shares $(\mathbf{a}, \mathbf{b})$ on the pins of the seam of S, on contours of positive real parts at which the seam function of S_1 and the word of the node converge,*

$$\int_{\Delta_S} (\boldsymbol{\varrho}^{\rho}_S)^{-(\mathbf{a},\mathbf{b})} \, d\phi^{\rho}_S = \int \prod_{j:\, s_j > 0} \frac{\prod_{D_1, D} \Gamma(e_{jD_1D})}{\prod_D \Gamma(a_{jD})} \prod_{j:\, t_j > 0} \frac{\prod_{D_1, D} \Gamma(f_{jD_1D})}{\prod_D \Gamma(b_{jD})} \times \int_{\Delta_{S_1}} (\boldsymbol{\varrho}^{\rho}_{S_1})^{-(\mathbf{a}^{(1)}, \mathbf{b}^{(1)})} \, d\phi^{\rho}_{S_1} \; P_{W(\mathbf{e},\mathbf{f})}(\mathbf{m}_{S \setminus S_1}),$$

the shares e_{jD_1D} and f_{jD_1D} one per nonzero entry of the transfer matrices, pinned by $\sum_{D_1} e_{jD_1D} = a_{jD}$, $\sum_{D_1} f_{jD_1D} = b_{jD}$ and the homogeneity of the node, with the loads $a^{(1)}_{jD_1} = \sum_D e_{jD_1D}$ and $b^{(1)}_{jD_1} = \sum_D f_{jD_1D}$, and $W(\mathbf{e},\mathbf{f})$ the word of the entries on $S \setminus S_1$ as in Corollary 29.5.

(iv) Repetition. *The rule of (iii) for a node repeated along a chain is one operator on seam functions, and on station transforms one operator on functions of $\mathbf{p}$; a chain of repeated nodes is its power applied to the first bunch.*

So every operation along a chain is a rule on the seam functions on contours, or on the station transforms: the representations (b) and (a) of Definition 23.19, at every width.

Definition 29.7 (Cyclic chains)**.** A family on $\mathcal{E} = B_1 \sqcup \cdots \sqcup B_k$, $k \geq 2$, the *segments* B_i indexed by $\mathbb{Z}_k$, is a *cyclic chain* with the finite sets of *states* $\mathcal{J}_0, \ldots, \mathcal{J}_{k-1}$, $\mathcal{J}_k = \mathcal{J}_0$, and the *top layer* $h \in \mathbb{N}$, when every active letter L is

$$L = [\varepsilon^h] \operatorname{tr} \prod_{i=1}^{k} \mathbf{M}_{L,i}(\alpha_{B_i}; \varepsilon),$$

the coefficient of ε^h in the trace of a product of matrices $\mathbf{M}_{L,i}$ indexed by $\mathcal{J}_{i-1} \times \mathcal{J}_i$, the *segment matrices*, whose entries are polynomials in α_{B_i} and ε with nonnegative coefficients.

Theorem 29.8 (Cyclic chains)**.** *(i) Let every table j of a family be a closed chain of cells $\mathcal{A}_{j,1}, \ldots, \mathcal{A}_{j,k}$ with several hinges spliced along hinge pairs (Theorem 21.14(ii)), the cells $\mathcal{A}_{j,i}$ of all tables having the marks B_i besides their hinges, and the pairs I_i joining the cell i to the cell $i+1$ named alike in every table, each pair named once. The family is a cyclic chain with the top layer 0: its states at the boundary i are the sets $J \subseteq I_i$ of the pairs whose hinge on the side of the cell i is occupied, and the segment matrices of the letters of table j are the channels of its cells (Definition 21.13),*

$$\mathbf{M}_{K_j,i}[J, J'] = K_{\mathcal{A}_{j,i},((I_{i-1} \setminus J) \sqcup J')}, \qquad \mathbf{M}_{\Psi_j,i}[J, J'] = \Psi_{\mathcal{A}_{j,i},((I_{i-1} \setminus J) \sqcup J')}.$$

(ii) Widen the states by layers, $\mathcal{J}_i \times \{0, \ldots, h\}$, a term in ε^μ of an entry raising the layer by μ, and write $\widetilde{\mathbf{M}}_{L,i}$ for the widened segment matrices. Then $L = \sum_{J \in \mathcal{J}_0} \mathbf{e}^{\mathsf{T}}_{(J,0)} \prod_i \widetilde{\mathbf{M}}_{L,i}\, \mathbf{e}_{(J,h)}$: for every starting state a chain in the sense of Theorem 29.3(i), the segment matrices as transfer matrices. In this statement write w_L for the exponent of the active letter L. Open every active letter first over the starting states J at which its term $\mathbf{e}^{\mathsf{T}}_{(J,0)} \prod_i \widetilde{\mathbf{M}}_{L,i}\, \mathbf{e}_{(J,h)}$ is not zero, with shares $c_{L,J}$, $\sum_J c_{L,J} = w_L$, and then every chain as in Corollary 29.5: one share $e^{(J)}_{L,i}$ per starting state J and per nonzero entry of a widened segment matrix that lies on a path from $(J,0)$ to (J,h), the shares of each starting state a flow from $(J,0)$, with the total $c_{L,J}$, to (J,h), conserved at every boundary, $a^{(J)}_{L,i}$ the loads it leaves at the boundary after the segment i, and $e^{(J)}_{L,1} = a^{(J)}_{L,1}$. On contours of positive real parts at which the words of the segments converge,

$$P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \int \prod_L \frac{1}{\Gamma(w_L)} \prod_{L,J} \frac{\prod_{i=2}^{k} \prod \Gamma(e^{(J)}_{L,i})}{\prod_{i=2}^{k-1} \prod \Gamma(a^{(J)}_{L,i})} \prod_{i=1}^{k} P_{W_i}(\mathbf{m}_{B_i}),$$

the inner products over the entries and over the states, W_i the word on B_i of the entries of the segment i at their total shares $\sum_J e^{(J)}_{L,i}$, and the fibre pinned by the conservation and by the homogeneity of every segment but one.

(iii) For k copies of one segment the integrand of (ii), read at each boundary as a function of the loads of all the starting states, is the kernel of one operator $\mathcal{C}$, restricted at each boundary to the loads of the states that lie on a path there, which integrates the loads out over the fibre pinned by the homogeneity of the segment. With $\mathcal{C}_\circ$ the same kernel without that pin, which for one segment is implied by those of the others, the letter totals and the balance, the period is

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \int \prod_L \frac{\prod_J \Gamma(c_{L,J})}{\Gamma(w_L)} \left(\mathcal{C}^{k-1}\mathcal{C}_\circ\right)(\mathbf{c},\mathbf{c})\, d\mathbf{c},$$

a power of one operator taken from the loads $\mathbf{c}$ at the starting states back to them. Its price is that of one segment and the binary digits of k (Chapter 33); evaluated, the power takes at most $\lfloor \log_2 k \rfloor$ squarings of $\mathcal{C}$ and as many products.

A closed chain is a chain whose last boundary is glued back to its first: the trace sums over the states at one boundary, and each starting state carries its own flow around the closed chain. Cells spliced along any graph of hinge pairs stay tables (Theorem 21.14); around a closed chain their letters are traces of products of channel matrices, and repeated cells give the power of one operator.

29.2 The procedure

The Newton sums of Lemmas 28.9 and 29.4 can be degenerate. When every station of room sides is a single room side, every room station letter is a monomial, the room word is a monomial, and its period diverges at every share; the period is then read by Theorem 28.10(i) or (ii), or on the share side of Theorem 28.12 with $\vec{\mathcal{N}}_R = 0$.

Definition 29.9 (The seam procedure)**.** *Given*: a family F with real data on its balance wall, every proper wall positive. *Classification*, from the tables alone: the molecules, the readings at the centre and the Foreman tree (Definition 16.14, steps (1)–(5)); for a molecule with a connected active table the tree is a chain whose bunches $B_0, \dots, B_{d-1}$ (Corollary 20.8) are the steps of the chain of bunches $S_k = B_0 \sqcup \cdots \sqcup B_{k-1}$, the leaf being the last step. *Seams*, from the tables alone, at every bunch S_k:

(1) group the patterns of S_k of each excess by their weighted children up to positive multiples, and the room sides by their weighted room children, with the multipliers normalized by their largest value (Definition 28.1); the stations, the station letters and the pair constants are determined;

(2) record the seam matrices H_i and the transfer matrices $\mathbf{N}_k^K$, $\mathbf{N}_k^\Psi$ of Theorem 29.3(i);

(3) record the orbits of the stations under the bijections that keep S_k and keep the potential (Proposition 28.6, Lemma 14.18).

Evaluation at a point $(\mathbf{m};\mathbf{s},\mathbf{t})$:

(4) the law of $S_1 = B_0$ (Definition 28.5), with its canonical scale;

(5) the transfers of the laws from bunch to bunch (Theorem 29.3(ii)), one operator for repeated nodes (Theorem 29.3(iii)), the transfer entries of pairs of stations in one orbit being images of one another (Proposition 28.6(i));

(6) the period at the leaf with its stand-in at the seam point of the last bunch S_d, integrated against the law of that bunch (Theorem 28.10(i)); equivalently the word of Corollary 29.5

on the contour through the native shares of Lemma 29.4, with the transverse pins of Theorem 28.12 at every bunch or node whose Newton sum is degenerate, every node a Newton word with multilinear letters closed by its peak series with the references of Theorem 15.13(i) and every seam Gramma by its peak closing with the sharp references (Proposition 28.16(i)).

Output: the period, with the seams, the transfer matrices and the law on every bunch, ready to be reused when a node is changed. At a general Foreman tree the bunches of a node with several childcules are composed by Theorem 29.1, the childcules of a peel being the pieces of the core.

Nothing in the procedure is chosen. The tree is the Foreman tree (Definition 14.4); the stations are fixed by the children, and their multipliers by the normalization of the largest one; the scale of a piece is the geometric mean of the oriented extreme ratios of the active letters, each taken to the root of its width, kept by the symmetries of the family (Proposition 28.6(iii)); inside a seam Gramma the stations of the bunch are integrated before those of the room, the Foreman's order (Proposition 28.15), and another choice of the stations that are not kept changes the pins by a unimodular matrix; the real point of the share contour, where the word is used, is the native split at the stations and the entries (Lemmas 28.9 and 29.4); the references of the closings are those of Theorem 15.13(i) and the sharp ones, read off the coefficients. Repetition is paid once: stations in one orbit carry data that are images of one another, and repeated nodes one operator.

Proposition 29.10 (What the work depends on)**.** *(i) The law of a piece depends on the piece only through the joint law of the seam letters of its active letters under the measure $u^{\mathbf{m}_B-\mathbf{1}}d\omega_B$, with its exponents and wall: two pieces, on sets of any sizes, whose seam letters have the same joint law have equal laws and are interchangeable in every glue (Theorem 28.19); in particular so are two pieces whose seam letters and masses correspond under a bijection of their marks.*

(ii) Along a chain the letters cost one product of matrices of the sizes $|\mathcal{D}(S_l)|$, and a seam Gramma of a part without circuits costs no integration (Definition 28.13, Corollary 2.6).

(iii) The law of a bunch depends on the room only through the room children of the bunch, the tables on the bunch that the room presents to it: changing the room while keeping its room children and their stations changes no law below the bunch.

29.3 The correspondence

The procedure reads a realization forward, from its tables to its word. The other direction asks what the periods distinguish, and it has two answers: as a function of the masses the period determines the potential, which carries the classes of marks and the tree; at one realization each bunch is seen by its room through its wall and its law, and only through them.

Theorem 29.11 (The period function determines the potential)**.** *Let a family have real exponents $s_j, t_j \geq 0$ with $s_j + t_j > 0$ for every j and a period that converges at some masses on its balance wall, and let U be the set of the complex masses on the balance wall at which it converges.*

(i) With the measure dy on the hyperplane $\mathbf{1}^\perp = \{y \in \mathbb{R}^{\mathcal{E}} : \langle \mathbf{1}, y\rangle = 0\}$ of the section $\prod_e \alpha_e = 1$ (Lemma 16.2),

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \int_{\mathbf{1}^\perp} e^{\langle \mathbf{m},y\rangle - \Phi(y)}\, dy, \qquad \mathbf{m} \in U,$$

Φ the potential at the table's gauge (Definition 8.18). The function $P_F(\cdot;\mathbf{s},\mathbf{t})$ on U determines Φ, and is determined by it.

(ii) Two families on the same marks with the same exponents have the same period function exactly when they have the same irreducible factors with their exponents $(L, w_{\mathbf{E}}(L), w_{\mathbf{O}}(L))$ *(Theorem 10.6) and the same constant* $\Phi(0) = \sum_j (s_j + t_j) \log K_j(\mathbf{1})$*; at the centre, every* $\delta_j = 0$*, exactly when they have the same* $(L, w_{\mathbf{E}}(L))$ *and the same constant. In particular a family and the family of its dual tables (Proposition 8.15), the bases replaced by their complements, have the same period function at the centre.*

(iii) A bijection g *of the marks keeps the period function,* $P_F(g^*\mathbf{m}; \mathbf{s}, \mathbf{t}) = P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$ *on* U*, exactly when it keeps the potential, both parts. For a molecule, two marks lie in one class exactly when a bijection keeping the period function takes one to the other (Lemma 14.18), and when its children's weights factor across the childcules at every node, every such bijection carries the Foreman tree onto itself, with its classes, units, atoms, bunches and childcules (Proposition 14.21).*

(iv) At the centre the bijections that carry the family and those that exchange it keep the period function; at a lean the carrying ones keep it, and an exchanging one sends it to the period function of the opposite lean (Proposition 11.14). For a molecule of one table two marks lie in one class at the centre exactly when a bijection carrying or exchanging the table takes one to the other, and at a lean exactly when a carrying one does (Corollary 11.16), and a class of the centre that is not a class at a lean is there two classes of equal size, which an exchange swaps (Theorem 11.17).

So two marks of a molecule are told apart by the period function of the centre, or of a lean, exactly when no bijection keeping that potential joins them; for one table these are, at the centre, the bijections carrying or exchanging the table, and at a lean the carrying ones. The confusable classes, the classes of a lean that share a class of the centre, are exactly what the period function of the centre does not separate and that of a lean does. The tree is read off the period function but does not determine it; the irreducible factors with their exponents, and the constant $\Phi(0)$, do.

Theorem 29.12 (The correspondence)**.** *Let a molecule be read at a realization with masses on its balance wall and every proper wall positive, its children's weights factoring across the childcules at every node.*

(i) Forward. *Its period is the reassembly of the laws of the bunches of its Foreman tree with the leaves, by the seam procedure: the law of the first bunch on its seam torus, transferred along the chain by the later bunches as nodes, the childcules of a node composed at its core, and glued to the leaves by the stand-ins; nothing in it is chosen (Definition 29.9, Theorems 29.1 and 29.3).*

(ii) Backward at the realization. *At the node reached after* k *peels the room sees the bunch* S_k*, the union of the bunches peeled down to it, through its wall and its law, and only through them: bunches with the same stations, exponents, walls and laws are interchangeable in every family glued on that room, and under the hypotheses of Theorem 28.19 two different laws are told apart by the tinkers of one room and by plain partners (Theorems 28.19 and 28.22); the laws of nested bunches compose by Theorems 29.2 and 29.3.*

Whether the molecule has an atomic realization is read at a centre: it has one exactly when some centre is atomic, and an atom at a lean is an atom at the centre (Theorems 11.8 and 11.1). The word of the tree is the forward procedure written out, and retention is the statement that it loses nothing that a room could detect.

Chapter 30

Foreman fusion

A table of rank r and corank r^* is the contraction of $c = r^* - r$ new marks in an identically self-dual table, in which the new marks form a bunch in level form and their deletion leaves the dual table, exactly when every cocircuit of the table is a union of circuits and, at $c = 0$, the table has the weights of its dual. The bases of the larger table are then unique, and at $c \leq 1$ the larger table itself: they are those of the level cell of the pair formed by the dual table and the table, the new marks are its fusion bunch, and their children on the marks of the table are the lifts of the table toward its dual, one for each level, whose weights between the two extremes, the middle weights, are a choice paired by complement, all 1 unless others are named. This is Foreman fusion, and the table is Foreman-embedded in its fusion. The fused table is identically self-dual, so each of its marks comes off by one Beta corner at every pair of exponents (Corollary 20.19); its automorphisms contain those of the table that keep the middle weights, all of them when the middle weights are 1, times the permutations of the fusion bunch, and are often more; and every identically self-dual table is the fusion of each of its one-mark contractions. At the fusion width one the fusion bunch is one mark g, the letter of the fused table is $\Psi + \alpha_g K$, and the table is read off it by one Beta corner: the law of the fusion bunch is a point. At the width c the seam of the fusion bunch is one rectangle at every excess, its seam letters are the elementary symmetric polynomials of the new marks up to constants, all 1 for a list, and the fused table is the glue (Theorem 28.10) of a universal piece of width c, which does not depend on the table, with the lift partner, whose room letters are the letters of the lifts. The law of the universal piece is the image of a measure on the torus of the fusion bunch, of dimension $c-1$, and the law of the lift partner is a point only when its lift ratios are constant, which they are not at $c \geq 2$: these two laws are the price of width. Down the partial fusions the first step is a Beta corner and every later step is a cell whose law is not a point. Every one-mark contraction of the fused table has the fusion width one and fuses back into it: these cousins share one period up to Beta corners, and an automorphism of the fused table carries the cousin at a mark onto the cousin at the image of that mark. Across a two-sum of lists the widths add, the condition is read at the hinge by four conditions on each cell, and at the total width one a two-sum fuses exactly when both cells fuse, the cell of the width zero being then identically self-dual. A table of the fusion width $c \geq 0$ that does not fuse has uncovered marks, or has the width zero and the bases but not the weights of its dual; doubling the uncovered marks in parallel, or one mark in the second case, gives a table that fuses. The chapter ends with the branch these statements set at every node of the Foreman tree.

30.1 Quotients, lifts and the level cell of a pair

Definition 30.1 (Quotients; lifts; the level cell of a pair)**.** Let $\mathcal{M}$ and $\mathcal{N}$ be tables on one set of marks $\mathcal{E}$, of the ranks $r_{\mathcal{M}}$ and $r_{\mathcal{N}}$, with the rank functions $r_{\mathcal{M}}(Y)$ and $r_{\mathcal{N}}(Y)$ (Definition 7.4). $\mathcal{N}$ is a *quotient* of $\mathcal{M}$ when every set that is maximal for its rank in $\mathcal{N}$ is maximal for its rank in $\mathcal{M}$, as the child at $p+b$ is of the child at p (Proposition 12.6); its *rank difference* is $c = r_{\mathcal{M}} - r_{\mathcal{N}}$. For $0 \le j \le c$ the *j-th lift of $\mathcal{N}$ toward $\mathcal{M}$* is the table $\mathcal{L}_j(\mathcal{M},\mathcal{N})$ on $\mathcal{E}$ with the rank function

$$r_{\mathcal{L}_j(\mathcal{M},\mathcal{N})}(Y) = \min\big(r_{\mathcal{M}}(Y),\ r_{\mathcal{N}}(Y)+j\big) \qquad (Y \subseteq \mathcal{E}),$$

a table by Proposition 30.2(iii) below; for a bunch B of a table and $(\mathcal{M},\mathcal{N}) = (\mathcal{B}|B, \mathcal{B}/R)$ these are the lifts of Proposition 12.17. For a set G of c new marks the *level cell* of the pair $(\mathcal{M},\mathcal{N})$ is the table on $\mathcal{E} \sqcup G$ whose bases are the sets $X \sqcup Q$ with $Q \subseteq G$ and X a basis of $\mathcal{L}_{c-|Q|}(\mathcal{M},\mathcal{N})$; for $(\mathcal{B}|B, \mathcal{B}/R)$ it is the level cell of the bunch B (Lemma 28.27). It carries any positive weights, and G is in level form in it (Proposition 14.12) when the weight of $X \sqcup Q$ depends on X and $|Q|$ alone.

Proposition 30.2 (The level cell of a pair)**.** *Let $\mathcal{N}$ be a quotient of $\mathcal{M}$ on $\mathcal{E}$ with the rank difference c, let G be a set of c new marks, and in this statement write $\mathcal{L}_j$ for $\mathcal{L}_j(\mathcal{M},\mathcal{N})$.*

(i) For tables $\mathcal{M}$ and $\mathcal{N}$ on $\mathcal{E}$, $\mathcal{N}$ is a quotient of $\mathcal{M}$ exactly when $r_{\mathcal{M}}(Y) - r_{\mathcal{M}}(X) \ge r_{\mathcal{N}}(Y) - r_{\mathcal{N}}(X)$ for all $X \subseteq Y \subseteq \mathcal{E}$. Then $c \ge 0$, every set independent in $\mathcal{N}$ is independent in $\mathcal{M}$, every set spanning $\mathcal{M}$ spans $\mathcal{N}$, and a quotient of $\mathcal{N}$ is a quotient of $\mathcal{M}$.

(ii) The level cell of $(\mathcal{M},\mathcal{N})$ is a table of rank $r_{\mathcal{M}}$ with the rank function

$$r^{\natural}(Y \sqcup P) = \min\big(r_{\mathcal{M}}(Y) + |P|,\ r_{\mathcal{N}}(Y) + c\big) \qquad (Y \subseteq \mathcal{E},\ P \subseteq G).$$

In it every subset of G is a pattern of the bunch G, $d(G) = 0$ and $c(G) = c$; the child at $Q \subseteq G$ is $\mathcal{L}_{c-|Q|}$; the deletion of G is $\mathcal{M}$ and the contraction of G is $\mathcal{N}$; and every permutation of G maps its bases onto themselves.

(iii) Each $\mathcal{L}_j$ is a table of rank $r_{\mathcal{N}}+j$ whose bases are the sets of $r_{\mathcal{N}}+j$ marks that are independent in $\mathcal{M}$ and span $\mathcal{N}$; $\mathcal{L}_0 = \mathcal{N}$, $\mathcal{L}_c = \mathcal{M}$, and $\mathcal{L}_j$ is a quotient of $\mathcal{L}_{j'}$ for $j \le j'$. Lifts compose: for $0 \le a \le b \le c$ and $0 \le i \le b-a$,

$$\mathcal{L}_i(\mathcal{L}_b, \mathcal{L}_a) = \mathcal{L}_{a+i}.$$

(iv) For disjoint $C, D \subseteq G$ the minor of the level cell contracting C and deleting D is the level cell of the pair $(\mathcal{L}_{c-|C|}, \mathcal{L}_{|D|})$ on $\mathcal{E} \sqcup \big(G \setminus (C \cup D)\big)$.

The level cell stores a whole chain of lifts on c new marks: one level of the bunch G for each lift, the deletion of G at the top and its contraction at the bottom, and every interval of the chain as a minor at the marks of G. Nothing in its bases is chosen except the names of the new marks, which every permutation of G moves without moving the bases; its weights are a choice.

30.2 The fused table

Lemma 30.3 (Complements of the lifts toward the dual)**.** *Let $\mathcal{B}$ be a table of rank r on $\mathcal{E}$, $n = |\mathcal{E}|$, which is a quotient of its dual table $\mathcal{B}^*$, of rank $r^* = n - r$ (Definition 30.1), let $c = r^* - r$, and let $\mathcal{L}_j = \mathcal{L}_j(\mathcal{B}^*, \mathcal{B})$, $0 \le j \le c$. Then X is a basis of $\mathcal{L}_j$ exactly when $\mathcal{E} \setminus X$ is a basis of $\mathcal{L}_{c-j}$: the dual table of $\mathcal{L}_j$ has the bases of $\mathcal{L}_{c-j}$.*

Definition 30.4 (Fusion width; Foreman fusion; majors)**.** Let $(\mathcal{B},\theta)$ be a table of rank r and corank r^* on $\mathcal{E}$, $n=|\mathcal{E}|$, with its dual table $(\mathcal{B}^*,\theta^*)$, $\theta^*_{\mathcal{E}\setminus T}=\theta_T$ (Definition 7.1), and with the rank function $r(Y)$ and the dual rank function $r^*(Y)$ (Definition 7.12). Its *fusion width* is $c=r^*-r=n-2r$, and $(\mathcal{B},\theta)$ is *fusable* when $\mathcal{B}$ is a quotient of $\mathcal{B}^*$ (Definition 30.1) and, at the fusion width zero, $\theta^*=\theta$. A quotient forces $c\ge 0$ (Proposition 30.2(i)), and a quotient of the same rank has the same bases, so a fusable table of the fusion width zero is identically self-dual (Corollary 23.12(iii)), and a list of the fusion width zero is fusable exactly when it is identically self-dual. Let $c\ge 0$, and let G be a set of c new marks, the *fusion bunch*.

(i) A *major* of $(\mathcal{B},\theta)$ is a table on $\mathcal{E}\sqcup G$ whose contraction of G is $(\mathcal{B},\theta)$ and whose deletion of G is $(\mathcal{B}^*,\theta^*)$.

(ii) The *lifts* of a fusable $(\mathcal{B},\theta)$ are $\mathcal{L}_j=\mathcal{L}_j(\mathcal{B}^*,\mathcal{B})$, $0\le j\le c$, with the weights $\theta^{(j)}$: $\theta^{(0)}=\theta$ on $\mathcal{L}_0=\mathcal{B}$, $\theta^{(c)}=\theta^*$ on $\mathcal{L}_c=\mathcal{B}^*$, and for $0<j<c$ the *middle weights*, positive weights with $\theta^{(c-j)}_{\mathcal{E}\setminus X}=\theta^{(j)}_X$, complement mapping the bases of $\mathcal{L}_j$ onto those of $\mathcal{L}_{c-j}$ (Lemma 30.3), a choice, all 1 unless others are named; so the lifts of a list are lists unless other middle weights are named. Its *lift letters* are $L_l=K_{\mathcal{L}_{c-l}}$, $0\le l\le c$, read with these weights, so that $L_0=\Psi$ and $L_c=K$, and its *lift ratios* are $z_j=K^2_{\mathcal{L}_j}/(K_{\mathcal{L}_{j-1}}K_{\mathcal{L}_{j+1}})$, $0<j<c$.

(iii) The *Foreman fusion* of a fusable $(\mathcal{B},\theta)$, with its middle weights, is the level cell of $(\mathcal{B}^*,\mathcal{B})$ on $\mathcal{E}\sqcup G$ with the weight $\theta^{(c-|Q|)}_X$ on $X\sqcup Q$, written $(\mathcal{B}^\sharp,\theta^\sharp)$; $(\mathcal{B},\theta)$, the contraction of the fusion bunch in it, is its *Foreman embedding*. For $G'\subseteq G$ the *partial fusion* at G' is $\mathcal{B}^\sharp/(G\setminus G')$, written $\mathcal{B}^\sharp_i$ for $|G'|=i$ when the marks of G' are not named; $\mathcal{B}^\sharp_0=\mathcal{B}$ and $\mathcal{B}^\sharp_c=\mathcal{B}^\sharp$.

At the fusion width zero G is empty and $\mathcal{B}^\sharp=\mathcal{B}$. A table of negative fusion width c has a dual of the fusion width $-c$, and the dual is the table that is fused.

Theorem 30.5 (Foreman fusion)**.** *Let $(\mathcal{B},\theta)$ be fusable, of the fusion width $c\ge 0$, rank r and corank r^*, with its Foreman fusion $(\mathcal{B}^\sharp,\theta^\sharp)$ on $\mathcal{E}\sqcup G$ and its lifts $\mathcal{L}_j$.*

(i) $\mathcal{B}^\sharp$ is a table of rank r^* on $n+c=2r^*$ marks with the rank function

$$r^\sharp(Y\sqcup P)=\min\big(r^*(Y)+|P|,\ r(Y)+c\big)\qquad (Y\subseteq\mathcal{E},\ P\subseteq G),$$

its contraction of G is $(\mathcal{B},\theta)$ and its deletion of G is $(\mathcal{B}^*,\theta^*)$: it is a major of $(\mathcal{B},\theta)$.

(ii) The dual of each lift is a lift, weights included: $\mathcal{L}^*_j=\mathcal{L}_{c-j}$. So $(\mathcal{B}^\sharp,\theta^\sharp)$ is identically self-dual (Corollary 23.12(iii)), and

$$K^\sharp=\Psi^\sharp=\sum_{l=0}^{c}e_l(\alpha_G)\,L_l(\alpha_{\mathcal{E}}),\qquad L_l=K_{\mathcal{L}_{c-l}}=\Psi_{\mathcal{L}_l}.$$

(iii) Every basis of every major of $(\mathcal{B},\theta)$ is a basis of $\mathcal{B}^\sharp$.

(iv) Every major of $(\mathcal{B},\theta)$ in which G is in level form, equivalently that every permutation of G carries, has the bases of $\mathcal{B}^\sharp$, the weights θ on the bases $X\sqcup G$ and θ^* on the bases $X\sqcup\varnothing$, and on the others positive weights depending on X and $|Q|$ alone; it is identically self-dual exactly when these weights, read as middle weights $\theta^{(c-|Q|)}_X$ on the bases $X\sqcup Q$, are paired as in Definition 30.4(ii), and then it is the Foreman fusion with these middle weights. So the identically self-dual majors in level form are the Foreman fusions with all the choices of middle weights, and for a list $\mathcal{B}^\sharp$ is the only one that is a list. For every bijection β of $\mathcal{E}$ carrying $(\mathcal{B},\theta)$ with $\theta^{(j)}\circ\beta=\theta^{(j)}$ for $0<j<c$, as for the middle weights 1, and every permutation π of G, $\beta\sqcup\pi$ carries $(\mathcal{B}^\sharp,\theta^\sharp)$.

(v) *At the fusion width one, $G = \{g\}$, the bases of $\mathcal{B}^\sharp$ are the sets $T + g$ and $\mathcal{E} \setminus T$, $T \in \mathcal{B}$, both with the weight θ_T, $K^\sharp = \Psi + \alpha_g K$, and $(\mathcal{B}^\sharp, \theta^\sharp)$ is the only major of $(\mathcal{B}, \theta)$.*

The fusion stores the table and its dual as the two extreme children of one bunch, and fills the levels between them with the lifts, which is the only way to fill them in level form that the exchange property allows (Proposition 28.29(d)): the containment (iii) says that no major has a basis the fusion lacks, and level form at G selects the bases of the fusion among the majors, its weights between the extremes being a choice paired by complement. Self-duality comes from the chain of lifts turning over under duality, the j-th lift onto the $(c - j)$-th. At the fusion width one there is no level between the extremes, and the fusion is the only major; at the width c the middle levels admit majors that are not in level form, among them identically self-dual ones, and the bases of the fusion are the ones that every permutation of the new marks keeps.

Theorem 30.6 (The tell)**.** *For a table $(\mathcal{B}, \theta)$ of the fusion width c, conditions (a), (b) and (c) are equivalent and imply $c \geq 0$. The table is fusable exactly when they hold and, at $c = 0$, $\theta^* = \theta$; so a list, or a table of the fusion width $c \geq 1$, is fusable exactly when (a) holds. For $c \geq 0$ the table is fusable exactly when (d) holds.*

(a) *$\mathcal{B}$ is a quotient of $\mathcal{B}^*$.*

(b) *Every cocircuit of $\mathcal{B}$ is a union of circuits of $\mathcal{B}$ (Definition 7.4).*

(c) *For every mark e and every split $\mathcal{E} \setminus \{e\} = A \sqcup A'$, the rank of A or the rank of A' does not grow when e is added to it.*

(d) *$(\mathcal{B}, \theta)$ has a major (Definition 30.4(i)); for $c \geq 1$, equivalently, some table on $\mathcal{E} \sqcup G$, $|G| = c$, has $\mathcal{B}^*$ and $\mathcal{B}$ as the children of the empty pattern and of the full pattern of its bunch G.*

A table that satisfies (b) has no coloop. For $c < 0$ the dual table has the fusion width $-c$, and the theorem read on it has (b) in the form: every circuit of $\mathcal{B}$ is a union of cocircuits.

The tell is read on the Skeleton of the table (Definition 7.12): the cocircuit layer must be covered by the circuit layer, cocircuit by cocircuit, before anything is integrated. In the form (c) it is a statement about one mark at a time: however the other marks are split in two, one half spans the mark. A coloop fails it at once, being a cocircuit of one mark; a loop lies in no cocircuit and never fails it. The weights enter only at the width zero, where the bases of a table that passes are those of its dual and the table fuses when its weights are those of its dual as well.

Corollary 30.7 (The fused tables are the identically self-dual tables)**.** *(i) Let $(\mathcal{H}, \theta)$ be identically self-dual on $\mathcal{E}'$ and $C \subseteq \mathcal{E}'$ independent, every transposition of two marks of C carrying $(\mathcal{H}, \theta)$. Then $\mathcal{H}/C$ is fusable of the fusion width $|C|$, and $(\mathcal{H}, \theta)$ is its Foreman fusion with the fusion bunch C and the middle weights read off θ. In particular every identically self-dual table on at least one mark is the Foreman fusion of each of its one-mark contractions, and the fused tables are exactly the identically self-dual tables.*

(ii) *If $\mathcal{B}$ is connected and fusable, $\mathcal{B}^\sharp$ is connected.*

Proposition 30.8 (Partial fusions and inner lifts)**.** *Let $(\mathcal{B}, \theta)$ be fusable of the fusion width $c \geq 1$, with its lifts $\mathcal{L}_j$.*

(i) *For disjoint $C, D \subseteq G$, $\mathcal{B}^\sharp/C \setminus D$ is the level cell of $(\mathcal{L}_{c-|C|}, \mathcal{L}_{|D|})$ on $\mathcal{E} \sqcup \big(G \setminus (C \cup D)\big)$, with the weights of $\mathcal{B}^\sharp$.*

(ii) *The partial fusion at G', $|G'| = i$, is the level cell of $(\mathcal{L}_i, \mathcal{B})$ on $\mathcal{E} \sqcup G'$. It has the fusion width $c - i$, it is fusable, and its Foreman fusion with the middle weights read off $\theta^\sharp$ is $(\mathcal{B}^\sharp, \theta^\sharp)$ with*

the fusion bunch $G \setminus G'$. So $\mathcal{B} = \mathcal{B}_0^\sharp, \mathcal{B}_1^\sharp, \dots, \mathcal{B}_c^\sharp = \mathcal{B}^\sharp$, each the contraction of the next at one mark, all fuse into one table.

(iii) $\mathcal{L}_j$ has the fusion width $c - 2j$. For $2j \le c$ it is fusable, with the Foreman fusion $\mathcal{B}^\sharp/C \setminus D$, $|C| = |D| = j$, its middle weights read off $\theta^\sharp$. For even c the middle lift $\mathcal{L}_{c/2}$ is identically self-dual; for odd c the lift $\mathcal{L}_{(c-1)/2}$ has the fusion width one and fuses into $\mathcal{B}^\sharp/C \setminus D$ with $|C| = |D| = (c-1)/2$.

So the fused table holds, at its minors on the fusion bunch, the fusion of every table in the chain between $\mathcal{B}$ and $\mathcal{B}^*$: each partial fusion fuses into it again, and each inner lift fuses into the minor that deletes as many marks of G as it contracts.

Remark 30.9 (Examples). (i) The uniform list $\binom{\mathcal{E}}{r}$ with $n \ge 2r$ is fusable, its cocircuits having $r^* + 1 \ge r + 1$ marks; its lifts are the uniform lists $\binom{\mathcal{E}}{r+j}$, and its fusion is $\binom{\mathcal{E} \sqcup G}{r^*}$: the fusion of $\binom{[n]}{r}$ is $\binom{[2r^*]}{r^*}$, and the fusion of $\binom{[5]}{2}$ is $\binom{[6]}{3}$; for $\binom{[2r+1]}{r}$, $r \ge 2$, the fusion $\binom{[2r+2]}{r+1}$ is the table one mark larger of Proposition 39.64(ii).

(ii) A list of rank two with no loop has as its bases the pairs of marks in different classes of a partition of its marks, the classes of two or more marks being its parallel classes (Definition 19.1). With $k \ge 3$ classes it is fusable exactly when $k \ge 4$, or $k = 3$ and every class has at least two marks: its cocircuits are the complements of the classes, and a mark of a class P' lies in a circuit inside the complement of another class P exactly when P' has a second mark or two classes other than P and P' exist. So the list $\binom{[3]}{2}$ and every such list with three classes one of which is a single mark fail, and those with four or more classes pass at every fusion width (receipt `t03_rank2_census.py`, every connected list of rank two on 5 to 9 marks).

(iii) The list of rank two on $n \ge 5$ marks with one parallel pair P and every other mark in a class of its own has the fusion width $n - 4$, and its fusion has exactly two sets of $n - 2$ marks that are not bases, the complementary halves $P \sqcup G$ and $\mathcal{E} \setminus P$; its automorphisms are the $2((n-2)!)^2$ bijections keeping this pair of halves, transitive on the marks. At $n = 5$ the fusion is the two-sum of two copies of $\binom{[4]}{2}$.

(iv) Of the 108 lists of rank three on seven marks, up to the names of the marks, 22 are fusable, of the fusion width one, and they fuse into the 17 identically self-dual lists on eight marks; of the 18 that are prime (Theorem 23.16), 10 are fusable, those whose lines all have three marks and meet pairwise (receipts `census7.py`, `atoms7.py`).

(v) The majors of $\binom{[4]}{1}$ that are lists, of the fusion width two, are 79 lists on six marks; 7 of them are identically self-dual and one is in level form at G, and that one is the fusion $\binom{[6]}{3}$ (receipt `t02_majors_U14.py`). At rank three the following are fusable, of the fusion widths two and three: $\binom{[8]}{3}$ and $\binom{[9]}{3}$; the list F_7 on the marks $\mathbb{Z}/7$ whose dependent sets of three marks are the seven sets $\{i, i+1, i+3\}$, with a free mark added; the list A_9 on the marks $\mathbb{F}_3^2$ whose dependent sets of three marks are the twelve sets $\{a, a+d, a+2d\}$, $d \ne 0$, and A_9 less a mark; the list Z_9 on the marks a_i, b_i, c_i, $i = 1, 2, 3$, whose dependent sets of three marks are $\{a_1, a_2, a_3\}$, $\{b_1, b_2, b_3\}$, $\{c_1, c_2, c_3\}$ and the six sets $\{a_i, b_j, c_{i+j-2}\}$ with $i \ne j$; and five further lists of rank three whose dependent sets of three marks form configurations of lines; and their fusions have the seam of Proposition 30.10 (receipt `w01_seam_rank3.py`).

30.3 The seam of the fusion bunch and the glue

Proposition 30.10 (The seam of the fusion bunch)**.** *Let $(\mathcal{B}, \theta)$ be fusable of the fusion width $c \ge 1$, with its fusion $(\mathcal{B}^\sharp, \theta^\sharp)$, its lifts $\mathcal{L}_j$ and its lift letters L_l.*

(i) In $\mathcal{B}^\sharp$ the bunch G has $\mathrm{pat}(G) = 2^G$, $d(G) = 0$ and $c(G) = c$, and it is in level form. At the excess l (Definition 28.1) there is one station of patterns, all $Q \subseteq G$ with $|Q| = l$, with the multipliers 1 and the station letters $e_l(\alpha_G)$ and $e_{c-l}(\alpha_G)$, and one station D_l of room sides, the bases of $\mathcal{L}_{c-l}$, whose room children are positive multiples of $\binom{G}{l}$. Every excess is one rectangle, $\mathcal{B}^\sharp$ is its own level envelope (Theorem 28.28), and the room-station factorization (Proposition 28.2(iii)) is

$$K^\sharp = \sum_{l=0}^{c} e_l(\alpha_G)\, L_l(\alpha_\mathcal{E}), \qquad \Psi^\sharp = \sum_{l=0}^{c} e_{c-l}(\alpha_G)\, L_{c-l}(\alpha_\mathcal{E}).$$

The seam letters of G are $K_{(D_l)} = \mu_l e_l(\alpha_G)$ and $\Psi_{(D_l)} = \mu_l e_{c-l}(\alpha_G)$, with μ_l the largest weight of $\mathcal{L}_{c-l}$, the room-station letters are L_l/μ_l and L_{c-l}/μ_l, and the pair constants are μ_l; for a list every μ_l is 1.

(ii) The interaction of G (Definition 12.18) and its dual interaction are

$$\iota_G = \iota_G^* = \sum_{j=0}^{c} (-1)^j \binom{c}{j} \log K_{\mathcal{L}_j}(\alpha_\mathcal{E}),$$

and $\iota_G = -\log z_1$ at $c = 2$.

(iii) At the table's gauge the pattern probabilities of the excess l add up to $\Pi_l = \binom{c}{l} L_l(\mathbf{1})/K^\sharp(\mathbf{1})$, with $\Pi_l = \Pi_{c-l}$, and the peel of $((\mathcal{B}^\sharp, \theta^\sharp); s, t)$ at G (Definition 14.1) is the family of the lifts $((\mathcal{L}_j, \theta^{(j)}); \Pi_j s, \Pi_j t)_{0 \le j \le c}$, whose word is $\prod_j K_{\mathcal{L}_j}^{-2\sigma\Pi_j}$.

Between the extremes the seam of a bunch can carry several rectangles (Proposition 28.3(iii)); the fusion bunch carries one at every excess, with the multipliers 1 on its patterns and the pair constants μ_l, and what it presents to its room at the excess l is the elementary symmetric polynomial of degree l of its own marks. These letters do not depend on the table. Everything the table contributes sits on the other side of the seam, in the letters of its lifts.

Definition 30.11 (The universal piece; the lift partner)**.** For $c \ge 1$ the *universal piece of width* c is the piece on a set G of c marks for one table (Definition 28.4) with the stations $D_0, \dots, D_c$, D_l of the excess l, the seam letters $V_{D_l} = e_l(\alpha_G)$ and $V_{D_l}^* = e_{c-l}(\alpha_G)$, and $d = d^* = 0$. The *lift partner* of a fusable $(\mathcal{B}, \theta)$ of the fusion width c is the partner on $\mathcal{E}$ with the same stations, the room letters $L_{D_l} = L_l$ and $L_{D_l}^* = L_{c-l}$, and $e = e^* = r$.

By Proposition 30.10(i) and Proposition 28.2(iii) the glue of the universal piece of width c and the lift partner of $(\mathcal{B}, \theta)$ is the fusion $(\mathcal{B}^\sharp, \theta^\sharp)$. Since $\mathcal{B}^\sharp$ is identically self-dual its word at the exponents (s, t) is $K^{\sharp\,-2\sigma}$, $\sigma = \frac{s+t}{2}$ the strength (Definition 8.1), and the fused table is read below as the family $((\mathcal{B}^\sharp, \theta^\sharp); 2\sigma, 0)$, with the one active letter $K^\sharp$; its walls are those at (s, t), d and d^* agreeing on an identically self-dual table. Its balance wall is $m_\mathcal{E} + m_G = 2\sigma r^*$. In this section $H_G = \{w \in \mathbb{R}^G : \sum_g w_g = 0\}$ is the torus of G in logarithmic coordinates, with the measure $d\lambda_G(w) = dw_{g_1} \cdots dw_{g_{c-1}}$ for an order $g_1, \dots, g_c$ of G, and $\mathbf{e}(y) = (e_0(y), \dots, e_c(y))$ for $y \in (0, \infty)^G$.

Theorem 30.12 (The glue of a fused table)**.** *Let $(\mathcal{B}, \theta)$ be fusable of the fusion width $c \ge 1$, with its fusion $(\mathcal{B}^\sharp, \theta^\sharp)$ at a strength $\sigma > 0$ and masses $\mathbf{m}$ on $\mathcal{E} \sqcup G$ on its balance wall. For $\mathbf{x} = (x_0, \dots, x_c) \in (0, \infty)^{c+1}$ let $W[\mathbf{x}]$ be the Newton word on $\mathcal{E} \sqcup \{g\}$, g the stand-in of the universal piece, with the one letter $\sum_{l=0}^{c} x_l\, \alpha_g^l\, L_l(\alpha_\mathcal{E})$ at the exponent 2σ (Definition 25.1).*

(i) The universal law. *The scale of the universal piece is* $\gamma_G^{\rho} = e_c(\alpha_G)^{1/c}$, *its seam vector at the excess* l *is* $e_l(\alpha_G)/\gamma_G^{\rho}(\alpha_G)^l$, *and its law is the image of the measure* $c\, e^{\langle \mathbf{m}|_G, w\rangle}\, d\lambda_G(w)$ *on* H_G *under* $w \mapsto \mathbf{e}(e^w)$.

(ii) The torus form. *In* $[0,\infty]$,

$$P_{\mathcal{B}^\sharp}(\mathbf{m}; s, t) = c \int_{H_G} e^{\langle \mathbf{m}|_G, w\rangle}\, P_{W[\mathbf{e}(e^w)]}\big(\mathbf{m}|_{\mathcal{E}}, m_G\big)\, d\lambda_G(w),$$

the stand-in carrying the mass m_G, *the wall of the universal piece.*

(iii) The scale of the stand-in. *At a fixed* $\alpha_{\mathcal{E}}$ *write* $\sum_l x_l L_l\, y^l = x_c L_c \prod_{i=1}^{c}(y + \xi_i)$; *the* ξ_i, *in* $\mathbb{C} \setminus (-\infty, 0]$, *are the Skeleton values of the stand-in, read on the letter of* $W[\mathbf{x}]$ *as in Definition 12.10. For* $0 < m_G < 2\sigma c$,

$$\int_0^\infty \rho^{m_G - 1} \Big(\sum_l x_l \rho^l L_l \Big)^{-2\sigma} d\rho = (x_c L_c)^{-2\sigma}\, \Gamma_c^2 \begin{bmatrix} m_G, & 2\sigma c - m_G \\ 2\sigma, & \dots, \ 2\sigma \end{bmatrix}\, \mathsf{B}^{\{J\}}_{(2\sigma)_{i\in J},\, 2\sigma c - m_G;\, I_J}(\boldsymbol{\xi}),$$

the Breta of one bunch $J = \{1, \dots, c\}$ *of Proposition 15.1, coincident Skeleton values merging.*

(iv) One share per level. *On every contour of shares* $\mathbf{a} = (a_0, \dots, a_c)$ *with positive real parts on the pins* $\sum_l a_l = 2\sigma$ *and* $\sum_l l\, a_l = m_G$ *at which the two periods below converge, as at the native split at the stations when every proper wall of* $\mathcal{B}^\sharp$ *is positive (Theorem 28.10(iii)),*

$$P_{\mathcal{B}^\sharp}(\mathbf{m}; s, t) = \int_{\sum_l a_l = 2\sigma,\ \sum_l l\, a_l = m_G} \Gamma_1^{c+1} \begin{bmatrix} \mathbf{a} \\ 2\sigma \end{bmatrix}\, P_{\prod_{l=1}^{c} e_l^{-a_l}}\big(\mathbf{m}|_G\big)\, P_{\prod_{l=0}^{c} L_l^{-a_l}}\big(\mathbf{m}|_{\mathcal{E}}\big),$$

a fibre integral of the dimension $c - 1$.

(v) The universal factor. *For* $c \geq 2$, $P_{\prod_{l=1}^{c} e_l^{-a_l}}(\mathbf{m}|_G) = P_{\prod_{l=1}^{c-1} e_l^{-a_l}}(\mathbf{m}|_G - a_c \mathbf{1})$, *the period on* G *of the uniform lists* $\binom{G}{l}$, $0 < l < c$, *at the exponents* $(a_l, 0)$ *and the masses* $\mathbf{m}|_G - a_c \mathbf{1}$; *at* $c = 1$ *it is* 1.

The universal piece is absorbed into its stand-in at its own scale, the geometric mean of the scales of G, and what is left of it is a point of the torus of G, entering the letter of the stand-in through the elementary symmetric polynomials of the exponentials of that point. The stand-in enters with the degree c, so $W[\mathbf{x}]$ is not the word of a table for $c \geq 2$ (Theorem 28.24), and integrating its scale is one Breta over the c Skeleton values of the stand-in. Opened on its shares, the fused table carries one share per level and two pins, the strength and the scale, so $c - 1$ shares are free; the universal factor is the period of the family of its lifts, in which the table itself is the member with $a_1 = \dots = a_{c-1} = 0$, $P_{L_0^{-a_0} L_c^{-a_c}}(\mathbf{m}|_{\mathcal{E}}) = P_{\mathcal{B}}(\mathbf{m}|_{\mathcal{E}}; a_c, a_0)$.

Corollary 30.13 (Width one)**.** *At the fusion width one, on the balance wall of* $\mathcal{B}^\sharp$ *with every proper wall positive,*

$$P_{\mathcal{B}^\sharp}(\mathbf{m}|_{\mathcal{E}}, m_g; s, t) = \Gamma_1^2 \begin{bmatrix} m_g, & 2\sigma - m_g \\ & 2\sigma \end{bmatrix}\, P_{\mathcal{B}}\big(\mathbf{m}|_{\mathcal{E}}; m_g, 2\sigma - m_g\big)\ :$$

the exponents of the table are read off the mass of the fusion bunch. The universal piece is the mark g *itself, the laws of the universal piece and of the lift partner are points, and the share form of Theorem 30.12(iv) has no free share.*

Corollary 30.14 (Width two). *Let $c=2$, $G=\{g_1,g_2\}$, with the masses m_1,m_2 on g_1,g_2.*

(i) On a line of one free share a_2, with $a_1=m_1+m_2-2a_2$ and $a_0=2\sigma-m_1-m_2+a_2$,

$$P_{\mathcal{B}^\sharp}(\mathbf{m};s,t)=\frac{1}{2\pi i}\int\frac{\Gamma(a_0)\,\Gamma(a_2)\,\Gamma(m_1-a_2)\,\Gamma(m_2-a_2)}{\Gamma(2\sigma)}\,P_{L_0^{-a_0}L_1^{-a_1}L_2^{-a_2}}\big(\mathbf{m}|\mathcal{E}\big)\,da_2:$$

the universal factor is the Beta corner $\Gamma_{\,1}^{\,2}\Big[\begin{matrix}m_1-a_2,\ m_2-a_2\\ a_1\end{matrix}\Big]$, and the Gamma of the middle level cancels.

(ii) The universal law is the image of $2v^{m_1-m_2-1}dv$ on $(0,\infty)$ under $v\mapsto(1,v+v^{-1},1)$, and

$$P_{\mathcal{B}^\sharp}(\mathbf{m};s,t)=2\int_0^\infty v^{m_1-m_2-1}\,P_{(L_0+(v+v^{-1})\alpha_gL_1+\alpha_g^2L_2)^{-2\sigma}}\big(\mathbf{m}|\mathcal{E},m_1+m_2\big)\,dv.$$

(iii) At a fixed $\alpha_{\mathcal{E}}$, for $0<m_1<2\sigma$ and $0<m_2<2\sigma$,

$$\int_{(0,\infty)^2}\alpha_{g_1}^{m_1-1}\alpha_{g_2}^{m_2-1}K^{\sharp\,-2\sigma}\,d\alpha_G$$
$$=\Gamma_{\,1}^{\,2}\Big[\begin{matrix}m_2,\ 2\sigma-m_2\\ 2\sigma\end{matrix}\Big]\,L_0^{m_1+m_2-2\sigma}L_1^{-m_1-m_2}\int_0^\infty x^{m_1-1}(1+x)^{m_2-2\sigma}\big(1+z_1^{-1}x\big)^{-m_2}dx,$$

a Beta corner times a Breta of one bunch with the two coefficients 1 and z_1 (Proposition 15.1). At $m_1=m_2=1$, $2\sigma=2$ it is $\log z_1/(L_1^2-L_0L_2)$ where $z_1\neq1$ and L_1^{-2} where $z_1=1$, and at integer $m_1,m_2,2\sigma$, where $z_1\neq1$, it is $L_0^{m_1+m_2-2\sigma}L_1^{-m_1-m_2}\big(R_1(z_1)+R_2(z_1)\log z_1\big)$ with rational functions R_1,R_2.

30.4 The price of width

Lemma 30.15 (Products of lifts). *Let $\mathcal{N}$ be a quotient of $\mathcal{M}$ with the rank difference c, its lifts $\mathcal{L}_j=\mathcal{L}_j(\mathcal{M},\mathcal{N})$ carrying any positive weights. For $0\le i'<i\le j<j'\le c$ with $i+j=i'+j'$, $K_{\mathcal{L}_i}K_{\mathcal{L}_j}$ has a monomial in which exactly $r_{\mathcal{N}}+i$ exponents equal 2, while in every monomial of $K_{\mathcal{L}_{i'}}K_{\mathcal{L}_{j'}}$ at most $r_{\mathcal{N}}+i'$ do; so the two products are not proportional. In particular, for $c\ge2$, no ratio $K_{\mathcal{L}_j}^2/(K_{\mathcal{L}_{j-1}}K_{\mathcal{L}_{j+1}})$, $0<j<c$, is constant on the orthant.*

Theorem 30.16 (The price of width). *Let $(\mathcal{B},\theta)$ be fusable of the fusion width $c\ge1$, with its fusion read at a strength $\sigma>0$ as in Theorem 30.12, its lift letters L_l and its lift ratios z_j.*

(i) The law of the universal piece is carried by one point exactly when $c=1$. The law of the lift partner is carried by one point exactly when every lift ratio is constant, that is exactly when $c=1$.

(ii) The Skeleton braid. *Write $\sum_l\binom{c}{l}L_l\,x^l=L_0\prod_{i=1}^c(1+\eta_ix)$; the η_i are the reciprocals of the Skeleton values of G at the gauge $(\mathbf{1}_G,\alpha_{\mathcal{E}})$ (Definition 12.10). Then*

$$K^\sharp=\frac{L_0}{c!}\sum_{\pi\in S_c}\prod_{i=1}^c\big(1+\alpha_{g_i}\eta_{\pi(i)}\big)=\frac{L_0}{c!}\,\mathrm{per}\,\big(\mathbf{1}\mathbf{1}^{\mathsf{T}}+\alpha_G\boldsymbol{\eta}^{\mathsf{T}}\big),$$

$\mathbf{1}\mathbf{1}^{\mathsf{T}}$ the $c\times c$ matrix of ones and per *the permanent: $K^\sharp$ is L_0 times the average, over the bijections from the marks of G to the Skeleton values, of products of c letters of one mark. At a gauge $\alpha_{\mathcal{E}}$ the η_i coincide exactly when every lift ratio is 1 there, and for $c\ge2$ they coincide on no open set of the orthant: $K^\sharp$ is not $L_0\prod_{g\in G}(1+\alpha_g\eta)$ for any one function η.*

(iii) The partial fusions. *For $1 \le i \le c$, $G' \subseteq G$ with $|G'| = i$ and $g \in G'$, read the partial fusion at G' as a cell with the hinge g (Definition 21.1). For $i = c$ its ratio is* 1*, and on the balance wall of $\mathcal{B}^\sharp$ with every proper wall positive*

$$P_{\mathcal{B}^\sharp}(\mathbf{m}; s, t) = \Gamma_{\begin{smallmatrix}2\\1\end{smallmatrix}}\begin{bmatrix} m_g, & 2\sigma - m_g \\ & 2\sigma \end{bmatrix} P_{\mathcal{B}^\sharp/g}\big(\mathbf{m}|_{\mathcal{E}\sqcup G-g};\, m_g,\, 2\sigma - m_g\big);$$

for $i < c$ its ratio is not constant, and at any exponents $s, t > 0$ and masses its law is not carried by one point (Corollary 23.12(i)).

At the fusion width one both laws are points and the glue is a product: one Beta corner. At the width $c \ge 2$ neither is: the universal law spreads over the $(c-1)$-dimensional torus of G, and the lift partner's seam vector moves with the room because the lifts are not a geometric chain, the lift ratios being not constant. Read on the Skeleton values of the fusion bunch, the letter of the fused table is an average over the bijections from the marks of G to the Skeleton values, and it is one product of c letters of one mark on no open set, and at no gauge for a list (Remark 30.19(i)); one product is what c independent fusions of width one would give. Read down the partial fusions, only the step at the top is free.

Among the plain extensions of a table by one mark with connected hinge minors, the fusion is the only one that is free in this way, up to one constant on the weights of the bases avoiding the new mark.

Proposition 30.17 (The free extensions by one mark)**.** *Let $\mathcal{A}$ be a plain cell on $\mathcal{E} \sqcup \{g\}$, $|\mathcal{E}| \ge 2$, whose hinge minors $\mathcal{A}\setminus g$ and $\mathcal{A}/g$ are connected. Its ratio $\varrho_{\mathcal{A}}$ (Definition 21.1) is constant exactly when $\mathcal{A}/g$ is the dual of $\mathcal{A}\setminus g$ with its weights multiplied by one constant $\mu > 0$; then $\varrho_{\mathcal{A}} \equiv \mu^2$, $\mathcal{A}/g$ has the fusion width one, and $\mu K_{\mathcal{A}}(\alpha_{\mathcal{E}}, \alpha_g) = K^\sharp(\alpha_{\mathcal{E}}, \mu\alpha_g)$, $K^\sharp$ the letter of the Foreman fusion of $\mathcal{A}/g$: $\mathcal{A}$ is that fusion with the weights of its bases avoiding g divided by μ. For a list, $\varrho_{\mathcal{A}}$ is constant exactly when $\mathcal{A}$ is identically self-dual, that is when $\mathcal{A}$ is the Foreman fusion of $\mathcal{A}/g$. So, at any exponents $s, t > 0$ and masses, the law of $\mathcal{A}$ is a point (Corollary 23.12(i)) exactly when $\mathcal{A}$ is the Foreman fusion of $\mathcal{A}/g$ up to one constant on the weights of the bases avoiding g, and for a list exactly when it is that fusion.*

Corollary 30.18 (A pinned set of one list is a dual pair)**.** *Let $\mathcal{B}$ be a list on $\mathcal{E}$, let $s, t > 0$, and let $S \subsetneq \mathcal{E}$, $|S| \ge 2$, with $S' = \mathcal{E} \setminus S$, be such that $\mathcal{B}|S$ and $\mathcal{B}/S'$ are connected. Then S is pinned (Theorem 28.25) exactly when it has width one and $\mathcal{B}/S' = (\mathcal{B}|S)^*$: the cell of the bunch $\mathcal{B}_S^+$ (Theorem 19.4) is a dual pair.*

Remark 30.19 (The lift ratios at a gauge; width three). (i) Let $\mathcal{B}$ be a list. The room sides of G in $\mathcal{B}^\sharp$ are the sets independent in $\mathcal{B}^*$ that span $\mathcal{B}$: the bases of the identity map from $\mathcal{B}^*$ to its quotient $\mathcal{B}$ read as a morphism of matroids, the arena property that Theorem 30.6(a) supplies. For such a morphism Eur and Huh (*Logarithmic concavity for morphisms of matroids*, Corollary 4.6) show that the basis generating polynomial, each basis counted once and homogenized by one more variable to the power n less the size of the basis, is Lorentzian, and a linear change of the variables with nonnegative coefficients keeps that property (Brändén and Huh), so at every gauge $\alpha_{\mathcal{E}}$ the values $K_{\mathcal{L}_j}(\alpha_{\mathcal{E}})/\binom{n}{r+j}$ form a log-concave sequence:

$$z_j(\alpha_{\mathcal{E}}) \;\ge\; \frac{(k+1)(n-k+1)}{k(n-k)} > 1, \qquad k = r + j,\ 0 < j < c.$$

So for a list at $c \ge 2$ the lift ratios exceed one at every gauge and the η_i of Theorem 30.16(ii) never coincide. The bound holds on the 6720 exact ratios of the receipt `t12_ratios_and_tell.py`,

with equality in 35 of them, and it is attained at the table's gauge whenever $\mathcal{L}_{j-1}$, $\mathcal{L}_j$ and $\mathcal{L}_{j+1}$ are uniform lists, as for every uniform list: there $K_{\mathcal{L}_i}(\mathbf{1}) = \binom{n}{r+i}$. The receipt `t08_logconcave.py` finds every lift ratio above one on 6720 exact ratios of its own. With weights the lift ratios can fall below one: $\binom{[4]}{1}$ with the weights 2 and the middle weights 1 has $K_{\mathcal{L}_0}(\mathbf{1}) = K_{\mathcal{L}_2}(\mathbf{1}) = 8$ and $K_{\mathcal{L}_1}(\mathbf{1}) = 6$, so $z_1 = \frac{9}{16}$ at the table's gauge.

(ii) At $c = 2$ the discriminant of $L_0 + 2L_1x + L_2x^2$ is $4L_0L_2(z_1 - 1)$, so the Skeleton values of G at $(\mathbf{1}_G, \alpha_{\mathcal{E}})$ are real and distinct where $z_1 > 1$, at every gauge for a list, and complex conjugate where $z_1 < 1$.

(iii) At $c = 3$, with the scale a of one mark of G held fixed, $K^\sharp$ is the letter of width two with the lift letters $L'_l = L_l + aL_{l+1}$, $0 \le l \le 2$; so at the masses 1 on G and $2\sigma = 2$ the integral over the scales of G at a fixed room point is, by Corollary 30.14(iii),

$$\int_0^\infty \frac{\log\big(L_1'^2/(L'_0L'_2)\big)}{L_1'^2 - L'_0L'_2}\,da, \qquad L_1'^2 - L'_0L'_2 = -\big((L_1L_3 - L_2^2)a^2 + (L_0L_3 - L_1L_2)a + (L_0L_2 - L_1^2)\big),$$

the coefficients of the quadratic being the 2×2 minors of the matrix with the rows (L_0, L_1, L_2) and (L_1, L_2, L_3), and its discriminant $-\frac{1}{27}$ times that of the diagonal level cubic $L_0+3L_1x+3L_2x^2+L_3x^3$ (receipts `t10_weight.py`, a rendering, and `t13_faces_and_cubic.py`). The cubic is real-rooted at all 560 gauges sampled on 8 lists of the fusion width three (receipts `w02_skeleton_braid.py`, `w03_real_c3.py`).

30.5 Cousins and hidden symmetry

Proposition 30.20 (Cousins)**.** *The* cousins *of an identically self-dual table are its one-mark contractions. Let $(\mathcal{B}, \theta)$ be fusable of the fusion width $c \ge 1$, and x a mark of $\mathcal{E} \sqcup G$.*

(i) The cousin $\mathcal{B}^\sharp/x$ has the fusion width one and is fusable, $\mathcal{B}^\sharp \setminus x$ is its dual, and its Foreman fusion is $(\mathcal{B}^\sharp, \theta^\sharp)$ with the fusion bunch $\{x\}$. For $x \in G$ the cousin is the partial fusion $\mathcal{B}^\sharp_{c-1}$, and at $c = 1$ the table $\mathcal{B}$ is the cousin at g.

(ii) On the balance wall of $\mathcal{B}^\sharp$ with every proper wall positive, for every two marks x, y,

$$\begin{aligned} P_{\mathcal{B}^\sharp}(\mathbf{m}; s, t) &= \Gamma\begin{bmatrix} m_x, & 2\sigma - m_x \\ 1 & 2\sigma \end{bmatrix} P_{\mathcal{B}^\sharp/x}\big(\mathbf{m}_{-x}; m_x, 2\sigma - m_x\big) \\ &= \Gamma\begin{bmatrix} m_y, & 2\sigma - m_y \\ 1 & 2\sigma \end{bmatrix} P_{\mathcal{B}^\sharp/y}\big(\mathbf{m}_{-y}; m_y, 2\sigma - m_y\big), \end{aligned}$$

$\mathbf{m}_{-x}$ the masses of the marks other than x: the cousins share one period up to Beta corners, each reading its exponents off the mass of the mark it lacks.

(iii) For every bijection β of $\mathcal{E} \sqcup G$ carrying $(\mathcal{B}^\sharp, \theta^\sharp)$, $P_{\mathcal{B}^\sharp}(\beta^*\mathbf{m}; s, t) = P_{\mathcal{B}^\sharp}(\mathbf{m}; s, t)$, with $(\beta^*\mathbf{m})_e = m_{\beta(e)}$. At $c = 1$ the function

$$(\mathbf{m}|_{\mathcal{E}}, s') \;\mapsto\; \Gamma\begin{bmatrix} s', & 2\sigma - s' \\ 1 & 2\sigma \end{bmatrix} P_{\mathcal{B}}\big(\mathbf{m}|_{\mathcal{E}}; s', 2\sigma - s'\big)$$

on the part of the hyperplane $m_{\mathcal{E}} + s' = 2\sigma r^*$ where every proper wall of $\mathcal{B}^\sharp$ is positive, which the automorphisms keep, is invariant under the automorphisms of $\mathcal{B}^\sharp$ acting on $\mathcal{E} \sqcup \{g\}$, s' read as the mass of g: an automorphism β with $\beta(g) = e \ne g$ makes the mass m_e the basis exponent and gives s' to the mark $\beta^{-1}(g)$ as its mass, and the transposition of g and e, when it is an automorphism, exchanges s' and m_e.

What fusion buys at every width is one step below the fused table. The fused table is identically self-dual and its automorphisms permute its marks; each cousin is the fused table with one mark integrated by a Beta corner, so the cousins are tables of fusion width one, often not isomorphic to one another, whose periods are one function. At the fusion width one, the table itself is a cousin and the hidden symmetry acts on its exponent and its masses together; at the width $c \geq 2$ the partial fusion $\mathcal{B}^{\sharp}_{c-1}$ is the cousin, and the table lies $c-1$ cells below it.

Remark 30.21 (Hidden symmetry). The index of the automorphisms of $\mathcal{B}$ times the permutations of G in those of $\mathcal{B}^{\sharp}$ measures the symmetry the fusion adds. For $\binom{\mathcal{E}}{r}$ it is $\binom{n+c}{c}$, all bijections of $\mathcal{E} \sqcup G$ carrying $\binom{\mathcal{E} \sqcup G}{r^*}$; for the list of rank two with one parallel pair of Remark 30.9(iii) it is $(n-2)(n-3)$; for the 10 fusable prime lists of rank three on seven marks the fusion is transitive and its group is 8 times that of the list (receipts `census_extra.py`, `atoms7.py`). At the fusion width two the index is 45 for $\binom{[8]}{3}$, 20 for one line of three marks and five free marks, 15 for one line of four marks and four free marks, 6 for two lines of three marks meeting in a mark and three free marks, 2 for two disjoint lines of three marks and two free marks, and 1 for F_7 with a free mark, for A_9 less a mark and for two disjoint lines of four marks; at the width three it is 220 for $\binom{[9]}{3}$ and 1 for A_9 and for Z_9 (receipt `w01_seam_rank3.py`). At $\binom{[2r+1]}{r}$, $r \geq 2$, the symmetric group of $\binom{[2r+2]}{r+1}$ accounts for a nonzero submodule that the closings miss at its centre, with every symmetry of the four kinds of its centre ray in the group (Proposition 39.64); at $\binom{[5]}{2}$ its part in the span of a box is a line (Exercise 54.20). Among 40 identically self-dual lists of rank five on ten marks drawn at random, in each of which the sets of five marks that are not bases form a family closed under complement whose members meet pairwise in at most three marks, 23 have ten cousins no two of which are isomorphic (receipt `random10.py`), and all the cousins of these 23 are prime (receipt `random10b.py`).

30.6 Two-sums and repair

Definition 30.22 (Covered marks; the conditions at a hinge). Let $\mathcal{B}$ be a table on $\mathcal{E}$. A mark e of a cocircuit D is *covered in* D when some circuit C has $e \in C \subseteq D$, and e is *uncovered* when some cocircuit contains it without covering it. For a cell $\mathcal{A}$ on $B \sqcup \{g\}$ with the hinge g (Definition 21.1) the *conditions at the hinge* are:

(a) every cocircuit avoiding g is a union of circuits;

(u) every cocircuit D through g covers every mark of $D \setminus \{g\}$;

(s) every cocircuit D through g covers every mark of $D \setminus \{g\}$ by circuits avoiding g;

(h) every cocircuit through g covers g.

For two cells $\mathcal{A}_1$, $\mathcal{A}_2$ the conditions are written a_1, u_1, s_1, h_1 and a_2, u_2, s_2, h_2.

Theorem 30.23 (Fusion across a two-sum). *Let $\mathcal{A}_1$ and $\mathcal{A}_2$ be cells that are lists, on $\mathcal{E}_1 \sqcup \{g\}$ and $\mathcal{E}_2 \sqcup \{g\}$ with n_1 and n_2 marks, of the ranks r_1, r_2 and the fusion widths c_1, c_2, and $\mathcal{S} = \mathcal{A}_1 \oplus_g \mathcal{A}_2$ their two-sum on $\mathcal{E}_1 \sqcup \mathcal{E}_2$ (Lemma 21.12).*

(i) $\mathcal{S}$ has the fusion width $c_1 + c_2$. Its circuits are the circuits of $\mathcal{A}_1$ and of $\mathcal{A}_2$ that avoid g and the sets $(C_1 \setminus g) \cup (C_2 \setminus g)$ with C_i a circuit of $\mathcal{A}_i$ through g; its cocircuits are the same with cocircuits in place of circuits; and $\mathcal{S}^* = \mathcal{A}_1^* \oplus_g \mathcal{A}_2^*$.

(ii) $\mathcal{S}$ is fusable exactly when

$$a_1 \text{ and } u_1 \text{ and } a_2 \text{ and } u_2 \text{ and } (s_1 \text{ or } h_2) \text{ and } (s_2 \text{ or } h_1),$$

and a cell, read as a table, is fusable exactly when a, u and h hold. So two fusable cells give a fusable two-sum.

(iii) If $\mathcal{S}$ is fusable, then $c_1, c_2 \geq 0$, and in $\mathcal{S}^\sharp$ the sets $\mathcal{E}_1$ and $\mathcal{E}_2$ are bunches of the widths c_1+1 and c_2+1.

(iv) If both cells are fusable, the two-sum $\mathcal{A}_1^\sharp \oplus_g \mathcal{A}_2^\sharp$, with the fusion bunch $G_1 \sqcup G_2$, is an identically self-dual major of $\mathcal{S}$. It is $\mathcal{S}^\sharp$ when $c_1 = 0$ or $c_2 = 0$. When $c_1, c_2 \geq 1$ its children at one mark of G_1 and at one mark of G_2 have the ranks $r_1^* - 1$ and r_1^* on $\mathcal{E}_1$, $r_1^* = n_1 - r_1$ the corank of $\mathcal{A}_1$, so $G_1 \sqcup G_2$ is not in level form in it and it is a major other than $\mathcal{S}^\sharp$.

(v) If $c_1 + c_2 = 1$, $\mathcal{S}$ is fusable exactly when both cells are fusable; then, for $c_2 = 0$, $\mathcal{A}_2$ is identically self-dual, $\mathcal{S}^\sharp = \mathcal{A}_1^\sharp \oplus_g \mathcal{A}_2$, and the hinge of $\mathcal{S}$ is a hinge of $\mathcal{S}^\sharp$.

The condition is local at the hinge: away from it each cell answers for itself, and through it a cocircuit of the two-sum joins a cocircuit of each cell, so a mark is covered either by a circuit of its own cell avoiding the hinge or by a circuit through the hinge continued by a circuit through the hinge on the other side; that continuation exists exactly when the other cell covers its hinge. In the fused table the hinge of a cell of positive width thickens into a bunch of that width plus one. Fusing cell by cell gives a major, identically self-dual, that is not the fusion as soon as two cells have positive width: the canonical fusion of a two-sum is the global level cell. At the total width one the hinge survives the fusion, with the identically self-dual cell on one side and the fusion of the other cell on the other.

Corollary 30.24 (A two-sum with an identically self-dual cell)**.** *Let $\mathcal{A}_1$ be identically self-dual and $s, t > 0$, with the masses $\mathbf{m}$ of $\mathcal{S} = \mathcal{A}_1 \oplus_g \mathcal{A}_2$ on its balance wall with every proper wall positive, and let $\kappa = m_{\mathcal{E}_1} - s(r_1 - 1) - t(|\mathcal{E}_1| - r_1)$ be the hinge wall of $\mathcal{A}_1$ (Definition 23.1). Then*

$$P_{\mathcal{S}}(\mathbf{m}; s, t) = P_{\mathcal{A}_1}\big(\mathbf{m}|_{\mathcal{E}_1}, 2\sigma - \kappa; s, t\big)\, P_{\mathcal{A}_2}\big(\mathbf{m}|_{\mathcal{E}_2}, \kappa; s, t\big) \Big/ \Gamma_1^2 \begin{bmatrix} 2\sigma - \kappa, & \kappa \\ & 2\sigma \end{bmatrix},$$

the hinge carrying $2\sigma - \kappa$ in $\mathcal{A}_1$ and κ in $\mathcal{A}_2$. When the cells are lists and $\mathcal{A}_2$ is fusable of the fusion width one, this is the period of $\mathcal{S}$ read across the hinge that $\mathcal{S}^\sharp = \mathcal{A}_1 \oplus_g \mathcal{A}_2^\sharp$ keeps.

By Corollary 20.19 at the hinge, the first factor divided by the Beta corner is the period $P_{\mathcal{A}_1 \backslash g}(\mathbf{m}|_{\mathcal{E}_1}; \kappa, 2\sigma - \kappa)$ of the deletion at the hinge. So identically self-dual cells attached at their hinges to one cell that is not identically self-dual cost the period of that cell and, for each of them, the period of its deletion at the hinge; two cells that are not identically self-dual on the two sides of a hinge pair two laws, and the hinge is a convolution (Theorem 23.9).

Proposition 30.25 (Uncovered marks and repair)**.** *Let $(\mathcal{B}, \theta)$ be a table on $\mathcal{E}$ of the fusion width c.*

(i) $\mathcal{B}$ has no uncovered mark (Definition 30.22) exactly when every cocircuit of $\mathcal{B}$ is a union of circuits. So a list, or a table of the fusion width $c \neq 0$, is fusable exactly when it has no uncovered mark, and a table of the fusion width zero exactly when it is identically self-dual.

(ii) For a set S of marks, none a loop, let $(\mathcal{B}_S, \theta)$ be the table in which each $h \in S$ is replaced by a block $\{h, h'\}$ of two marks by the first rule of Theorem 21.5, a parallel pair, every new basis keeping the weight of its basis, and $S' = \{h' : h \in S\}$. Then $\mathcal{B}_S$ has the fusion width $c + |S|$, $(\mathcal{B}_S, \theta) \setminus S' = (\mathcal{B}, \theta)$, and $\mathcal{B}_S$ has no uncovered mark exactly when S contains every uncovered mark of $\mathcal{B}$; when $\mathcal{B}$ is a list or $c + |S| \neq 0$, $\mathcal{B}_S$ is fusable exactly then.

(iii) If $\mathcal{B}_S$ is fusable, $(\mathcal{B},\theta) = (\mathcal{B}_S)^\sharp/G \setminus S'$ is a minor of an identically self-dual table. If $c \geq 0$ and $(\mathcal{B},\theta)$ is not fusable, $\mathcal{B}_S$ is fusable for S the set of the uncovered marks when there is one, and for S any one mark when there is none, no mark being then a loop. Doubling every mark of a list that is not a loop gives a fusable list.

(iv) At the full basis lean, where every other proper wall is positive, the residue of $P_{\mathcal{B}_S}(\mathbf{m};s,0)$ at the wall $m_{h'}=0$ of one copy h' is $P_{\mathcal{B}_{S-h}}(\mathbf{m}_{-h'};s,0)$ (Theorem 16.25); so $P_{\mathcal{B}}(\cdot;s,0)$ is the residue of $P_{\mathcal{B}_S}(\cdot;s,0)$ at the walls of the copies, taken one at a time.

A mark is uncovered when a cocircuit through it has no circuit through it inside: the cocircuit is a set the bases must meet, and the mark is not tied by any circuit to the other marks there. A parallel copy is a circuit of two marks through it inside every cocircuit through it, so doubling an uncovered mark covers it, and each doubled mark adds one to the fusion width. The list $\binom{[3]}{2}$, of the fusion width -1, has every mark uncovered: one or two doubled marks do not fuse, all three do, at the width two (receipts `t04_twosums.py`, `w04_repair.py`); its dual $\binom{[3]}{1}$, which the procedure below reads first, fuses as it is, into $\binom{[4]}{2}$.

30.7 The procedure

The statements of this chapter set a branch at every node of the Foreman tree (Definition 14.4), read before anything is integrated.

(1) *Peel.* If the realization of the node is not an atom, peel it at its Foreman bunch and continue on the room (Definition 14.4).

(2) *Go down.* If the table of the node is identically self-dual, every mark comes off by one Beta corner at every pair of exponents (Corollary 20.19); its cousins share its period (Proposition 30.20).

(3) *Go up.* Otherwise read the fusion width $c = r^* - r$, passing to the dual table when it is negative, and the tell on the Skeleton (Theorem 30.6). If the table is fusable, fuse it (Theorem 30.5); at $c = 0$ it is not, a fusable table of the width zero being identically self-dual. At $c = 1$ the fusion is free, one Beta corner (Corollary 30.13): the automorphisms of the identically self-dual table $\mathcal{B}^\sharp$ act on the exponent and the masses of the table, its cousins share its period, and its module carries over (Chapter 39). At $c \geq 2$ the table is the child of the full pattern of the fusion bunch of $\mathcal{B}^\sharp$; the fused table is the universal piece of width c glued to the lift partner (Theorem 30.12), both laws spread (Theorem 30.16), the step from $\mathcal{B}^\sharp$ to $\mathcal{B}^\sharp_{c-1}$ is a Beta corner and the $c-1$ steps below it are cells whose laws are not points.

(4) *Two-sums.* On a two-sum of lists the tell is read at the hinge (Theorem 30.23(ii)); at the total width one the hinge survives the fusion and the period is a product over one Beta corner (Corollary 30.24); when both cells are fusable and one has the width zero the fusion is the two-sum of the fusions of the cells, and when both cells have positive width it is the global level cell, not that two-sum (Theorem 30.23(iv)).

(5) *Repair.* If the table is not fusable and has uncovered marks, they are the obstruction: doubling exactly those in parallel gives a fusable table with the table as its deletion at the copies (Proposition 30.25), at the fusion width c plus the number of uncovered marks; a table of the width zero with no uncovered mark that is not identically self-dual, which needs weights, becomes fusable when any one mark is doubled.

The fusion width is the price, and it is read off the rank and the number of marks before any integral is taken: at the width one the fusion bunch is a single mark with a point for its law; at the width $c \geq 2$ it is the universal piece, whose law spreads over a torus of the dimension $c - 1$ against a lift partner whose law is not a point.

Chapter 31

Closing a glue along a direction

A glue opened on its shares is a fibre integral of Gammas and two seam functions (Theorem 28.10(iii)). It is closed by moving the contour along a direction of the shares, collecting a fibre integral of residues at every polar hyperplane crossed and showing that what is left tends to zero. The glue closes on the lattices of its Gammas along every direction whose rate, read off the two laws through the largest values of the monomials of their letter vectors, is negative (Theorem 31.2), and past the walls of the piece, or of the piece and the partner both, at the growths of the continued seam functions (Theorem 31.4). Moving the contour is exact at every step, and the limit needs only a bound that travels with it (Lemma 31.3): the series depends on the direction only through its chamber (Theorem 31.6), the laws can be closed one source point at a time and averaged, at the rate read on the support of the source measure rather than on its convex hull (Theorem 31.7), and past the walls of a piece the bound is read on the outline of a keyhole continuation, the modulus and the phase of the sector letters taken at one point (Theorem 31.11). At simple nonresonant crossings of a rational ray, a crossing term kept with its falling shares integrated on their strips is a finite sum of joint Trailmoments of fixed functions, a falling Gamma becoming a positive share and one Beta variable and a continued source factor a segment and circle integrals (Theorem 31.18); for a positive kernel its root rate is the exponential of the least Gamma rate of its chamber in every fibre dimension and, averaged, of the essential supremum over the source of that least rate, whose sign, when it is not zero, decides whether the terms tend to zero (Theorem 31.26, Corollary 31.27); and an averaged closing can converge where no direction of its chamber certifies it, at a family of tables whose seam has single stations (Theorem 31.8). Coincident crossings are packets of factors polar on one crossed hyperplane, assembled before a sign or a top is read (Theorem 31.30), and at the root rate one a positive moment sequence is decided by its law near its top (Theorem 31.32).

31.1 Closing along a direction

Definition 31.1 (Letter vectors)**.** Let a piece on B and a partner on R with the stations $\mathcal{D}$ be glued with masses on the balance wall of the glue (Definition 28.4), the glue read on its shares as in Theorem 28.10(iii) or Theorem 28.12. The *letter vectors* of the piece and of the partner are $\mathbf{V}_B = (V_{jD}, V_{jD}^*)_{j,D}$ and $\mathbf{V}_R = (L_{jD}, L_{jD}^*)_{j,D}$, and for a vector $\mathbf{v}$ of the coordinates of the shares $\mathbf{V}_B^{\mathbf{v}} = \prod_{j,D} V_{jD}^{v_{jD}} {V_{jD}^*}^{v_{jD}^*}$, and likewise $\mathbf{V}_R^{\mathbf{v}}$.

Theorem 31.2 (Closing the glue along a direction)**.** *In Theorem 28.12 let V be the space of the free directions of the shares, so that for $\mathbf{v} \in V$ the monomials $\mathbf{V}_B^{\mathbf{v}}$ and $\mathbf{V}_R^{\mathbf{v}}$ (Definition 31.1) are*

homogeneous of degree zero, and their suprema over the orthants do not change under $\vec{\mathcal{N}}_B^{\perp}$ *and* $\vec{\mathcal{N}}_R^{\perp}$. *When the seam word of the piece has a Newton sum of full dimension,* $\sup \mathbf{V}_B^{\mathbf{v}} = \sup_{u\in\Delta_B} \boldsymbol{\varrho}_B^{\rho}(u)^{\mathbf{v}}$, *the largest value of the monomial* $\mathbf{x}^{\mathbf{v}}$ *on the support of the law of the piece, and when the room word of the partner has a Newton sum of full dimension,* $\sup \mathbf{V}_R^{\mathbf{v}} = \sup_{v\in\Delta_R} \boldsymbol{\varrho}_R^{\rho}(v)^{\mathbf{v}}$, *the largest value on the support of the law of the partner; where the room letters of the partner are monomials,* $\sup \mathbf{V}_R^{\mathbf{v}} = \boldsymbol{\xi}^{\mathbf{v}}$, $\boldsymbol{\xi}$ *their coefficients. For* $\boldsymbol{\sigma} \in V$ *put*

$$h(\boldsymbol{\sigma}) = \sum_{j,D} \big(\sigma_{jD} \log|\sigma_{jD}| + \sigma^*_{jD} \log|\sigma^*_{jD}|\big) + \log\sup \mathbf{V}_B^{-\boldsymbol{\sigma}} + \log\sup \mathbf{V}_R^{-\boldsymbol{\sigma}},$$

with $0\log 0 = 0$, *the first sum over the shares of the active letters, the* rate *of the direction; it is homogeneous of degree one. Let* $h(\boldsymbol{\sigma}) < 0$, *and let the real point* $\mathbf{c}$ *of the pins lie off the null set of the points whose ray* $\mathbf{c} + \tau\boldsymbol{\sigma}$, $\tau \geq 0$, *meets two polar hyperplanes of the Gammas that are not parallel on the fibre at one point, or, for arbitrarily large* τ, *at points less than* τ^{-3} *apart. Then the ray meets only the hyperplanes* $a_{jD} = -n$ *with* $\sigma_{jD} < 0$ *and* $b_{jD} = -n$ *with* $\sigma^*_{jD} < 0$, $n \in \mathbb{N}$, *and*

$$P_{B\sqcup R}(\mathbf{m}) = \sum_{\text{crossings}} \mathcal{R},$$

the sum, in the order of crossing, of the fibre integrals $\mathcal{R}$ *of the residues of the integrand at the hyperplanes crossed, each pinned also by its hyperplane, of the dimension* $\dim V - 1$ *and of the same kind, at the point where the ray meets it; a hyperplane of the fibre on which several Gammas have poles is crossed once, for every* $\mathbf{c}$, *and its residue is a Laurent coefficient (Theorem 4.5). The sum converges absolutely: the residue at a crossing at* τ, *and the integral left after it, are* $O\big(e^{\tau(h(\boldsymbol{\sigma})+\epsilon)}\big)$ *for every* $\epsilon > 0$.

So the glue closes on the lattices of its Gammas along every direction of the cone $\{h < 0\}$ of V, the terms falling at least by the factor $e^{h(\boldsymbol{\sigma})}$ per unit of $\boldsymbol{\sigma}$. The cone and the rate are read off the laws through the largest values of the monomials of their letter vectors, and the term $\sum \sigma \log|\sigma|$ of the rate is the cost of moving shares between stations: it vanishes at width one with the stations of one excess merged, every letter then moving its two shares oppositely, and along the one direction of a node of width one the condition is that the ranges of the two ratios be separated, as in Section 20.7. A direction along which a law is unbounded, its supremum infinite, crosses the walls of its seam function as well. The seam function of a piece continues past its walls with a growth that its sector integrals bound, and the partner can be read in its monomials, which have no walls, or continued past its own walls in the same way.

31.2 Closing along a path

The closings of Theorems 31.2 and 31.4 move the contour of the share fibre along a ray, collect a fibre integral of residues at every polar hyperplane crossed, and show that what is left tends to zero. The two steps come apart. Moving the contour is exact at every step: the period is the sum of the crossing terms met so far and of the fibre integral at the current point, by Cauchy's theorem on bounded contours. Only the last step is a limit, and it asks for a bound on the remaining fibre integral at the points that the path passes through, not for a domination of the double family of crossings and fibres, which is what interchanging the sum over the crossings with the fibre integrals would ask, and what fails past the walls. The step is Lemma 31.3, with three consequences: a closing depends on its direction only through its chamber (Theorem 31.6); the laws can be closed one source point at a time and averaged (Theorem 31.7); and past the walls of a piece the bound

that travels is read on the outline of a keyhole continuation (Theorem 31.11). The bounds multiply over products, survive averaging and pass to the crossing terms (Proposition 31.13).

Lemma 31.3 (Closing along a path)**.** *Let A be the affine space of the real points of the real pins of a fibre integral and V its space of directions, of dimension $n \geq 1$, with the measure $d\boldsymbol{\vartheta}$, the fibre integral through a real point p being $\int_{p+iV} I$ (Definition 4.1) wherever it converges absolutely; and let $\Omega \subseteq A$ be open. Let I be meromorphic on the tube $\Omega + iV$, with its poles on the complex hyperplanes $\{\ell_H = 0\}$ of a family $\mathfrak{H}$ of real hyperplanes $H = \{\ell_H = 0\}$ of A, locally finite in Ω, each ℓ_H real, affine and not constant. Let $\gamma : [0, \infty) \to \Omega$ be continuous and piecewise linear, with finitely many breaks on every bounded interval and $\gamma(0) = \mathbf{c}$ off $\bigcup \mathfrak{H}$, and assume:*

(H0) Clean crossings. *γ meets $\bigcup \mathfrak{H}$ at a discrete set of times, its* crossings*, none of them a break of γ; at a crossing τ^* the hyperplanes of $\mathfrak{H}$ through $\gamma(\tau^*)$ are one hyperplane H, and $\ell_H \circ \gamma$ changes sign at τ^* with a nonzero slope.*

(H1) Local decay. *For every compact $Q \subset \Omega$ and $\delta > 0$ there are $C, c > 0$ with $|I(x+i\boldsymbol{\vartheta})| \leq Ce^{-c|\boldsymbol{\vartheta}|}$ whenever $x \in Q$ and $x + i\boldsymbol{\vartheta}$ lies at distance at least δ from every hyperplane $\{\ell_H = 0\}$ of the tube.*

(H2) A travelling bound. *There are times $\tau_1 < \tau_2 < \cdots$ tending to infinity, none a crossing, at which*

$$\beta(\tau_k) = \int_V \big|I(\gamma(\tau_k) + i\boldsymbol{\vartheta})\big|\, d\boldsymbol{\vartheta}$$

is finite and tends to zero.

Then for every k

$$\int_{\mathbf{c}+iV} I = \sum_{\tau^* < \tau_k} \mathcal{R}_{\tau^*} + \int_{\gamma(\tau_k)+iV} I, \qquad \Big|\int_{\gamma(\tau_k)+iV} I\Big| \leq (2\pi)^{-n}\beta(\tau_k),$$

so that $\int_{\mathbf{c}+iV} I = \lim_k \sum_{\tau^* < \tau_k} \mathcal{R}_{\tau^*}$. The crossing term *at a crossing τ^* of the hyperplane H is*

$$\mathcal{R}_{\tau^*} = \pm(2\pi)^{1-n} \int_{V_H} \mathrm{Res}_{w=0}\, I\big(\gamma(\tau^*) + w\,\mathbf{e} + i\boldsymbol{\vartheta}'\big)\, d\mu_H(\boldsymbol{\vartheta}'),$$

with $V_H \subset V$ the kernel of the linear part ℓ_H^{lin} of ℓ_H, μ_H the measure on V_H with $d\boldsymbol{\vartheta} = d\mu_H\, d\ell_H^{\mathrm{lin}}(\boldsymbol{\vartheta})$, $\mathbf{e} \in V$ any vector with $\ell_H^{\mathrm{lin}}(\mathbf{e}) = 1$, on which the term does not depend, and the sign $+$ when ℓ_H decreases along γ and $-$ when it increases. The residue is that of the whole integrand, a Laurent coefficient where several of its factors are polar on H, and the crossing term is its fibre integral, pinned also by $\ell_H = 0$. If some τ_k lies between any two consecutive crossings and $\sum_k \beta(\tau_k) < \infty$, the crossing terms are absolutely summable, a crossing between τ_k and τ_{k+1}, the only one there, having $|\mathcal{R}_{\tau^*}| \leq (2\pi)^{-n}\big(\beta(\tau_k) + \beta(\tau_{k+1})\big)$.

Theorem 31.4 (Closing past the walls)**.** *Let the seam function of the piece converge at a real point of the pins of the seam with positive shares, so that its seam word has a Newton sum of full dimension (Theorem 25.2). Read the partner in its monomials, $L_{jD} = \sum_k \xi_{jDk}\, \alpha_R^{\mathbf{n}_{jDk}}$ and $L^*_{jD} = \sum_k \xi^*_{jDk}\, \alpha_R^{\mathbf{n}^*_{jDk}}$, with one share a_{jDk} or b_{jDk} for each monomial, and write $\bar{a}_{jD} = \sum_k a_{jDk}$ and $\bar{b}_{jD} = \sum_k b_{jDk}$; bars mark sums over the monomials.*

(i) On every contour of shares with positive real parts, pinned by the letter totals and by $\sum_{j,D,k}(a_{jDk}\mathbf{n}_{jDk} + b_{jDk}\mathbf{n}^*_{jDk}) = \mathbf{m}_R$, at which the seam function of the piece converges, the

period of the glue converging,

$$P_{B\sqcup R}(\mathbf{m}) = \int_{pins} \prod_{j:\, s_j>0} \frac{\prod_{D,k} \Gamma(a_{jDk})\, \xi_{jDk}^{-a_{jDk}}}{\Gamma(s_j)} \prod_{j:\, t_j>0} \frac{\prod_{D,k} \Gamma(b_{jDk})\, {\xi^*_{jDk}}^{-b_{jDk}}}{\Gamma(t_j)}\; P_{W_B(\bar{\mathbf{a}},\bar{\mathbf{b}})}(\mathbf{m}_B).$$

(ii) Fix $e_0 \in B$ and a fan of the seam word*: finitely many rational simplicial cones of dimension $|B|-1$ with disjoint interiors covering $\mathbb{R}^{B\setminus e_0}$, each contained, for every seam letter V of an active letter, in a set $\{\mathbf{v} :\ \langle \mathbf{t}, \mathbf{v}\rangle \le \langle \mathbf{t}', \mathbf{v}\rangle$ for every exponent $\mathbf{t}'$ of the support of $V\}$, $\mathbf{t}$ one exponent of that support, the pairings taken on $B \setminus e_0$. On a cone π of it, a* sector*, with the primitive integral generators $\mathbf{v}_{\pi,1}, \dots, \mathbf{v}_{\pi,|B|-1}$, write the logarithmic coordinates $x = \log \alpha_{B\setminus e_0}$ of the section $\alpha_{e_0} = 1$ as $x = -\sum_k u_k \mathbf{v}_{\pi,k}$, $u_k \ge 0$; the $q_k = e^{-u_k} \in (0,1]$ are the* sector coordinates*. On the section a seam letter V of an active letter is $V = \prod_k q_k^{\langle \mathbf{t}, \mathbf{v}_{\pi,k}\rangle}\, k_{V,\pi}(q)$, $\mathbf{t}$ the exponent of its support at which every generator of π pairs least, and its* sector letter *$k_{V,\pi}$ is a polynomial in q with nonnegative coefficients and a positive constant term. Write $k_{jD,\pi}$ and $\psi_{jD,\pi}$ for the sector letters of V_{jD} and V^*_{jD}, $\mathbf{t}_{jD,\pi}$ and $\mathbf{t}^*_{jD,\pi}$ for their exponents, and for a generator $\mathbf{v}$ of π call*

$$\kappa_{\mathbf{v}}(\mathbf{z}) = \Big\langle \mathbf{m}_B - \sum_{j,D} \big(\bar{a}_{jD}\, \mathbf{t}_{jD,\pi} + \bar{b}_{jD}\, \mathbf{t}^*_{jD,\pi}\big),\ \mathbf{v} \Big\rangle, \qquad \mathbf{z} = (\bar{\mathbf{a}}, \bar{\mathbf{b}}),$$

the pairing on $B \setminus e_0$, the wall *of $\mathbf{v}$: affine in the shares with a rational linear part, and the same for every sector of which $\mathbf{v}$ is a generator. On the pins of the seam, at every real point at which every wall is positive,*

$$P_{W_B(\mathbf{z})}(\mathbf{m}_B) = \sum_{\pi} |\det(\mathbf{v}_{\pi,1}, \dots, \mathbf{v}_{\pi,|B|-1})| \int_{[0,1]^{|B|-1}} \prod_k q_k^{\kappa_{\mathbf{v}_{\pi,k}}(\mathbf{z})-1} \prod_{j,D} k_{jD,\pi}(q)^{-\bar{a}_{jD}}\, \psi_{jD,\pi}(q)^{-\bar{b}_{jD}}\, dq,$$

and the seam function converges at a real point exactly when every wall is positive there. It continues meromorphically to all complex shares, with poles, of order at most $|B|-1$, only on the hyperplanes on which a wall lies in $-\mathbb{N}$, and for every $\theta > 0$ there are M, C_0 and n_1 with

$$\big|P_{W_B(\mathbf{z})}(\mathbf{m}_B)\big| \le C_0\, \delta^{-(|B|-1)} (1+|\mathbf{z}|)^{n_1} M^{|\operatorname{Re}\mathbf{z}|_1} e^{\theta |\operatorname{Im}\mathbf{z}|_1},$$

δ the smaller of 1 and the distance of $\mathbf{z}$ from these hyperplanes. The piece is of tables *when at every station the seam letters of the active letters are the basis and the cobasis polynomials of one table on B with the bases $\mathcal{B}_{jD}$ and positive weights, as for a bunch of a family of tables (Proposition 28.2(i)). Its seam word then has a Newton sum of full dimension exactly when the family of these tables is connected; the sectors of the orders π of B (Theorem 8.5(ii)) form a fan of it, every determinant being 1, the sector letters being those of the tables $\mathcal{B}_{jD}$ and the generators $\mathbf{1}_{U_k} - (\mathbf{1}_{U_k})_{e_0}\mathbf{1}$ on $B \setminus e_0$, U_k the tails; the wall of the generator of U is the proper wall $\kappa_U = m_U - \sum_{j,D} \big(\bar{a}_{jD}\, d_{jD}(U) + \bar{b}_{jD}\, d^*_{jD}(U)\big)$, d_{jD} and d^*_{jD} the counts of $\mathcal{B}_{jD}$.*

(iii) For a direction $\boldsymbol{\sigma}$ of the shares of (i) and $\theta \ge 0$ let $g(\boldsymbol{\sigma};\theta)$, at the real point $\bar{\mathbf{c}}$ of the pins of the seam, be the infimum of the M for which there are C, n_1 and n_2 with

$$\big|P_{W_B(\bar{\mathbf{c}}+\tau\bar{\boldsymbol{\sigma}}+i\bar{\boldsymbol{\vartheta}})}(\mathbf{m}_B)\big| \le C\, \delta^{-n_2} (1+\tau+|\boldsymbol{\vartheta}|)^{n_1} M^{\tau} e^{\theta|\boldsymbol{\vartheta}|_1}$$

for $\tau \ge 0$ and $\boldsymbol{\vartheta}$ in the directions of the shares, δ the smaller of 1 and the distance from the polar hyperplanes: the growth *of the continued seam function along $\boldsymbol{\sigma}$ at the angle θ, the*

growth of Definition 20.33 read along any direction with the angle fixed. It is finite for $\theta > 0$, and $g(\boldsymbol{\sigma}; 0) = \sup \mathbf{V}_B^{-\bar{\boldsymbol{\sigma}}}$ when no wall of the seam word falls along $\bar{\boldsymbol{\sigma}}$, which is exactly when that supremum is finite. Put

$$h_\Gamma(\boldsymbol{\sigma}) = \sum_l \sigma_l \log|\sigma_l| - \sum_l \sigma_l \log \xi_l, \qquad h_\theta(\boldsymbol{\sigma}) = h_\Gamma(\boldsymbol{\sigma}) + \log g(\boldsymbol{\sigma}; \theta) + \frac{2\theta^2}{\pi} \sum_{l:\, \sigma_l > 0} \sigma_l,$$

l running over the shares and ξ_l being the coefficient of the monomial of the share l; h_Γ is the Gamma rate *of the direction. Let the real point $\mathbf{c}$ of the pins lie off the null set of Theorem 31.2, taken with the polar hyperplanes of the seam function as well, and let g and h_θ be taken at its sums $\bar{\mathbf{c}}$. If $h_\theta(\boldsymbol{\sigma}) < 0$ for some $\theta \in [0, \pi/8)$, then*

$$P_{B \sqcup R}(\mathbf{m}) = \sum_{crossings} \mathcal{R},$$

the sum, in the order of crossing, of the fibre integrals of the residues of the integrand at the polar hyperplanes met by the ray $\mathbf{c} + \tau\boldsymbol{\sigma}$: the hyperplanes $a_l = -n$ of the shares with $\sigma_l < 0$, $n \in \mathbb{N}$, and the hyperplanes on which a wall of (ii) that falls along $\bar{\boldsymbol{\sigma}}$ lies in $-\mathbb{N}$, a hyperplane polar for several factors being crossed once, with its full residue. The sum converges absolutely, the terms at τ and the integrals left after them being $O\big(e^{\tau(h_\theta(\boldsymbol{\sigma})+\epsilon)}\big)$ for every $\epsilon > 0$.

(iv) Both sides continued. *Let the glue be read on the share side of Theorem 28.10(iii), one share a_{jD} or b_{jD} per station, in place of the reading of (i), and let the seam functions of the piece and of the partner both converge at a real point $\mathbf{c}$ of the pins with positive shares. By (ii), applied to the piece and to the partner, a piece on R read with the reversed excesses (Definition 28.4), both continue meromorphically to all complex shares of the pins, with their poles on the hyperplanes on which a wall of the seam word of the piece or of the room word of the partner lies in $-\mathbb{N}$, each with the bound of (ii). For a direction $\boldsymbol{\sigma}$ of the shares and $\theta \geq 0$ let $g_B(\boldsymbol{\sigma}; \theta)$ and $g_R(\boldsymbol{\sigma}; \theta)$ be the growths of the two continued seam functions along $\boldsymbol{\sigma}$ at $\mathbf{c}$, defined as in (iii) with the shares in place of their sums, and put*

$$h_{\theta_B, \theta_R}(\boldsymbol{\sigma}) = \sum_l \sigma_l \log|\sigma_l| + \log g_B(\boldsymbol{\sigma}; \theta_B) + \log g_R(\boldsymbol{\sigma}; \theta_R) + \frac{2(\theta_B + \theta_R)^2}{\pi} \sum_{l:\, \sigma_l > 0} \sigma_l.$$

Let $\mathbf{c}$ lie off the null set of Theorem 31.2, taken with the polar hyperplanes of both seam functions as well. If $h_{\theta_B, \theta_R}(\boldsymbol{\sigma}) < 0$ for some $\theta_B, \theta_R \geq 0$ with $\theta_B + \theta_R < \pi/8$, then $P_{B \sqcup R}(\mathbf{m}) = \sum_{crossings} \mathcal{R}$, the sum, in the order of crossing, of the fibre integrals of the residues of the integrand at the polar hyperplanes met by the ray $\mathbf{c} + \tau\boldsymbol{\sigma}$: the hyperplanes $a_l = -n$ of the shares with $\sigma_l < 0$, $n \in \mathbb{N}$, and those on which a wall of either word that falls along $\boldsymbol{\sigma}$ lies in $-\mathbb{N}$, a hyperplane polar for several factors being crossed once, with its full residue. The sum converges absolutely, the terms at τ and the integrals left after them being $O\big(e^{\tau(h_{\theta_B, \theta_R}(\boldsymbol{\sigma})+\epsilon)}\big)$ for every $\epsilon > 0$. A side along whose direction no wall of its word falls has the growth $\sup \mathbf{V}^{-\boldsymbol{\sigma}}$ of its letter vector at every angle, the largest value of the monomial on the support of its law (Theorem 31.2).

Along a direction in which the seam function converges, (iii) at $\theta = 0$ is the bound of Theorem 31.2 for the glue read in the monomials of the partner, and past a wall the residues of the seam function join those of the Gammas at the cost $\log g$ of its continuation, as the walls of the two families join the lattice at width one (Theorem 20.34(iii)). Read in its monomials as well,

any piece contributes only its coefficients: the integrand is then Gammas and coefficients, every supremum of a monomial of the letter vectors is a monomial in the coefficients, and every direction of the shares with $h_\Gamma(\boldsymbol{\sigma}) < 0$ closes, by Theorem 31.2. In which representation to close is a choice of rate: a law bounded along the direction closes at the largest value of its monomial, a side past its walls at the growth of its continuation, a side read in monomials at its coefficients, at the price of one pin for each of its marks. So (iii) and (iv) read each side at its own rate, the coefficients $-\sum_l \sigma_l \log \xi_l$ for a side read in its monomials and the logarithm of the growth of its continued seam function for a side read in its seam letters; at width one, where the share side has one free share, (iv) continues both families of the node, as Theorem 20.34(iii) does.

Expanding each active letter L, with its exponent e_L, in some of its terms, $L = Y_L + X_L$ with $X_L = \sum_k X_{L,k}$ the chosen terms, gives the multiple lattice whose terms are $(-1)^{|\mathbf{n}_L|}(e_L)_{|\mathbf{n}_L|}/\mathbf{n}_L!$ times the periods of $\alpha^{\mathbf{m}-\mathbf{1}} \prod_L Y_L^{-e_L-|\mathbf{n}_L|} \prod_k X_{L,k}^{n_{L,k}}$, positive words up to sign. Summed term by term in absolute value, it converges absolutely exactly when $X_L \le Y_L$ on the orthant for every active letter and the integral of $\alpha^{\mathbf{m}-\mathbf{1}} \prod_L (Y_L - X_L)^{-e_L}$ over a section is finite (Proposition 2.10). This needs the Newton polytope of X_L inside that of Y_L, so it never holds for a letter of a table, all of whose monomials are vertices of its Newton polytope: for families of tables the lattices close only in the order of a direction.

Theorems 31.2 and 31.4 are the lemma along a ray: (H0) holds off a null set of starting points, (H1) from the exponential decay of the Gamma factors in the imaginary directions (Theorem 2.11 at one scale, carried to negative real parts by the shift of Proposition 1.3(iii)), and (H2) from the largest values of the monomials on the supports of the laws or from the growth of the continued seam function. Two closings of one fibre integral along two paths agree at all times up to their remainders,

$$\sum_{\tau^* < \tau_k} \mathcal{R}_{\tau^*} - \sum_{\tau'^* < \tau'_k} \mathcal{R}'_{\tau'^*} = \int_{\gamma'(\tau'_k)+iV} I - \int_{\gamma(\tau_k)+iV} I,$$

and one of them may converge while the other does not. Each crossing term is a fibre integral of one dimension less, of an integrand of the same kind, which the lemma can close again along a path of its own when a bound travels with it there; this is how multiple lattices arise.

Definition 31.5 (Chambers of a closing)**.** Let I be meromorphic on the tube $\Omega + iV$ of Lemma 31.3 over an open convex $\Omega \subseteq A$, with its poles on the complex hyperplanes on which one of finitely many real affine functions ℓ on A, not constant, lies in $-\mathbb{N}$: its *polar functions*. A direction $\boldsymbol{\sigma} \in V$ *falls* a polar function ℓ when $\partial_{\boldsymbol{\sigma}} \ell < 0$, at the *falling rate* $-\partial_{\boldsymbol{\sigma}} \ell$. For a real point $\mathbf{c} \in \Omega$ at which every polar function is positive, the *chamber* $C(\boldsymbol{\sigma})$ of a direction $\boldsymbol{\sigma}$ whose ray $\mathbf{c} + \tau\boldsymbol{\sigma}$, $\tau \ge 0$, lies in Ω is the set of the $\boldsymbol{\sigma}' \in V$ whose ray lies in Ω and which fall exactly the polar functions that $\boldsymbol{\sigma}$ falls, each at the same falling rate; it is convex. In Theorem 31.2 the polar functions are the shares of the active letters, and Ω is the interior of the set of the real points of the pins at which the seam functions of the piece and of the partner converge, their reduced periods in Theorem 28.12, which is convex by Hölder's inequality and contains the ray $\mathbf{c} + \tau\boldsymbol{\sigma}$, $\tau \ge 0$, from a point $\mathbf{c} \in \Omega$ whenever $\sup \mathbf{V}_B^{-\boldsymbol{\sigma}}$ and $\sup \mathbf{V}_R^{-\boldsymbol{\sigma}}$ are finite. In Theorem 31.4(iii) they are the shares and the walls of the seam word, read as affine functions of the shares through their sums (Theorem 31.4(ii)), and $\Omega = A$. In a fibre integral of Gammas and coefficients, as the share side of a Gramma (Proposition 4.2) and the kernel of Theorem 31.7 below, they are the shares and $\Omega = A$, so that

$$C(\boldsymbol{\sigma}) = \{\boldsymbol{\sigma}' \in V : \ \sigma'_l = \sigma_l \text{ where } \sigma_l < 0, \ \ \sigma'_l \ge 0 \text{ elsewhere}\},$$

a compact convex polytope when the pins fix the total of the shares of every letter; the walls of source factors that are cube integrals (Definition 31.16 below) are polar functions as well.

Theorem 31.6 (A closing depends only on its chamber)**.** *Let I, $\mathbf{c}$ and $\boldsymbol{\sigma}$ be as in Definition 31.5, let I have the local decay (H1) of Lemma 31.3 on Ω, and let $\boldsymbol{\sigma}' \in C(\boldsymbol{\sigma})$. The rays $\mathbf{c}+\tau\boldsymbol{\sigma}$ and $\mathbf{c}+\tau\boldsymbol{\sigma}'$ meet the same polar hyperplanes at the same times, and (H0) holds along one of them exactly when it holds along the other; at every other time the fibre integrals through their two points are equal, and at a crossing their crossing terms are equal. So the closings along the two directions are one series, with the same remainders: the closing along $\boldsymbol{\sigma}$ converges, with the bounds of its terms and of its remainders, as soon as the closing along some direction of its chamber does. In Theorem 31.2, or in Theorem 31.4(iii), if $\mathbf{c}$ lies off the null set of Theorem 31.2, taken for Theorem 31.4(iii) with the polar hyperplanes of the seam function as well, the closing along $\boldsymbol{\sigma}$ converges absolutely as soon as*

$$\inf_{\boldsymbol{\sigma}' \in C(\boldsymbol{\sigma})} h(\boldsymbol{\sigma}') < 0,$$

h the rate of Theorem 31.2, the infimum being taken for Theorem 31.4(iii) over the rates h_θ, $\theta \in [0, \pi/8)$, as well; its terms and the integrals left after them are then $O(e^{\tau(h'+\epsilon)})$ for every $\epsilon > 0$, h' that infimum. On the chamber the rate h of Theorem 31.2 is convex.

So the closing along a direction converges as soon as some direction of its chamber is in the cone of Theorem 31.2, and its best certified rate is a convex problem in the free coordinates of the chamber. A chamber has positive dimension when the shares that do not fall have free directions on the pins, which stations of one excess supply. Theorem 31.2 reads both laws along one direction, through the largest values of the monomials of their letter vectors. The glue is also the average over the laws of the stand-in kernel (Theorem 28.10(ii)), whose integrand at one source pair has no walls, and, with the partner read in its monomials, the average over the law of the piece alone of an integrand without walls; each source point can therefore close along its own best direction of the chamber, and the averages of the crossing terms close the glue.

Theorem 31.7 (Averaging the laws)**.** *Take a share side, on pins that fix the total of the shares of every active letter, with V the space of the directions of the shares on the pins, whose integrand is*

$$\prod_{j\colon s_j>0} \frac{\prod \Gamma(a_l)}{\Gamma(s_j)} \prod_{j\colon t_j>0} \frac{\prod \Gamma(a_l)}{\Gamma(t_j)} \int e^{-\langle \mathbf{a}, y(\zeta)\rangle}\, d\lambda(\zeta),$$

the products over the shares l of K_j and of Ψ_j, $\mathbf{a}$ the vector of all the shares, λ a positive measure on a source, the source measure*, whose points are the* source points *ζ, and $y = (y_l)_l$ a continuous map of the source to the space of the shares. In Theorem 28.10 two share sides are of this kind, their shares l those of the active letters:*

- *(A) that of Theorem 28.10(iii), with one share per station; $\lambda = (\boldsymbol{\varrho}_B^\rho)_* \phi_B^\rho \otimes (\boldsymbol{\varrho}_R^\rho)_* \phi_R^\rho$, a source point $\zeta = (\mathbf{x}, \mathbf{x}')$ is a seam point of the piece and one of the partner, and $y_l(\zeta) = \log(x_{jD} x'_{jD})$ or $\log(x^*_{jD} x'^*_{jD})$ for the share of the station D of the letter;*
- *(B) that of Theorem 28.12 with the partner read in its monomials, one share per monomial, written as in Theorem 31.4(i), the seam word of the piece having a Newton sum of full dimension; $\lambda = (\boldsymbol{\varrho}_B^\rho)_* \phi_B^\rho$ is the law of the piece, a source point is a seam point $\zeta = \mathbf{x}$ of the piece, and $y_l(\zeta) = \log x_{jD} + \log \xi_l$ or $\log x^*_{jD} + \log \xi_l$ for the share of the monomial of the coefficient ξ_l at the station D.*

Let S_λ be the support of the image of λ under y, the log-support *of the source measure, $\mathbf{c}$ a real point of the pins with positive coordinates at which $\int e^{-\langle \mathbf{c}, y\rangle}\, d\lambda$ converges (in (A) the seam functions of the piece and of the partner converge there, in (B) that of the piece), $\boldsymbol{\sigma} \in V$, and $C = C(\boldsymbol{\sigma})$ the*

chamber of Definition 31.5 of the kernel below, whose polar functions are the shares:

$$C = \{\boldsymbol{\sigma}' \in V :\ \sigma'_l = \sigma_l \text{ where } \sigma_l < 0,\quad \sigma'_l \geq 0 \text{ elsewhere}\},$$

a compact convex polytope. Two shares are in one bundle *when they belong to one letter and have one column in the pins: in (A) when their stations have one excess, in (B) when moreover they carry one monomial of the partner. For y in the space of the shares put*

$$h(\boldsymbol{\sigma}'; y) = \sum_l \sigma'_l \log|\sigma'_l| - \langle \boldsymbol{\sigma}', y\rangle, \qquad h_C(y) = \min_{\boldsymbol{\sigma}' \in C} h(\boldsymbol{\sigma}'; y), \qquad \hat{h}_C = \sup_{y \in S_\lambda} h_C(y) \in (-\infty, \infty],$$

the rate *of $\boldsymbol{\sigma}'$ at y, the* chamber rate *of the kernel at y, concave in y, and the* averaged rate.

Let $\mathbf{c}$ be interior, relative to the pins, to the set of the real points at which the Laplace transform $\int e^{-\langle \mathbf{a}, y\rangle}\, d(y_*\lambda)(y)$ of $y_*\lambda$ converges; equivalently, for a basis $\mathbf{v}_1, \dots, \mathbf{v}_d$ of V there is $\eta > 0$ with

$$\sum_{\boldsymbol{\epsilon} \in \{-1,1\}^d} \int \exp\Big(- \Big\langle \mathbf{c} - \eta \sum_i \epsilon_i \mathbf{v}_i,\, y \Big\rangle \Big)\, d(y_*\lambda)(y) < \infty, \tag{31.1}$$

a finite certificate that $\mathbf{c}$ is interior to the set where that Laplace transform converges, that set being convex. Put $|y|_V = \sum_i |\langle \mathbf{v}_i, y\rangle|$, let p be the largest total order of the Gamma factors polar on one hyperplane that the ray of $\boldsymbol{\sigma}$ crosses, at most their number, and in this statement write $w(y) = e^{-\langle \mathbf{c}, y\rangle}(1 + |y|_V)^{p-1}$. Every power of $1 + |y|_V$ is at most a constant times $e^{\eta |y|_V} \leq \sum_{\boldsymbol{\epsilon}} \exp(\eta \sum_i \epsilon_i \langle \mathbf{v}_i, y\rangle)$, so (31.1) gives $\int w\, d(y_*\lambda) < \infty$.

(i) The kernel. *The* kernel *at a source point ζ is the fibre integral on the pins*

$$\int_{pins} \prod_{j:\, s_j > 0} \frac{\prod \Gamma(a_l)}{\Gamma(s_j)} \prod_{j:\, t_j > 0} \frac{\prod \Gamma(a_l)}{\Gamma(t_j)}\ e^{-\langle \mathbf{a}, y(\zeta)\rangle},$$

of an integrand without walls, and the fibre integral of the share side is its integral against λ, which in (A) and (B) is $P_{B \sqcup R}(\mathbf{m})$; in (A) the kernel is $\Gamma(\kappa_B)\, \mathsf{Z}_{(\kappa_B, \mathbf{s}, \mathbf{t}); t_{\mathcal{D}}}(\mathbf{x} \circ \mathbf{x}')$ of Theorem 28.10(ii). Let $\mathbf{c}$ lie off the null set of Theorem 31.2 for the direction $\boldsymbol{\sigma}$. For every $\epsilon > 0$ there is C_ϵ, not depending on the source point, such that the crossing terms $\mathcal{R}_k(\zeta)$ of the closing of the kernel along $\boldsymbol{\sigma}$, at their crossing times τ_k, satisfy

$$|\mathcal{R}_k(\zeta)| \leq C_\epsilon\, w(y)\, e^{\tau_k (h_C(y) + \epsilon)}, \qquad y = y(\zeta),$$

and the integrals left at times separating the crossings satisfy the same bound at the time τ with $e^{-\langle \mathbf{c}, y\rangle}$ in place of $w(y)$. When every crossed hyperplane carries a simple pole, $p = 1$ and $w(y) = e^{-\langle \mathbf{c}, y\rangle}$.

(ii) The averaged closing. *If $\hat{h}_C < 0$, the fibre integral of the share side is*

$$\sum_k \int \mathcal{R}_k\, d\lambda,$$

the sum in the order of crossing, absolutely convergent, its terms $O(e^{\tau_k(\hat{h}_C + \epsilon)})$ for every $\epsilon > 0$. At a crossing whose point along some $\boldsymbol{\sigma}' \in C$ lies in the interior of the set where $\int e^{-\langle \mathbf{a}, y\rangle}\, d\lambda$ converges, the averaged term is the crossing term of the share side there; so when it converges along the ray of $\boldsymbol{\sigma}$, the averaged closing is the closing of the share side along $\boldsymbol{\sigma}$, in (A) and (B) that of Theorem 31.2.

(iii) One direction reads the convex hull. $\min_{\boldsymbol{\sigma}'\in C}\sup_{y\in S_\lambda} h(\boldsymbol{\sigma}';y) = \sup_{y\in\operatorname{conv} S_\lambda} h_C(y) \geq \hat{h}_C$, *and* $\sup_{y\in S_\lambda} h(\boldsymbol{\sigma}';y)$ *is the rate of the closing of the share side along* $\boldsymbol{\sigma}'$ *read through the largest value of* $e^{-\langle\boldsymbol{\sigma}',y\rangle}$ *on the log-support, in (A) and (B) the rate* $h(\boldsymbol{\sigma}')$ *of Theorem 31.2: the best single direction of the chamber reads the convex hull of the log-support, the averaged closing the log-support itself. In a bundle* G *of shares that* $\boldsymbol{\sigma}$ *does not fall, the least value of* $\sum_{l\in G}(\sigma'_l\log\sigma'_l - \sigma'_l y_l)$ *over the* $\sigma'_l \geq 0$ *with* $\sum_G \sigma'_l = g$ *is* $g\log g - g\log\sum_{l\in G} e^{y_l}$*, attained at* $\sigma'_l = g\,e^{y_l}/\sum_{l'\in G} e^{y_{l'}}$*: at each source point the best direction merges the bundle into the sum* $e^{y_G} = \sum_{l\in G} e^{y_l}$*, which in (A) is the sum* $\sum_D x_{jD}x'_{jD}$ *that the kernel reads at the excess, splitting* g *in the proportions of its terms.*

At width one the share side of a node merged by its bundles has at most one free share and the seam torus is a half-line, so the log-support is an interval, its own hull, and one direction loses nothing. A gap between the averaged rate and the best single direction needs a chamber of positive dimension and a log-support that is not convex in its directions: the best split at each source point moves with it, and one direction must take one split for all of them. Averaging can reach a rate that no single direction certifies, and an averaged closing is in general no closing of one share side along one ray: its terms are averages of the crossing terms of the kernel, and it can converge past walls that every ray of the chamber meets. Where the averaged rate is infinite, a closing past the walls can still converge, at the rate of the best source point: past its walls the law is read through its expansion at its falling end, not through its moments, as at width one (Theorem 20.44). Past the walls of a piece the bound that travels is read on the sector letters (Theorem 31.11).

Theorem 31.8 (An averaging gap at a family of tables)**.** *There are three tables with the bases* $\binom{\{1,2,3,4\}}{2}$*, at the exponents* $s_j = 1$*,* $t_j = 0$ *and the masses* $\frac{3}{2}$ *on every mark, whose bunch* $\{1,2\}$*, with the room* $\{3,4\}$*, read through its seam with the product of the two laws as the source measure, the kind (A) of Theorem 31.7, has one station at each excess of each letter, so that every bundle of Theorem 31.7 is a single share, and a chamber* C *with*

$$\min_{\boldsymbol{\sigma}\in C}\sup_{y\in S_\lambda} h(\boldsymbol{\sigma};y) = 0, \qquad \hat{h}_C = \sup_{y\in S_\lambda}\min_{\boldsymbol{\sigma}\in C} h(\boldsymbol{\sigma};y) < 0 :$$

no direction of the chamber certifies the closing (Theorem 31.2), and the averaged closing converges geometrically (Theorem 31.7(ii)). Two directions of the chamber, the better one taken at each source point, already give the bound.

Remark 31.9 (What the gap separates). The gap lies between the averaged closing and the directions of one share side, the seam of the bunch with its bundles merged, and no merging of stations removes it, every bundle being a single share. It is not a gap against every closing of the period: closing each source point along its own direction, as the bound does with two directions, is itself a closing of the period, and so is completing another inner read before closing. A gap in every closing is a statement about a specified set of closings; for the closings of one share side by the directions of its chamber, the family of Theorem 31.8 has one, while at a seam whose two stations of one excess multiply the same monomial of the partner, merging the two stations can remove such a gap.

Definition 31.10 (Keyhole continuations along a direction; ceiling and phase)**.** In Theorem 31.4 let $\boldsymbol{\sigma}$ be a direction of the shares and $\bar{\boldsymbol{\sigma}}$ its sums over the monomials of the partner, and fix a fan of the seam word (Theorem 31.4(ii)). For a sector π of it let $q = (q_k)_k$ be its sector coordinates, $\kappa_k = \kappa_{\mathbf{v}_{\pi,k}}$ the walls of its generators and $\mathbf{k}_\pi = (k_{jD,\pi}, \psi_{jD,\pi})_{j,D}$ the vector of its sector letters, so

that the seam function on the pins is the sum over the sectors of

$$|\det(\mathbf{v}_{\pi,1},\dots,\mathbf{v}_{\pi,|B|-1})|\int_{[0,1]^{|B|-1}}\prod_k q_k^{\kappa_k(\bar{\mathbf{a}},\bar{\mathbf{b}})-1}\,\mathbf{k}_\pi(q)^{-(\bar{\mathbf{a}},\bar{\mathbf{b}})}\,dq,$$

the walls affine in the shares; for a piece of tables and the sectors of the orders π of B these are the walls κ_{U_k} of the tails and the sector letters of the tables $\mathcal{B}_{jD}$ (Theorem 8.5(ii)). Put $\dot\kappa_k=\partial_{\bar{\boldsymbol\sigma}}\kappa_k$, the derivative of the wall along $\bar{\boldsymbol\sigma}$, and

$$\varrho_{\pi,\bar{\boldsymbol\sigma}}(q)=\prod_k q_k^{\dot\kappa_k}\;\mathbf{k}_\pi(q)^{-\bar{\boldsymbol\sigma}},$$

the *directional ratio in the sector* of π; its *falling variables* along $\bar{\boldsymbol\sigma}$ are the q_k with $\dot\kappa_k<0$. A *keyhole continuation along* $\bar{\boldsymbol\sigma}$ is defined as in Definition 20.47, with the sectors in place of the orders, with these falling variables, and with the sector letters of $\mathbf{k}_\pi$ required not to vanish on the sets Y of its boxes; its *outline* $\mathcal{O}$ is the union of the sets $\mathcal{O}$ of its boxes, and its *ceiling along* $\bar{\boldsymbol\sigma}$ is the largest value of $|\varrho_{\pi,\bar{\boldsymbol\sigma}}|$ on the outline, π the sector of the box. Each set Y is a product of a box and of keyholes, simply connected, and on a neighbourhood of it the sector letters have logarithms real at the real points; the *phase* of the continuation at a point q of the outline of a box of π is the linear function $\boldsymbol\vartheta\mapsto\langle\bar{\boldsymbol\vartheta},\arg\mathbf{k}_\pi(q)\rangle$ on the directions of the shares, arg the imaginary part of the logarithm and the bars marking sums over the monomials of the partner.

The modulus $|\varrho_{\pi,\bar{\boldsymbol\sigma}}(q)|$ is the factor by which the part of the integrand that grows with τ along $\bar{\boldsymbol\sigma}$ is multiplied per unit of τ at the point; the phase is the linear function by which the imaginary parts of the shares enter it. With no falling variables the outline is the real cube, the letters are positive there, the phase vanishes, and the ceiling is $\sup\mathbf{V}_B^{-\bar{\boldsymbol\sigma}}$, the largest value of the monomial of Theorem 31.2; at width one, along the fall of the share b^d of Section 20.7, the directional ratio in the sector is the ratio ϱ_π of Definition 20.46.

Theorem 31.11 (The travelling bound past the walls)**.** *In Theorem 31.4 let $\boldsymbol\sigma$ be a direction of the shares and take a keyhole continuation along $\bar{\boldsymbol\sigma}$ (Definition 31.10) with the outline $\mathcal{O}$.*

(i) For every $\epsilon>0$ there is C such that for $\tau\ge0$ and $\boldsymbol\vartheta$ in the directions of the shares

$$\big|P_{W_B(\bar{\mathbf{c}}+\tau\bar{\boldsymbol\sigma}+i\bar{\boldsymbol\vartheta})}(\mathbf{m}_B)\big|\le C\,\delta^{-(|B|-1)}\sup_{q\in\mathcal{O}}\Big(|\varrho_{\pi,\bar{\boldsymbol\sigma}}(q)|^\tau\,e^{\tau\epsilon+\langle\bar{\boldsymbol\vartheta},\arg\mathbf{k}_\pi(q)\rangle}\Big),$$

δ the smaller of 1 and the distance of $\bar{\mathbf{c}}+\tau\bar{\boldsymbol\sigma}$ from the hyperplanes on which a wall of the fan of Definition 31.10 lies in $-\mathbb{N}$, which hold the poles of the seam function.

(ii) Let $\boldsymbol\upsilon$ be a bounded function on $\mathcal{O}$ with values in the vectors indexed by the shares, with $\langle\bar{\boldsymbol\vartheta},\arg\mathbf{k}_\pi(q)\rangle=\sum_l\upsilon_l(q)\vartheta_l$ for $\boldsymbol\vartheta$ in the directions of the shares and $|\upsilon_l(q)|\le\frac{\pi}{2}-\epsilon_0$ for some $\epsilon_0>0$; representatives differing by a vector orthogonal to the directions give the same phase on the fibre. Put

$$h_{\boldsymbol\upsilon}(\boldsymbol\sigma)=h_\Gamma(\boldsymbol\sigma)+\sup_{q\in\mathcal{O}}\Big(\log|\varrho_{\pi,\bar{\boldsymbol\sigma}}(q)|-\sum_{l:\,\sigma_l>0}\sigma_l\log\cos\upsilon_l(q)\Big),$$

h_Γ the Gamma rate of Theorem 31.4(iii). If $h_{\boldsymbol\upsilon}(\boldsymbol\sigma)<0$ and the real point $\mathbf{c}$ of the pins lies off the null set of Theorem 31.2, taken with these hyperplanes as well, the conclusion of Theorem 31.4(iii) holds along $\boldsymbol\sigma$, its terms and the integrals left after them being $O(e^{\tau(h_{\boldsymbol\upsilon}(\boldsymbol\sigma)+\epsilon)})$ for every $\epsilon>0$.

Corollary 31.12 (When the phase costs nothing)**.** *In Theorem 31.11(ii) let $H_{\mathcal{O}}$ be the ceiling of the continuation along $\bar{\boldsymbol{\sigma}}$. Then $h_{\boldsymbol{\upsilon}}(\boldsymbol{\sigma}) = h_\Gamma(\boldsymbol{\sigma}) + \log H_{\mathcal{O}}$ in each of two cases:*

(i) $\upsilon_l(q) = 0$ for every $q \in \mathcal{O}$ and every share with $\sigma_l > 0$: the phase sits on shares that fall or stay, whose Gammas absorb it;

(ii) $-\sum_{l:\,\sigma_l>0} \sigma_l \log\cos\upsilon_l(q) \le \log H_{\mathcal{O}} - \log|\varrho_{\pi,\bar{\boldsymbol{\sigma}}}(q)|$ for every $q \in \mathcal{O}$: the modulus lost away from the highest points pays for the phase.

With no falling variables (i) holds with $\boldsymbol{\upsilon} = 0$, and the rate is that of Theorem 31.2 for the glue read in the monomials of the partner.

Theorem 31.4(iii) pays for an allowed growth $e^{\theta|\operatorname{Im}\mathbf{z}|_1}$ of the seam function with the term $\frac{2\theta^2}{\pi}\sum_{\sigma_l>0}\sigma_l$; Theorem 31.11 pays only for the phase that the letters have at the points where the ceiling is read, and at the exact price $-\log\cos\upsilon_l$ of the rotation. Enlarging the radii of the keyholes, as far as the sector letters do not vanish, can lower the ceiling; it comes down to the reach at simple tops that do not cancel (Theorem 32.15(iii)). The joint words of Section 31.3 complete the retained fibre on its strips before a modulus is taken, and their bound $r_G c_{\max}$ has no phase term; the ceiling $c_{\max}$ of the joint word need not be the ceiling of this outline.

Proposition 31.13 (How travelling bounds compose)**.** *(i)* Products. *When the share integrand carries several continued factors, each bounded as in Theorem 31.11(i) on its own outline, their product is bounded on the product of the outlines by the products of their moduli and of the exponentials of their phases, and Theorem 31.11(ii) holds with these on the product outline: the phases of different factors at one point of it may cancel.*

(ii) Averaging. *Let integrands I_ζ, for ζ in a source with a measure λ, have fibre integrals that close along one path with their crossings at the same times, with the crossing terms $\mathcal{R}_k(\zeta)$, and with crossing terms and remainders, at times τ_k separating the crossings, at most $M(\zeta)\beta(\tau_k)$, where M is integrable against λ and $\sum_k \beta(\tau_k) < \infty$. Then $\int \big(\int_{\mathbf{c}+iV} I_\zeta\big)\, d\lambda(\zeta) = \sum_k \int \mathcal{R}_k\, d\lambda$, absolutely convergent, the k-th term at most $\|M\|_1\beta(\tau_k)$. When for some $\hat{h} < 0$ the bound holds with $\beta(\tau) = e^{\tau(\hat{h}+\epsilon)}$ for every small $\epsilon > 0$, M depending on ϵ, the terms are $O(e^{\tau(\hat{h}+\epsilon)})$: the rate is the bound $\hat{h}$ shared by the source points, read on the support of λ, the uniformity over the source being the hypothesis on M. Where the fibre integral and the source integral of a crossing term converge absolutely together, $\int \mathcal{R}_k\, d\lambda$ is the crossing term of the averaged integrand $\int I_\zeta\, d\lambda$.*

(iii) Crossing. *The crossing terms of the closings of Theorems 31.4(iii) and 31.11 are fibre integrals of one dimension less of integrands of the same kind. At a share crossing $a_l = -n$ the Gamma becomes $(-1)^n/n!$ and the other factors are read on the hyperplane. At a wall crossing where the pole of the seam function is simple, its residue is the* face coefficient *of the walls through the hyperplane: the sum, over the generators $\mathbf{v}$ of a fan of the seam word (Theorem 31.4(ii)) whose wall $\kappa_{\mathbf{v}}$ takes a value $-n_{\mathbf{v}} \in -\mathbb{N}$ on the hyperplane and over the sectors π of which they are generators, of $|\det(\mathbf{v}_{\pi,1},\dots,\mathbf{v}_{\pi,|B|-1})|$ times the cube integral over the other coordinates of the sector of the $n_{\mathbf{v}}$-th Taylor coefficient at $q_{\mathbf{v}} = 0$ of the rest of the integrand (Lemma 8.4), $q_{\mathbf{v}}$ the sector coordinate of $\mathbf{v}$, each divided by the derivative of $\kappa_{\mathbf{v}}$ along the vector $\mathbf{e}$ of Lemma 31.3; its letters are the sector letters at $q_{\mathbf{v}} = 0$, positive on the face, and its numerators are polynomials in the shares and in the derivatives of the letters. For a piece of tables and the sectors of the orders the generators are those of the tails U, and the sectors the orders of which they are tails. Where the pole is multiple, because several factors, or two walls of one sector, are polar on the hyperplane, the residue is a*

Laurent coefficient, a finite sum of derivatives in the shares of products of such terms, which brings powers of the logarithms of the letters and of the q_k. A keyhole continuation of the seam function restricts to one of each face coefficient, $q_{\mathbf{v}} = 0$ lying in the disc of the keyhole of $q_{\mathbf{v}}$, and Cauchy's estimate on its circle bounds the Taylor coefficients by the values on the outline; so each crossing term can be closed again by Lemma 31.3 whenever a travelling bound of its own tends to zero.

Completing an inner read is not a crossing. Merging the stations of one excess by Corollary 4.4, integrating a source before closing, or finishing a transverse fibre replaces the integrand by a completed one, with a smaller fibre; the identity between the two integrands holds where the completed read converges and persists under continuation, but the travelling bound does not pass from one to the other, and the completed object can grow along the outer path where the uncompleted integrand does not. Completing an inner read is free when the completed object obeys, along the outer path, a bound already in hand. Merging the stations of one excess reads the law through the sum of their seam letters, whose expansion at the falling end of the law can stop at an edge of the support nearer than the far edge that the stations read, and the merged closing can then diverge where the station closing converges. The two closings agree at every step up to their remainders (Lemma 31.3), and only the remainder of the station closing need tend to zero. On the shares, merging the stations is conditioning on their merged seam letter: integration commutes with completing the fibre, and continuation commutes with it only while the level sets of the merged seam letter stay inside the region where the expansion of the law at its falling end represents it. Completing the inner fibre before closing and keeping its inherited cut are two representations, whose finite heads agree together with their boundary words; the regions on which a law equals its expansion, with their cuts and boundary words, are built in Section 32.1, and a convergent germ alone does not equal the law.

31.3 Retained crossings as joint words

31.3.1 Completing the retained fibre before taking its size

Theorem 31.11 bounds the share integrand before its fibre is completed, and pays for the phase of the letters where it reads the ceiling. The procedure for joint words completes the retained shares first. It keeps the sectors and coordinate cuts of every continued source and its finite heads, and its auxiliary variables are part of one joint input of a Trailmoment (Definition 5.1), their number not growing along a retained cohort (Definition 31.16): a falling Gamma kept inside a crossing term becomes a positive share and one Beta variable, and a continued source strip becomes a segment and a few circle integrals whose powers on the circles have integral exponents.

Lemma 31.14 (A Gamma strip as a Beta input)**.** *Let $\delta \geq 1$ be an integer, $b = a + \delta$, and $0 < \operatorname{Re} b < 1$. For a nonzero coefficient ξ, with one fixed logarithm,*

$$\Gamma(a)\,\xi^{-a} = \frac{(-1)^{\delta}\xi^{\delta}}{\Gamma(\delta)} \int_0^1 (1-u)^{\delta-1}\,\Gamma(b)\,(\xi u)^{-b}\,du.$$

The identity is pointwise in every remaining share. So on a fibre $P\mathbf{a} = \boldsymbol{\pi}$ replacing a_l by $b_l = a_l + \delta_l$ changes the pins to $P\mathbf{b} = \boldsymbol{\pi} + P(\delta_l)_l$ and does not move the contour. A share with positive real part is left unchanged, with $\delta_l = 0$ and no auxiliary variable. In a family $\operatorname{Re} a_l(n) = a_l^0 - d_l n$ with $d_l \in \mathbb{N}$ and $a_l^0 \notin \mathbb{Z}$ one may take $\delta_l(n) = d_l n + \delta_l(0)$ with $0 < a_l^0 + \delta_l(0) < 1$, the lift being used at the n with $\delta_l(n) \geq 1$, all but finitely many when $d_l \geq 1$: one Beta input serves at every n.

Lemma 31.15 (A continued source strip in six integrals)**.** *Let g be holomorphic near $\{|q| \le r_2\} \cup [r,1]$, and choose $0 < r < r_1 < rT < r_2$ and $T > 1$. If $\ell \ge 1$ is an integer and $0 < \operatorname{Re}(\kappa + \ell) < 1$, the continued integral $I_\kappa = \operatorname{Reg} \int_0^1 q^{\kappa-1} g(q)\, dq$ (Definition 1.5) is*

$$I_\kappa = \int_r^1 q^{\kappa-1} g(q)\, dq + R_\ell + R'_\ell,$$

all circles run counterclockwise, with

$$R_\ell = \frac{1}{2\pi i} \int_0^r q^{\kappa+\ell-1} \oint_{|\zeta|=r_1} \frac{g(\zeta)\, \zeta^{-\ell}}{\zeta - q}\, d\zeta\, dq,$$
$$R'_\ell = -\frac{r^\kappa}{2\pi i} \Big(\int_1^T u^{\kappa-1} \oint_{|\zeta|=r_2} + \int_T^\infty u^{\kappa-1} \oint_{|\zeta|=r_1} \Big) g(\zeta)\, \frac{1 - (ru/\zeta)^\ell}{\zeta - ru}\, d\zeta\, du.$$

Splitting the numerator of R'_ℓ gives four absolutely convergent integrals, six in all. This remains true with holomorphic parameters and other source variables on compact sets, uniformly when the strip and the radius inequalities have positive margins. For $\kappa(\mathbf{a}, n) = \kappa_0(\mathbf{a}) - dn$ and $\ell(n) = \ell_0 + dn$, $d \in \mathbb{N}$, each of the six has a fixed domain and is a fixed function times an n-th power; the exponent of ζ that contains $\ell(n)$ is integral and independent of the shares that move. At a simple wall $\kappa = -N$, $N \in \mathbb{N}$, the residue is the single coefficient input

$$[q^N] g(q) = \frac{1}{2\pi i} \oint_{|\zeta|=r_1} g(\zeta)\, \zeta^{-N-1}\, d\zeta.$$

A cut upper end $q_0 > 0$ is kept by applying the same formula after $q = q_0 v$, the factor q_0^κ included; a positive lower cut is an ordinary segment throughout.

Two of the six integrals simplify by Cauchy's formula: the integral of R'_ℓ over $[1, T]$ with the numerator 1 is $-\int_r^{rT} q^{\kappa-1} g(q)\, dq$, and the integral over (T, ∞) with the numerator 1 vanishes, its pole ru lying outside the smaller circle. So I_κ is the segment $\int_{rT}^1 q^{\kappa-1} g$, the remainder R_ℓ on the circle of radius r_1, and the two integrals of R'_ℓ with the numerator $(ru/\zeta)^\ell$; along a family $\kappa_0 - dn$ the segment carries the n-th power of q^{-d}, at most $(rT)^{-d}$, and the circle integrals that of ζ^{-d}, of modulus r_1^{-d} or r_2^{-d}. The radius r splits the contour, not the source: the sum does not depend on it.

Definition 31.16 (A rational retained cohort)**.** A *retained cohort* is one sequence of simple crossing terms, or one sequence of travelling fibre integrals, of a fibre integral of Gammas, coefficients and source factors whose pins carry a *grading*, a rational vector $\mathbf{v}$ with $\langle t_l, \mathbf{v} \rangle = 1$ for the column t_l of every share in the pins, such as the share side of Theorem 31.4 and the kernel of Theorem 31.7, graded by their letter totals, and the share side of a Gramma whose configuration has a grading (Proposition 4.2), with the following data retained: the pins; the inherited contour; the crossed hyperplane and its orientation, if any; the source sectors and their coordinate cuts. The contours have the real points $\mathbf{a}^0 + n\mathbf{d}$ with $\mathbf{d}$ rational. Nonresonance is tested against the full displayed arrangement of the polar hyperplanes of the Gammas and of the source walls, including candidate walls which might cancel after the sectors are added: the real points lie on none of these hyperplanes other than the one being crossed, and at a source crossing each contributing sector has just one wall on that hyperplane. The constant terms of the shares and walls and the indices are real. Finitely many initial terms may be removed and kept as a finite head. Passing to finitely many arithmetic subsequences makes the changes of all falling shares and walls integral; this is the *integer step* of

the cohort, and its index n always refers to that step. The same definition permits a finite product of source factors that are cube integrals in their charts (Lemma 8.4)

$$\operatorname{Reg}\int_{(0,1)^k} q^{\boldsymbol{\kappa}(\mathbf{a})-\mathbf{1}}\prod_i P_i(q)^{-w_i(\mathbf{a})}\,dq,$$

the P_i with nonnegative coefficients and positive constant terms and the affine functions κ_i, w_i with rational linear parts. A growing wall is eventually positive; a stationary wall may be negative and off the integers, and is then continued with a constant integer ℓ in Lemma 31.15. Finite coordinate box cuts are part of the retained data. The sector integrals of a fan of a seam word (Theorem 31.4(ii)), those of tables among them (Corollary 8.6), have these properties.

Proposition 31.17 (Computing the cohorts of a rational ray)**.** *Let the pins and the finitely many candidate polar functions ℓ_i be rational, and let a rational open box in the affine space of the pins be given on which the required initial walls and shares are positive. For a prescribed rational direction a rational starting point in that box can be chosen such that distinct polar hyperplanes never meet the ray at the same time; factors on the same hyperplane are kept together. After a finite head, the crossing order and the separating gaps are a finite repeated pattern, and its crossing cohorts, endpoint cohorts, the integers ℓ of Lemma 31.15 and a uniform positive separation are computed by finite rational arithmetic. More precisely, with the direction multiplied by a common denominator so that every falling polar function decreases at an integer falling rate $d_i > 0$, there are at most $\sum_i d_i$ crossings in each interval of length one of this parameter; neither that number nor the stored source sectors depend on how many such intervals are read.*

Theorem 31.18 (A finite procedure for a retained cohort)**.** *For a rational retained cohort there is a finite procedure, using the pins and the monomials of the source factors, with the following output, the* joint word *of the cohort, after a finite head and a possible change to the integer step:*

$$\mathcal{R}_n = G_n\sum_i\int_{Y_i} c_i(x)^n\,\phi_i(dx) = G_n\sum_i\big(\mathsf{T}_{-n;(1)}[c_i]\,\phi_i\big)(Y_i),\qquad n\in\mathbb{N},\tag{31.2}$$

a finite sum over i. Here Y_i is a compact cube times finitely many circles, the coefficient function c_i is continuous on it, and the input ϕ_i is a complex measure of finite total variation; the coefficients, their branches, the orientations and every cut are retained. On every Y_i each coefficient of a letter is a real Laurent monomial times a coefficient factor*, holomorphic there, with its real part bounded below by a positive constant and its modulus bounded above, uniformly on the compact variables; these two bounds are the* margins *of the coefficient factors, and the radii $r < r_1 < rT < r_2$ of Lemma 31.15 are admissible while the margins hold. At the integer index $-n$ the Zamma of the one-term configuration is the polynomial $\mathsf{Z}_{-n;(1)}(c) = c^n$, at $c = 0$ as well, so the second expression is the Trailmoment of Definition 5.1 extended to a continuous complex coefficient function and a complex input of finite variation, as Theorem 5.21(ii) extends its reads to complex data where every integral converges absolutely.*

The scalar is explicit. Let $\mathbf{v}$ be the grading of the pins (Definition 31.16) and $w = \langle \mathbf{v}, \boldsymbol{\nu}\rangle$, $\boldsymbol{\nu}$ the values of the pins, the total of the shares on the pins, which on the share sides of Theorems 31.4 and 31.7 is $|\mathbf{s}| + |\mathbf{t}|$, the sum of the exponents of the active letters. Let $\mathcal{S}_-$ be the shares treated by Lemma 31.14, with $\delta_l(n) = \delta_l(0) + d_l n$. At a Gamma crossing let $-N(n)$, with $N(n) = N_0 + d_0 n$, be the pole of its Gamma that is crossed; at a source crossing or for a travelling fibre omit N and the factor $\Gamma(N+1)$ of G_n, and put $d_0 = 0$. Up to fixed nonzero factors of the share side, as $1/\Gamma(s_j)$

and $1/\Gamma(t_j)$, and the inherited crossing sign,

$$G_n = \frac{(-1)^{N(n)+\sum_{l\in\mathcal{S}_-}\delta_l(n)}\,\Gamma\big(w+N(n)+\sum_{l\in\mathcal{S}_-}\delta_l(n)\big)}{\Gamma(N(n)+1)\prod_{l\in\mathcal{S}_-}\Gamma(\delta_l(n))},$$

fixed nonzero constants may equally be put in the inputs. With $\bar d = d_0+\sum_{l\in\mathcal{S}_-} d_l$,

$$\lim_{n\to\infty}|G_n|^{1/n} = r_G = \frac{\bar d^{\,\bar d}}{d_0^{d_0}\prod_{l\in\mathcal{S}_-} d_l^{d_l}}, \qquad 0^0 = 1;$$

when $\bar d = 0$ the scalar is constant and $r_G = 1$, and in all cases $|G_n| \le C(n+1)^p r_G^n$ for computable C and p. The procedure introduces at most six integrals per continued source wall and one Beta variable per negative retained Gamma, whatever n. Its remaining work is a finite common Newton fan and simplicial subdivision; this fan, the inputs and the coefficient functions c_i serve for every n, and the procedure does not expand the Taylor head of degree $\ell(n)-1$ of Lemma 31.15 or a residue coefficient of degree $N(n)$ into its monomials.

Corollary 31.19 (Finite bounds and the exact positive root rate)**.** *For the joint word of Theorem 31.18 put $c_{\max} = \max_i \max_{Y_i}|c_i|$ and $M = \sum_i \|\phi_i\|$. Then*

$$|\mathcal{R}_n| \le M\,|G_n|\,c_{\max}^n \le CM(n+1)^p (r_G c_{\max})^n,$$

and $c_{\max}$ is the ceiling *of the joint word. Every quantity in this bound has a finite certificate: the margins of the coefficient factors and the sector walls bound M, and compact subdivision bounds $c_{\max}$; with computable input coefficients a strict inequality $r_G c_{\max} < r < 1$ is certified by finite subdivision and gives a computable geometric tail. If the original source has a convergent positive representation on every contour of the cohort, no source continuation or coefficient input is needed, and the remaining constant terms are real, then the output of the procedure has, after its common scalar sign is removed, one positive input ϕ and a coefficient function $c \ge 0$, and*

$$\lim_{n\to\infty}|\mathcal{R}_n|^{1/n} = r_G \operatorname*{ess\,sup}_{\phi} c.$$

For a positive read on an unbounded domain, before it is compactified, the same holds with an infinite essential supremum whenever the moments exist. So averaging over a positive source measure takes the essential supremum on the joint input of the source, Beta and shape variables; it does not reverse the order of an infimum over directions and a supremum over source points.

Definition 31.20 (Simple tops of the joint word)**.** For (31.2) with $c_{\max} > 0$, tops are read as in Definition 20.50, with the coefficient function c_i in place of ϱ_π, the oriented Y_i in place of the keyhole contour and the input ϕ_i in place of ϕ_π: a simple top is a point p with $|c_i(p)| = c_{\max}$ for which local real coordinates on the oriented Y_i are $(\mathbf{x},\mathbf{y}) \in [0,\epsilon)^{b_1}\times(-\epsilon,\epsilon)^{b_2}$, and

$$\log\frac{c_i(\mathbf{x},\mathbf{y})}{c_i(p)} = -\langle\boldsymbol{\lambda},\mathbf{x}\rangle - \tfrac12\,\mathbf{y}^{\mathsf T}\mathbf{Q}\,\mathbf{y} + O\big(|\mathbf{x}|^2+|\mathbf{x}|\,|\mathbf{y}|+|\mathbf{y}|^3\big), \qquad \phi_i = \prod_{j=1}^{b_1} x_j^{\kappa_j-1}\,g(\mathbf{x},\mathbf{y})\,d\mathbf{x}\,d\mathbf{y},$$

with $\kappa_j > 0$, $g(0,0)\neq 0$, $\operatorname{Re}\lambda_j > 0$ and $\operatorname{Re}\mathbf{Q}$ positive definite, $\mathbf{Q}$ complex symmetric, and g, continuous and bounded near $(0,0)$, including the orientation and every factor of the circle integrals. Its exponent and its coefficient are

$$\operatorname{ex}(p) = \sum_j \kappa_j + \tfrac{b_2}{2}, \qquad A(p) = g(0,0)\,(2\pi)^{b_2/2}(\det\mathbf{Q})^{-1/2}\prod_j \Gamma(\kappa_j)\,\lambda_j^{-\kappa_j},$$

the square root continued from positive definite real matrices. The subdivisions of the procedure, the splits of the Beta intervals and of the scales and the cones of the fan, divide one domain into parts on which the integrand is the restriction of one function; tops are read with these parts reassembled, a point on a common boundary of the parts being a simple top when the expansion holds on its reassembled neighbourhood, in the coordinates before the subdivision. Parts that are different integrals, as the segment and the circle integrals of Lemma 31.15, keep their own coefficients, and the contributions at one point are added before noncancellation is tested.

Theorem 31.21 (The joint tops give the root rate of a complex word)**.** *Let the largest values of $|c_i|$ on the joint word of Theorem 31.18 sit at finitely many simple tops. Let ex_0 be the least of their exponents, and for $|\zeta| = 1$ let A_ζ be the sum of the coefficients $A(p)$ of the tops with $\mathrm{ex}(p) = \mathrm{ex}_0$ and $c_i(p) = c_{\max}\,\zeta$. If some A_ζ is not zero, then*

$$\limsup_{n\to\infty} |\mathcal{R}_n|^{1/n} = r_G\, c_{\max}.$$

No separate price of the phase is added to $c_{\max}$: the completed fibre and its source phases belong to the one coefficient function and the oriented input. A largest value of $|c_i|$ alone is not the hypothesis; the expansion includes the stationarity of the complex phase in every tangential variable.

This is Theorem 20.51 for joint words: the coordinates $\mathbf{x}$ that vanish at a top carry the Gammas of the boundary, the coordinates $\mathbf{y}$ the factor $(2\pi)^{b_2/2}(\det \mathbf{Q})^{-1/2}$, and the coefficients of the tops of least exponent and one phase add before the root rate is read.

Remark 31.22 (Where the tops of a continued source factor sit)*.* In the integrals of Lemma 31.15 a falling wall carries the n-th power of q^{-d} on the segment and of ζ^{-d} on the circles. On a circle the modulus of ζ^{-d} is constant and its phase turns, so a largest value of $|c_i|$ there is a simple top only where the other factors make the phase stationary, a saddle in the radius. The radii r, r_1, r_2 and T are free within the margins of the coefficient factors, and the sum does not depend on them; Theorem 31.21 is applied after the radii are chosen. When the largest values of $|c_i|$ sit at simple tops of the segment, of the shape or of the Beta inputs, or at saddles of the circles, and do not cancel, the root rate is $r_G c_{\max}$; a largest value spread over a circle, or one at the end $q = rT$ of the segment, which moves with the radii, certifies the upper bound only, and the radii may be moved, within the margins, to lower it. Where the law has log expansions the continuation is made on the law, and its bound has no phase and no margin (Proposition 32.14).

Corollary 31.23 (Closing along a path under an endpoint condition)**.** *In Lemma 31.3 keep (H0) and (H1) and replace (H2) by the weaker condition $\int_{\gamma(\tau_k)+iV} I \to 0$ along times $\tau_k \to \infty$ off the poles. Then the sums of the signed crossing terms before τ_k converge to $\int_{\mathbf{c}+iV} I$. If the crossing terms are absolutely summable, this is their absolutely convergent ordered sum; (H2) remains a sufficient condition for the endpoint condition.*

Corollary 31.24 (Closing with the joint words)**.** *For a rational ray with simple nonresonant crossings, compute the finitely many arithmetic cohorts of crossings and one cohort of endpoints off the poles in each repeating gap. If each crossing cohort and each required endpoint cohort has a certified upper root rate $r_G c_{\max} < 1$, the crossing terms are absolutely summable and their ordered sum is the initial fibre integral. The finite head is retained, and the bounds of Corollary 31.19 give an effective stopping rule. A cohort with the positive hypothesis of Corollary 31.19, or the noncancelling simple tops of Theorem 31.21, has the stated exact root rate and cannot tend to zero when it exceeds one.*

The procedure keeps the falling rates, which fix the crossed heads, and the cut source; within the chamber the growing shares can still be changed by Theorem 31.6, the completed word being the same. The bound $r_G c_{\max}$ has no phase term: $c_{\max}$ is the ceiling of this joint word, which need not equal the ceiling of a keyhole continuation read before the fibre is completed, nor the least ceiling over all joint words.

Lemma 31.25 (Positive capacity and the growing shares)**.** *Let $t_g \in \mathbb{R}^r$, $g \in G$, be a finite nonempty configuration with a grading $\langle t_g, \mathbf{v}\rangle = 1$, let $\xi_g > 0$, $w > 0$ and $\langle \mathbf{v}, \nu\rangle = w$, and in this statement write $L(X) = \sum_{g\in G} \xi_g X^{t_g}$ and $\Pi(\nu, w) = \{\mathbf{b} \in [0,\infty)^G : \ \sum_g b_g = w,\ \sum_g b_g t_g = \nu\}$. With $0^0 = 1$ and the infimum of the empty set equal to $+\infty$,*

$$\sup_{X\in(0,\infty)^r} \frac{X^\nu}{L(X)^w} = \inf_{\mathbf{b}\in\Pi(\nu,w)} \prod_{g\in G} \Big(\frac{b_g}{w\,\xi_g}\Big)^{b_g},$$

the left side being the capacity *of L at (ν, w). The supremum may equally be taken on any logarithmic section transverse to $\mathbf{v}$. When ν/w lies in the relative interior of the convex hull of the t_g, the infimum has a unique positive minimizer and is attained by a gauge X, unique modulo the directions constant on all the t_g; on a proper face the same computation on that face gives the value, approached by suppressing the other monomials.*

The supremum on the left is the largest value of a monomial of the letter vector, and the logarithm of the infimum on the right is the least Gamma rate over the polytope $\Pi(\nu, w)$ of shares, less $w \log w$: the lemma is the duality that turns the chamber rate of a positive kernel into a capacity of its letter.

Theorem 31.26 (The exact positive rate of a retained chamber)**.** *Take a Gramma $\mathsf{G}_{\nu;t}(\boldsymbol{\xi})$ with rational configuration and real index read on its share side (Proposition 4.2), the pins $t\mathbf{a} = \nu$ with the grading of the letter totals and positive coefficients $\boldsymbol{\xi}$. Let a nonzero rational ray start at a positive real point of the pins, and consider any simple nonresonant Gamma crossing cohort of that ray, or any cohort of travelling fibres off the poles, with its integer step as in Definition 31.16. Write its direction per step as $\boldsymbol{\sigma}$, and put*

$$\mathcal{S}_- = \{l :\ \sigma_l < 0\}, \qquad d_l = -\sigma_l \ \ (l \in \mathcal{S}_-), \qquad \mathcal{S}_+ = \mathcal{S}_-^c,$$

t_l the columns of t, with the chamber of $\boldsymbol{\sigma}$ (Definition 31.5), the polar functions of the share side being the shares,

$$C = \{\boldsymbol{\sigma}' :\ t\boldsymbol{\sigma}' = 0,\ \sigma'_l = -d_l\ (l \in \mathcal{S}_-),\ \sigma'_l \geq 0\ (l \in \mathcal{S}_+)\}.$$

Then the retained terms have a common sign at each index, independent of $\boldsymbol{\xi}$, after their crossing orientation is fixed, and

$$\lim_{n\to\infty} |\mathcal{R}_n(\boldsymbol{\xi})|^{1/n} = \exp \min_{\boldsymbol{\sigma}'\in C} h_\Gamma(\boldsymbol{\sigma}'),$$

h_Γ the Gamma rate of Theorem 31.4(iii), the coefficients being those of the Gramma: the exponential of the least Gamma rate of the chamber. This minimizes over the growing shares, the falling rates d_l being fixed; if the integer step has the length Δ in the parameter of the ray, the logarithm is Δ times the rate per unit of that parameter.

Corollary 31.27 (Exact positive averaging at every retained dimension)**.** *In Theorem 31.26 let the coefficients be measurable positive functions $\xi_l(\zeta)$ of a source with a nonzero positive measure λ, the configuration, the index, the chamber and the integer step fixed across the source, and put*

$$h_C(\zeta) = \min_{\boldsymbol{\sigma}' \in C} \Big(\sum_l \sigma'_l \log|\sigma'_l| - \sum_l \sigma'_l \log \xi_l(\zeta) \Big), \qquad \hat{h}_C = \operatorname*{ess\,sup}_\lambda h_C.$$

Let one averaged retained term be absolutely integrable, so that after multiplication by $\prod_l \xi_l(\zeta)^{-a_l^0}$, $\mathbf{a}^0$ the real point at which the cohort starts (Definition 31.16), the joint positive input is finite. If $\hat{h}_C < \infty$, every later averaged term is integrable and

$$\lim_{n\to\infty} \Big| \int \mathcal{R}_n(\zeta)\, d\lambda(\zeta) \Big|^{1/n} = e^{\hat{h}_C};$$

if all these terms are finite and $\hat{h}_C = +\infty$, their root rate is $+\infty$. No estimate uniform over the source and no retained fibre of dimension one is needed. This applies to the kernel of Theorem 31.7 on rational pins along a rational ray whose crossings are simple and nonresonant, under a finite averaged rate and the certificate (31.1)*, whose bound supplies the finite first term. For a continuous coefficient map the essential supremum is the supremum on the support of the image of λ; it is $\operatorname{ess\,sup}_\zeta \min_C$, with no interchange to $\min_C \operatorname{ess\,sup}_\zeta$.*

Theorem 31.28 (Averaging is sharp)**.** *In the setting of Theorem 31.7, with its chamber C, its averaged rate $\hat{h}_C$, its source measure λ and the crossing terms $\mathcal{R}_k$ of the closing of its kernel at the crossing times τ_k, let the pins be rational, as in the kinds (A) and (B), let $\boldsymbol{\sigma}$ have rational coordinates, let the crossings of its ray be simple and nonresonant (Definition 31.16), and let $\hat{h}_C < \infty$. Along each cohort of crossings, with its integer step of length Δ in τ, the averaged terms have one sign at each index and $\lim_{n\to\infty} \big| \int \mathcal{R}_n\, d\lambda \big|^{1/n} = e^{\Delta \hat{h}_C}$ (Theorem 31.26, Corollary 31.27); so for every $\epsilon > 0$, $\big| \int \mathcal{R}_k\, d\lambda \big| \geq e^{\tau_k(\hat{h}_C - \epsilon)}$ for all large k, and the terms of the averaged closing, which are those of the closing of the share side along $\boldsymbol{\sigma}$ when $\int e^{-\langle \mathbf{a}, y\rangle}\, d\lambda$ converges along it, tend to zero when $\hat{h}_C < 0$ and do not when $\hat{h}_C > 0$. When every share that $\boldsymbol{\sigma}$ falls is alone in its bundle and the share side read with one share per bundle (Corollary 4.4 merging each bundle) has a fibre of dimension one, a positive multiple of $\boldsymbol{\sigma}$ has a direction with rational coordinates in its chamber, along which the closing is the same series after a change of scale of τ (Theorem 31.6); the crossings are simple and nonresonant as soon as no two lattices of the falling shares meet; and every crossing term is*

$$\mathcal{R}_k(\zeta) = r_k \prod_G e^{-\bar{a}_{k,G}\, y_G(\zeta)}, \qquad y_G = \log \sum_{l \in G} e^{y_l},$$

with r_k real and not depending on the source point and $\bar{\mathbf{a}}_k$ the crossing point of the merged shares.

So Theorem 31.28 holds in every retained dimension, with no condition on the bundles: the falling shares need not be alone in them, and the share side merged by its bundles may have any number of free shares. The chamber minimum is a finite convex problem, shared by all the cohorts of the ray once their common integer step is chosen, and the completed source average is one joint Trailmoment. The positivity belongs to the completed source average; a continued source factor, with its oriented circle integrals, is read by Theorem 31.21, its phases not being replaced by a supremum over a positive support. A completed crossing and the tail it inherits are different series: closing a retained share only through finitely many of its poles leaves an exact Taylor remainder whose rate depends on how many poles are taken with each crossing, and it can grow while the completed crossings fall.

31.3.2 Coincident crossings and the boundary at root rate one

A residue is taken after the factors on its hyperplane have been assembled. A deformation may separate those factors for computation, but its separate residues are then one packet. The finite operation of Theorem 31.30 retains that packet, including its vanishing factors, and extends Theorem 31.18 to coincident crossings.

Lemma 31.29 (A source pole with a uniform parameter margin)**.** *Use the radii of Lemma 31.15. Near $\kappa = -N$, $N \in \mathbb{N}$, put $z = \kappa + N$ and fix $0 < \eta < 1$. On $|\operatorname{Re} z| \le \eta$ the same continued source factor is exactly*

$$I_\kappa = \int_r^1 q^{\kappa-1} g(q)\, dq + R_{N+1} + R'_N + g_N \frac{r^z}{z}, \qquad g_N = \frac{1}{2\pi i} \oint g(\zeta)\, \zeta^{-N-1}\, d\zeta,$$

R_{N+1} and R'_N given by the formulas of that lemma with these indices, $R'_0 = 0$. The first three terms are uniformly absolutely convergent on the whole strip; splitting R'_N gives at most seven integrals in all, the circle integral g_N carrying the explicit pole r^z/z. If $N = N_0 + dn$, the domains stay fixed and their dependence on n is again in fixed powers; in particular a small complex circle of the parameter about $z = 0$ has a common integrable source representation after its displayed pole is removed.

Theorem 31.30 (A finite jet for a coincident crossing)**.** *Consider a rational affine family of crossing fibres, indexed by n, with n in one fixed arithmetic progression. Fix the inherited contour and the whole packet of factors polar on its crossed hyperplane, let the other polar hyperplanes be separated from this packet on the real contour by a positive constant, and let the total order of the packet be at most p, independent of n. Perturb the constant terms of all shares and walls by one parameter ε, with a fixed rational vector of perturbations, keeping the affine pins and their prescribed continuation; the vector can be chosen outside finitely many rational hyperplanes so that distinct members of the packet separate, factors forced to remain coincident being kept as one member. Let $\mathcal{R}_{n,j}(\varepsilon)$ be the inherited crossing terms of the separated members. Then*

$$\mathcal{R}_n = [\varepsilon^0] \sum_j \mathcal{R}_{n,j}(\varepsilon).$$

Each member has a pole of order at most $p - 1$ in ε if its separated pole is simple, and the same bound suffices after keeping forced multiple members intact; so the constant coefficient uses only the Taylor coefficients through the degree $p - 1$ of the holomorphic parts after their poles are removed. Further meromorphic normalizing factors raise this order by their known pole orders. Every coefficient is a jet of the Gammas, of the source or of the parameter; no limit in n is part of the computation. More generally, whenever a finite exact procedure returns terms $\mathcal{R}_{n,j} = \varepsilon^{-o_j} \widetilde{\mathcal{R}}_{n,j}$ with $\widetilde{\mathcal{R}}_{n,j}$ holomorphic, the required coefficients are exactly $[\varepsilon^{o_j}]\widetilde{\mathcal{R}}_{n,j}$; positive orders of a factor that vanishes at $\varepsilon = 0$ are retained just as negative orders of a polar factor are. The local decay hypothesis of Lemma 31.3 is used on the common enclosing contour, uniformly on a small disc of the parameter. For the Gamma words and the continued sector integrals a uniform procedure is available: factors whose Gamma poles lie on the crossed hyperplane are constant on its residual fibre and are put in the scalar Gamma word, each source wall coincident on that hyperplane is treated by Lemma 31.29, and the other walls and Gamma strips have strict margins.

The auxiliary parameter separates the poles of one assembled crossing; it does not identify the independent regulators of a product of words, which keep their separate constant terms (Proposition 44.2). If the value asked for is a finite part, its prescribed Mellin regulator is retained and its

constant coefficient taken as in Theorem 1.7 and Corollary 1.8; finite parts in different coordinates are not interchangeable (Lemma 1.9: a dilation of the coordinate moves a finite part by a polynomial in the logarithm of the dilation). Several such regulators give finitely many multivariate Laurent coefficients, with the coefficient order fixed by the value asked for, the retention of finitely many numbers at every corner (Theorem 46.10) applied to a whole crossing fibre. The separation hypothesis concerns the actual residual contour: a transverse meeting of different hyperplanes needs the finite ordered packet of the chosen crossing flag, with its iterated transverse contours, and does not allow an arbitrary order of point residues. Nor does a Laurent coefficient keep a sharp root rate by itself: the coefficient can vanish.

Proposition 31.31 (Bounds and top coefficients pass to jets)**.** *In Theorem 31.30 let the procedure of Theorem 31.18 for the separated terms give a uniform bound on a circle of the parameter,* $|\varepsilon^{o_j}\mathcal{R}_{n,j}(\varepsilon)| \le C_\delta(1+n)^{p'}(q+\delta)^n$ *for every* $\delta > 0$*, the circle allowed to shrink with* δ*. Then* $\limsup_n |\mathcal{R}_n|^{1/n} \le q$*. For perturbations of the constant terms only, the slopes in* n*, the linear parts of the pins, the letters and the coefficients fixed, Lemma 31.29 and the extraction of the scalar give more: one common fan serves on a small disc of the parameter, each coefficient function* c_i *is independent of the parameter, only the fixed amplitudes, the explicit polar factors and the constant terms of the Gammas varying, and their endpoint powers have positive margins once the explicit poles of Lemma 31.29 are removed; so the finitely many Laurent coefficients of each order have the same upper root rate as their common collection of coefficient functions and Gamma slopes, with only polynomial and logarithmic losses in* n*. If the joint word has finitely many simple tops (Definition 31.20), uniformly separated from the rest of its domain, its finitely many Laurent coefficients supply every prescribed finite order of the expansion of* $\mathcal{R}_n$ *at the tops: differentiate the exact integrand to the required order in the parameter, expand its phase and amplitude to the required Taylor order at each top, use* $\mathbf{x} = \mathbf{X}/n$ *in its decaying boundary coordinates and* $\mathbf{y} = \mathbf{Y}/\sqrt{n}$ *in its coordinates* $\mathbf{y}$*, integrate the resulting monomials against the Gamma densities in* $\mathbf{X}$ *and the density* $e^{-\frac{1}{2}\mathbf{Y}^{\mathsf{T}}\mathbf{Q}\mathbf{Y}}$ *in* $\mathbf{Y}$*, and expand the Gamma prefactors to the same order. Equal top phases are added before any test of nonvanishing. A surviving coefficient at the root rate* q *proves* $\limsup_n |\mathcal{R}_n|^{1/n} = q$*; if the tested coefficients cancel, the upper bound remains and no sharp lower bound follows.*

At the root rate one the boundary is decided exactly, without simple or isolated tops, by the law of the coefficient function that the procedure retains in the positive case; its geometry is computed once and answers several queries at the boundary.

Theorem 31.32 (The test at root rate one for a positive moment sequence)**.** *Let* ϕ *be a finite positive measure,* $0 \le c \le 1$ *on its support,* $m_n = \int c^n \, d\phi$*, and*

$$b_n = G_n \, m_n, \qquad G_n > 0, \qquad G_n \sim C \, n^\beta, \quad C > 0, \ \beta \in \mathbb{R} :$$

the form of Corollary 31.19 at the root rate one, the coefficient function divided by its positive largest value $c_{\max}$ *and the scalar multiplied by* $c_{\max}^n$*, the exponent* β *read from the explicit Gamma quotient and the scalar sign a fixed number of modulus one to the power* n*. Finitely many initial terms have no effect.*

(i) The series $\sum_n b_n$ *is finite exactly when:* $\beta < -1$*, always;* $\beta = -1$ *and* $\int \log \frac{1}{1-c} \, d\phi < \infty$*;* $\beta > -1$ *and* $\int (1-c)^{-\beta-1} \, d\phi < \infty$*; the integrands of the last two conditions having the value* $+\infty$ *at* $c = 1$*. These are also the exact conditions for absolute convergence after multiplication by any* ζ^n*,* $|\zeta| = 1$*.*

(ii) Let moreover G_n be a balanced Gamma quotient with its exponential factor removed, or more generally let its forward differences satisfy $\Delta^k G_n = O(n^{\beta-k})$ for every fixed k. For $|\zeta| = 1$, $\zeta \neq 1$, the ordered series $\sum_n \zeta^n b_n$ converges exactly when $b_n \to 0$, and with $M(t) = \phi\{c > 1-t\}$ this is: $\beta < 0$, always; $\beta = 0$ and $\phi\{c = 1\} = 0$; $\beta > 0$ and $M(t) = o(t^\beta)$ as $t \downarrow 0$.

So (i) and (ii) tell absolute convergence, conditional convergence and the failure of the term test apart with one retained law.

A certified law near its largest value of the form $M(t) \asymp t^a(\log(1/t))^j$ turns these criteria into comparisons of powers and logarithms; the criteria stay exact for nonisolated or degenerate maxima, Dirac measures and mixtures. They do not change the crossing order: a periodic family must be reassembled in its original order before a conditional verdict is used, since splitting an alternating series into its even and odd subseries loses exactly that information.

Proposition 31.33 (Finite certificates at the boundary from the jets of the tops)**.** *Let the assembled terms at the root rate one have a certified finite expansion*

$$\mathcal{R}_n = \sum_{\zeta \in Z} \zeta^n \sum_{\beta \geq -1} \sum_{j=0}^{J_\beta} c_{\zeta,\beta,j}\, n^\beta (\log n)^j + O(n^{-1-\delta}), \qquad \delta > 0,$$

Z a finite subset of the unit circle, the real exponents β a finite set and equal triples combined; the jets of the tops of Proposition 31.31 produce such a certificate to every order needed when its hypotheses on simple tops and uniformity hold. Then:

(i) the series is absolutely convergent if and only if every displayed coefficient vanishes;

(ii) it converges in its given order if and only if every coefficient with $\zeta = 1$ vanishes and every coefficient with $\beta \geq 0$ vanishes;

(iii) when (ii) holds and (i) does not, the convergence is conditional.

The verdict uses exact certificates of zero or nonzero for the finitely many assembled coefficients; where those are unavailable, the finitely many coefficients are the output, a numerical near cancellation not being a certificate of zero.

Chapter 32

Laws at their ends: regions of equality and reach

A closing past the walls reads a law where its moments diverge, at its falling ends, through its expansion there. The regions on which a law equals its expansion at an end are built from the sector letters, with the map from the motion of the shares to the exponents, the coefficients, the truncation bounds and exact boundary words (Theorems 32.2 and 32.4); the domain where a series converges and the region where it equals the law are kept apart (Proposition 32.6). The reach is read on the law along every rational direction of the shares, as at width one: along a rational direction the seam function is the Mellin transform of one measure on the half-line, the image of the law, multiplied by $\mathbf{x}^{-\mathbf{w}_0}$ for the starting point $\mathbf{w}_0$, under the directional ratio, and the reach is the far boundary of the region on which that measure is its own wall series (Theorem 32.10). Run on the laws of the two families at a node of width one, the same argument reads the growth of each family on its law and makes that of the bunch its reach (Corollary 32.11). For a piece the reach is bounded by the ceilings of the keyhole continuations along the direction, with no phase, and attained at their simple tops that do not cancel (Theorem 32.15). A closing past the walls converges when the exponential of the Gamma rate times the reach of its tube, the imaginary translates of the line through its starting point, is less than one, its terms then having at most that root rate, and a law with log expansions bounds that reach in every direction with nothing paid for the phase; with one free share the tube is the line, and the terms reach that root rate under conditions that keep the poles apart (Theorems 32.16 and 32.17, Corollary 32.18).

32.1 Regions on which a law is represented

A region of equality belongs to an expansion of a law: to the coordinates advanced, the coordinates retained, and the grouping of its terms. A disc in a sector variable is not by itself a region of equality of the law: the map to the seam torus can identify points, have critical values, or have an image of smaller dimension than its torus. The procedure of Theorem 32.4 keeps that map, and gives a law, with its tangential source retained, before any assertion about a density on the whole torus.

Definition 32.1 (A chart at an end of a law)**.** Let a part of the source of a law have the coordinates $(q, z) \in (0, r_1) \times \cdots \times (0, r_k) \times Z$ and the form

$$q^{\boldsymbol{\kappa}-\mathbf{1}} A(q, z)\, dq\, \phi(dz), \qquad \kappa_i > 0,$$

ϕ a finite positive measure retained as an input and A holomorphic in q on a neighbourhood of a closed polydisc, uniformly bounded there for $z \in Z$; complex densities are allowed, and a fixed

monomial in the seam coordinates can be included in the integrand and removed after integration. The selected seam coordinates of the law at the end are $\check{x}_i^{-1}$, with

$$\check{x}_i = \prod_{j=1}^{k} q_j^{N_{ij}}\, \mathfrak{u}_i(q,z), \qquad 1 \le i \le k,$$

$\mathbf{N} = (N_{ij})$ an invertible integer matrix and the *chart factors* $\mathfrak{u}_i$ positive on the real source and holomorphic and nonzero on the complex neighbourhood; the other coordinates of the seam point are a retained map $\mathbf{C}(q,z)$, and branches are continued from the positive source. The *chart coordinates* are

$$\mathfrak{t}_j = \prod_i \check{x}_i^{(\mathbf{N}^{-1})_{ji}} = q_j \prod_i \mathfrak{u}_i(q,z)^{(\mathbf{N}^{-1})_{ji}}.$$

A certificate of the chart supplies positive radii R_i and a uniform analytic inverse $q_j = \mathfrak{t}_j\, g_j(\mathfrak{t},z)$ for $|\mathfrak{t}_i| < R_i$, with bounds for the inverse, its Jacobian and the holomorphic functions used in Theorem 32.2 and Corollary 32.3 below; the cuts on Z are retained. Write $\mathbf{1}_{\mathrm{cut}}(\mathfrak{t},z)$ for the indicator of any further retained cut of the source, $\mathbf{1}_{\mathrm{cut}} = 1$ when there is none; if a cut of the source moves in these coordinates, its indicator is retained in the integrand and is neither differentiated nor included in a holomorphic coefficient.

Theorem 32.2 (Computing and using an end chart)**.** *For a chart of Definition 32.1 the following computations are effective.*

(i) A smaller certified polydisc exists whenever the holomorphy and nonvanishing conditions hold uniformly on a compact tangential source. In its coordinates the source form is

$$\mathfrak{t}^{\boldsymbol{\kappa}-\mathbf{1}}\, \widetilde{A}(\mathfrak{t},z)\, d\mathfrak{t}\, \phi(dz), \qquad \widetilde{A} = A(\mathfrak{t}g,z) \prod_j g_j^{\kappa_j - 1} \det \frac{\partial(\mathfrak{t}g)}{\partial \mathfrak{t}},$$

the determinant positive on a small enough positive chart. The seam map is $(\mathfrak{t},z) \mapsto \big(\mathfrak{t}^{\mathbf{N}}, \mathbf{C}(\mathfrak{t}g(\mathfrak{t},z),z)\big)$; with $\mathbf{C}_{\mathfrak{t}}(z) = \mathbf{C}(\mathfrak{t}g(\mathfrak{t},z),z)$, its density in the normal coordinates $\check{x}$, a measure in the tangential ones, is

$$\frac{\check{x}^{-\mathbf{1}}\mathfrak{t}^{\boldsymbol{\kappa}}}{|\det \mathbf{N}|}\, (\mathbf{C}_{\mathfrak{t}})_* \big(\mathbf{1}_{\mathrm{cut}}(\mathfrak{t},\cdot)\widetilde{A}(\mathfrak{t},\cdot)\,\phi\big)\, d\check{x},$$

a density only in the selected normal coordinates, whose tangential value may be a singular measure.

(ii) Write $\widetilde{A} = \sum_{\mathbf{n}\ge 0} \widetilde{A}_{\mathbf{n}}(z)\, \mathfrak{t}^{\mathbf{n}}$. The coefficients are tangential words computed by finite jet arithmetic on the original letters; the inverse certifies that they represent the source and is not evaluated. If $|\widetilde{A}| \le M$ on $|\mathfrak{t}_i| = R_i$, then $|\widetilde{A}_{\mathbf{n}}(z)| \le M \prod_i R_i^{-n_i}$. For every bounded measurable test function H, the law on the chart is, for real $0 < \mathfrak{t}_i < R_i$,

$$\mathfrak{t}^{\boldsymbol{\kappa}-\mathbf{1}} \sum_{\mathbf{n}\ge 0} \mathfrak{t}^{\mathbf{n}} \int_Z \widetilde{A}_{\mathbf{n}}(z)\, \mathbf{1}_{\mathrm{cut}}(\mathfrak{t},z)\, H\big(\mathfrak{t}^{\mathbf{N}}, \mathbf{C}(\mathfrak{t}g(\mathfrak{t},z),z)\big)\, \phi(dz)\, d\mathfrak{t}. \tag{32.1}$$

The same seam map and the same retained cut occur in every term. With rational data the inverse branch is algebraic, specified by the positive branch and the certificate; alternatively every exact pairing with a test function is kept on the original source (q,z) with that cut pulled back, and an inverse function need not be added to the operations. The series converges in

total variation on compact subcharts, the normal power included. If the tangential map and the cut do not depend on $\mathfrak{t}$*, its coefficients are the fixed face laws* $\mathbf{C}_*(\widetilde{A}_{\mathbf{n}}\phi)$*; otherwise* (32.1) *is a series of pairings on the one tangential source, not an assertion that those images are fixed.*

(iii) With $\vartheta_i = |\mathfrak{t}_i|/R_i < 1$*, truncating to* $0 \le n_i < k_i$ *has, before the normal power and for* $\|H\|_\infty \le 1$*, the error at most*

$$M\,\phi(Z)\prod_i (1-\vartheta_i)^{-1}\sum_i \vartheta_i^{k_i}. \tag{32.2}$$

It also has an exact boundary word: with T_i *the Taylor operator through the degree* $k_i - 1$ *in* $\mathfrak{t}_i$*,*

$$\widetilde{A} = \prod_i T_i\widetilde{A} + \sum_{\varnothing\neq I\subseteq\{1,\dots,k\}}\prod_{i\in I}(1-T_i)\prod_{j\notin I}T_j\widetilde{A}, \tag{32.3}$$

$$(1-T_i)\widetilde{A} = \frac{\mathfrak{t}_i^{k_i}}{2\pi i}\oint_{|\zeta_i|=R_i}\frac{\widetilde{A}(\mathfrak{t}_1,\dots,\zeta_i,\dots,\mathfrak{t}_k,z)}{\zeta_i^{k_i}(\zeta_i-\mathfrak{t}_i)}\,d\zeta_i :$$

there are $2^k - 1$ *boundary words, whatever the truncation orders* k_i*.*

(iv) The chart records the map from the motion of the shares to the exponents. The following statements about walls and continuation concern normal Mellin powers with an analytic tangential composite, or a further word with its own sector certificate; the bounded measurable test functions of (ii) have only the convergent identity and the error bound, and no continuation is asserted for them. For the Mellin power in the seam coordinates $\breve{x}_i^{-1}$ *at the shares* $\mathbf{z}$*, the normal exponent of a term is* $\boldsymbol{\kappa} + \mathbf{N}^{\mathsf{T}}\mathbf{z} + \mathbf{n} - \mathbf{1}$*. For a fixed tangential cut and a normal Mellin power, integrating these powers gives the walls* $\kappa_j + (\mathbf{N}^{\mathsf{T}}\mathbf{z})_j + n_j = 0$*; a moving cut keeps its indicator in the integrand, with no such set of poles. A motion* $\boldsymbol{\sigma}$ *of the shares in the coordinates of these Mellin powers has the wall slopes* $\mathbf{N}^{\mathsf{T}}\boldsymbol{\sigma}$*; for the original coordinates of the shares one first applies to* $\boldsymbol{\sigma}$ *the recorded linear change of the exponents of the Mellin powers. Other requested coordinates remain in the tangential word, and are not replaced by their values on the face unless that replacement is part of the stated test function.*

Corollary 32.3 (Face jets for an analytic test function)**.** *Let the tangential cut be fixed, the map* $\mathbf{C}(\mathfrak{t}g(\mathfrak{t},z),z)$ *holomorphic on a specified polydisc about* $\mathfrak{t} = 0$*, that point included, and* H *a bounded holomorphic tangential test function on a neighbourhood of its image. Expand* $\widetilde{A}(\mathfrak{t},z)\,H\big(\mathbf{C}(\mathfrak{t}g(\mathfrak{t},z),z)\big)$ *instead of* $\widetilde{A}$ *alone: its coefficient of degree* $\mathbf{n}$ *is a finite sum of tangential source integrals of derivatives of* H *at* $\mathbf{C}(0,z)$*, multiplied by jets of* $\widetilde{A}$*,* $\mathbf{C}$ *and* g *of degrees at most* $\mathbf{n}$*. These are fixed face functionals, and their series and boundary words obey the same coefficient bounds as in Theorem 32.2(ii), with the bound of this composite. A change of analytic tangential test function needs its jets, not a new continuation of the source. The normal monomial* $\mathfrak{t}^{\mathbf{N}}$ *remains unexpanded in the integrand; a normal test function may be expanded as well when its composite is holomorphic and bounded on the polydisc and its jets are supplied by finite operations, a further condition, since negative entries of* $\mathbf{N}$ *can give poles at* $\mathfrak{t} = 0$*.*

Theorem 32.4 (Certified regions of equality and composition)**.** *For rational positive polynomial letters and rational monomial seam coordinates the following is a procedure.*

(i) The finite sector data determine the exponent matrices and the chart factors of Definition 32.1. Every invertible normal minor gives a proposed end chart, with the other variables

and test functions retained; enumerating rational tangential boxes and radii and verifying the inequalities of the certificate and of nonvanishing produces certified charts. Every compact tangential set on the end face $q = 0$ on which the proposed chart has nonvanishing chart factors and an invertible normal matrix has a small enough normal neighbourhood covered by finitely many charts produced in this way. Extending a chart away from that face needs its certificate, or a new certificate of inverse functions for the full Jacobian; invertibility of $\mathbf{N}$ *alone does not supply it.*

(ii) The region of equality supplied by one chart is the image of its certified polydisc in $\mathfrak{t}$ *under* $\check{x} = \mathfrak{t}^{\mathbf{N}}$*, with the specified branches and cuts; its positive part satisfies* $\sum_i (\mathbf{N}^{-1})_{ji} \log \check{x}_i < \log R_j$*,* $1 \le j \le k$*, and need not be a rectangle in the original seam coordinates. A finite atlas is certified for a requested region of equality only after its source patches cover the inverse image of that region; a patch not yet covered is retained as its original source word. So at every step the output is an exact finite head together with the boundary words* (32.3) *and the uncovered source word, with bounds for the parts certified small; an uncovered word is never omitted.*

(iii) Atlases may be restricted to common source patches, added, transported by their seam maps, and composed with a further test function. On compact certified subregions every order of the absolutely convergent reads has the same value. At finite truncations the equality uses the boundary words (32.3)*, and moving a cut retains the source between the old and the new cut. For words whose sector certificate supplies a meromorphic continuation, the same finite identities hold there, the full Laurent coefficient taken before pairing with a test function at coincident poles; an arbitrary bounded test function is not thereby continued. An infinite read in another grouping is asserted only with its own bound of convergence or as the continuation of the retained word.*

The retained data are the sector syntax, the matrix $\mathbf{N}$, the cuts, the recursion for the inverse jets and its certificate, and the tangential coefficient words, computed once per distinct source chart. For a prescribed error on $|\mathfrak{t}_i| \le \vartheta_i R_i$ the orders k_i are read off (32.2); the finite head has $\prod_i k_i$ coefficient words and its exact remainder $2^k - 1$ boundary words. A repeated chart reuses its coefficient words, a new analytic test function supplies its finite face jets, and the certificate and the retained boundary remain valid when only the truncation changes.

Proposition 32.5 (When a retained chart carries a density)**.** *A retained chart is in general not a chart of an ambient density. It becomes one in the selected normal coordinates and further tangential coordinates* $\mathbf{y}$ *when their image has a certified local product parametrization over* $(\mathfrak{t}, \mathbf{y})$*, with compact fibres, fixed cuts, a holomorphic form and an integrable uniform bound; integration over those fibres then gives a holomorphic coefficient function, and the series of Theorem 32.2, or of Corollary 32.3, represents that density with the same bounds. For a source form made of integrable powers of the boundary coordinates of a cube times a holomorphic density, such parametrizations are built near every compact regular fibre of a rational map* $\mathbf{C}$ *on the cube, when the map is defined on a neighbourhood of the closed cube, its restriction to every face meeting the fibre has a surjective differential, and its letters are nonzero. To assert a density for the whole law, the target patch must have no other or uncovered preimages, and in particular no omitted pole face may supply further source patches; otherwise the procedure describes the covered part of the law only, and the further preimages remain uncovered source words under Theorem 32.4. With the cube coordinates* v_i *put*

$$\mathbf{J}_{ji} = v_i(1 - v_i)\, \partial_{v_i} C_j, \qquad X_j = \sum_i v_i(1 - v_i) \big[\mathbf{J}^{\mathsf{T}} (\mathbf{J}\mathbf{J}^{\mathsf{T}})^{-1}\big]_{ij} \partial_{v_i};$$

then $D\mathbf{C}(X_j) = \mathbf{e}_j$*. On a small enough neighbourhood the flows of these vector fields carry the reference fibre to the neighbouring fibres, keep all faces and give the product parametrization. Uniform nonvanishing of* $\det(\mathbf{J}\mathbf{J}^{\mathsf{T}})$*, of the letters and of the relevant Jacobians, together with a bound for the vector fields on a larger neighbourhood, is a finite certificate; the iteration of the integral equations of the flows, certified to converge geometrically, computes the local flows and their holomorphic extensions.*

The possible failures of this procedure are explicit: zeros of letters, loss of properness at an omitted face of the source, or loss of surjectivity of the differential of the seam map on a face. Their images are candidate boundaries, not automatically singularities of the law, since different contributions can cancel. If the source has smaller dimension than the number of requested seam coordinates, the retained law and its atlas still exist but no ambient density is asserted. A genuine edge of the support is an obstruction: if the law vanishes on an open set on one side of an edge and has positive measure arbitrarily close on the other, it has no analytic density across that edge, by the identity theorem, as in Theorem 20.44(iii).

Proposition 32.6 (Convergence domains and equality regions)**.** *Let the fixed face laws of a certified chart, or the face functionals for a fixed bounded set of analytic test functions, be* $\widetilde{A}_{\mathbf{n}}$ *in a Banach space. The interior* Ω_{abs} *of*

$$\Big\{\mathfrak{t} : \sum_{\mathbf{n}\geq 0} \|\widetilde{A}_{\mathbf{n}}\|\,|\mathfrak{t}^{\mathbf{n}}| < \infty\Big\}$$

is the logarithmically convex domain of absolute convergence *of that series, which contains with each of its points* $\mathfrak{t}$ *every* $\mathfrak{t}'$ *with* $|\mathfrak{t}'_i| \leq |\mathfrak{t}_i|$ *for all* i*, and every certified polydisc lies in it. Its* region of equality *is retained separately: the chart patches covered by the source on which the series is proved to read the law, together with the patches reached by a chain of transports of charts that keep the equality. The series represents the law only on the intersection of the domain* Ω_{abs} *and the region of equality; analytic continuation of the sum alone is not a transport of the equality across an edge of the support or a singular value of the law. For a positive integer vector* $\mathbf{d}$ *and a fixed point* $\mathfrak{t}$ *of the chart retain the grouping*

$$\widetilde{A}_{(N)}(\mathfrak{t}) = \sum_{\langle \mathbf{d},\mathbf{n}\rangle = N} \widetilde{A}_{\mathbf{n}}\,\mathfrak{t}^{\mathbf{n}};$$

the grouped analytic germ in one variable v *on the curve* $(\mathfrak{t}_i v^{d_i})_i$ *has the exact radius* R *with* $R^{-1} = \limsup_N \|\widetilde{A}_{(N)}(\mathfrak{t})\|^{1/N}$*: inside it the grouped series converges, and outside it its grouped terms do not tend to zero. These statements concern the germ, and they become statements about the law only where its region of equality is certified as well; on the boundary of convergence the coefficients decide. Completing another read replaces these grouped terms by their images, whose radius can be larger, the equality with the new expansion of the law still using the transported source and cuts. Neither radius is a reach of the law by definition, nor is it replaced by the supremum of an unintegrated modulus of the source.*

The comparison of radii for a bounded read coefficient by coefficient concerns the same normal coordinates and the same bank of coefficients. Merging a law and then choosing a new coordinate is another operation: the source is carried by that map and its expansion is regraded in the new coordinate, whose coefficients and grouped terms need not be bounded images of the old ones, and whose boundary of equality can come earlier. The old and the new expansion agree through their common source, with the cuts, the finite heads and the boundary words transported; their

domains of convergence and atlases of equality are recorded in their own coordinates. Maximal analytic continuation, and deciding every cancellation at a singular boundary, are neither used by the procedure nor concluded from a ceiling. In one selected coordinate with a fixed tangential test function the procedure certifies local patches of equality with the wall series, and the global inversion of Theorem 32.10 (Theorem 20.44 at width one) identifies the reach of the law along that coordinate; in several coordinates the certified atlas of equality, the domain of convergence of the series and its retained grouping are stored separately.

32.2 The reach along a direction

At width one the reach of a bunch is read on the law of its ratio, as the point beyond which the law is its own wall series (Theorem 20.44); it is bounded above by the ceilings of the keyhole continuations and attained at their simple tops that do not cancel (Theorems 20.49 and 20.51), and against a room bounded below the terms of the node have the root rate of the reach over the least ratio of the room, which infinitely many of them reach (Theorem 20.39). A closing past the walls at any width advances along one direction of the shares, and along a rational direction the seam function is the Mellin transform of one measure on the half-line, the directional law (Definition 32.9). The theory of width one applies to that measure line by line, and its counterparts are stated along a direction.

Definition 32.7 (Walls and growth bounds)**.** Let a piece have its seam function $P_{W_B(\mathbf{w})}(\mathbf{m}_B)$ on the pins of the seam, an affine space A_B of real shares $\mathbf{w} = (\mathbf{a}, \mathbf{b})$ of the active letters with the space of directions $\vec{A}_B$, of dimension $n_{\mathcal{D}}$; for $\mathbf{w} \in A_B + i\vec{A}_B$ it is $\int \mathbf{x}^{-\mathbf{w}}\, d\big((\boldsymbol{\varrho}_B^{\rho})_*\phi_B^{\rho}\big)(\mathbf{x})$ where this converges, the law being carried by the closure of the image of the open simplex under the seam vector. The seam function has *walls* when

(W1) there are finitely many affine functions κ_U on A_B with rational linear parts, its *walls*, such that it converges at a real point exactly when every wall is positive there, which happens on an open convex set $\Omega_B \subseteq A_B$, and it continues meromorphically to $A_B + i\vec{A}_B$ with its poles on the hyperplanes on which a wall lies in $-\mathbb{N}$;

and it has *growth bounds* when

(W2) for every $\theta > 0$ there are M, C_0, n_1 and n_2 with $|P_{W_B(\mathbf{z})}(\mathbf{m}_B)| \le C_0\, \delta^{-n_2}(1 + |\mathbf{z}|)^{n_1} M^{|\operatorname{Re}\mathbf{z}|_1} e^{\theta|\operatorname{Im}\mathbf{z}|_1}$, δ the smaller of 1 and the distance of $\mathbf{z}$ from these hyperplanes.

The same definitions apply to the period of any word whose exponents are affine functions of the shares.

Every piece whose seam function converges at a real point has walls and growth bounds, and so does the seam function of its seam letters merged by bundles: the seam word of a piece is a word in positive letters, and so is the word of the merged seam letters of Theorem 31.7, sums of seam letters of several stations of one excess, which are no longer letters of tables; such a word continues past its walls as the seam word of every piece does (Theorem 31.4(ii)).

Lemma 32.8 (A word in positive letters continues past its walls)**.** *(i) Let $W = \prod_l L_l^{-w_l}$ be a product of powers of positive letters on a set B (Definition 25.1), whose exponents w_l and masses $\mathbf{m}_B$ are affine functions of $\mathbf{z} \in \mathbb{C}^p$ with rational linear parts, the masses on the balance hyperplane of W for every $\mathbf{z}$, and let its period converge at a real point $\mathbf{z}_0$, the exponents there being of any sign. Then there are finitely many affine functions κ_U on $\mathbb{C}^p$ with rational linear parts, its walls, such that the period converges at a real point exactly when every κ_U is*

positive there, and $P_W(\mathbf{z})$ *continues meromorphically to* $\mathbb{C}^p$*, with its poles, of order at most* $|B|-1$*, on the hyperplanes* $\kappa_U(\mathbf{z}) \in -\mathbb{N}$*; and for every* $\theta > 0$ *there are* M*,* C_0 *and* n_1 *with*

$$|P_W(\mathbf{z})| \le C_0\, \delta^{-(|B|-1)} (1+|\mathbf{z}|)^{n_1} M^{|\operatorname{Re}\mathbf{z}|_1} e^{\theta |\operatorname{Im}\mathbf{z}|_1},$$

δ *the smaller of* 1 *and the distance of* $\mathbf{z}$ *from these hyperplanes.*

(ii) For a piece and a partner read in its monomials, as in Theorem 31.7(B), merge the shares of each bundle G *of Theorem 31.7 into* $\bar{a}_G$*, and put* $L_G = \sum_{l\in G} \xi_l\, V_{jD(l)}$ *for a bundle of shares of* K_j*, and* L_G *alike with the seam letters* V^*_{jD} *for a bundle of shares of* Ψ_j*. On the pins of the merged shares the* merged seam word $W^{\mathrm{m}}_B(\bar{\mathbf{a}}) = \prod_G L_G^{-\bar{a}_G}$ *is such a product at the masses* $\mathbf{m}_B$*, and its period, the* merged seam function*,*

$$P_{W^{\mathrm{m}}_B(\bar{\mathbf{a}})}(\mathbf{m}_B) = \int \prod_G e^{-\bar{a}_G\, y_G}\, d\lambda, \qquad y_G = \log \sum_{l\in G} e^{y_l},$$

reads the merged values y_G *at the source points, against the source measure* λ *(Theorem 31.28); it converges at the sums over the bundles of every real point with positive coordinates at whose sums over the monomials the seam function of the piece converges.*

For the seam word of a piece, at the masses $\mathbf{m}_B$ and with the shares as its exponents, Lemma 32.8(i) gives walls and growth bounds whenever the seam function converges at a real point, the functions κ_U of the lemma serving as the walls, with $n_2 = |B|-1$; when the shares are positive at that point the seam word has a Newton sum of full dimension (Theorem 25.2), and the walls of the generators of a fan of the seam word serve, with the sector integrals of Theorem 31.4(ii), the proper walls for a piece of tables. A piece whose seam function on the pins is a product of Beta corners $\Gamma_{\begin{smallmatrix}2\\1\end{smallmatrix}}\begin{bmatrix} x,\ y \\ x+y \end{bmatrix}$ of affine functions of the shares with rational linear parts and of real exponentials of the shares, converging exactly where those affine functions are positive, has walls, those functions, and growth bounds, by the reflection formula (Proposition 1.3(v)) and the asymptotic expansion of $\log\Gamma$ away from the negative real axis, and growth bounds even at $\theta = 0$ when for each Beta corner the linear parts of its two arguments on $\vec{A}_B$ are proportional, as when one argument does not depend on the shares.

Definition 32.9 (Directional ratios and laws; the reach along a direction)**.** Let a piece have walls and growth bounds (Definition 32.7), and let $\bar{\boldsymbol{\sigma}} \in \vec{A}_B \setminus \{0\}$ have rational coordinates. Its *directional ratio* is the positive function $\mathbf{x}^{-\bar{\boldsymbol{\sigma}}}$ on the seam torus. For $\mathbf{w}_0 \in \Omega_B$ and $\bar{\boldsymbol{\vartheta}} \in \vec{A}_B$ the *directional law* at $\mathbf{w}_0 + i\bar{\boldsymbol{\vartheta}}$ is the image

$$\lambda_{\bar{\boldsymbol{\sigma}},\mathbf{w}_0+i\bar{\boldsymbol{\vartheta}}} = \left(\mathbf{x}^{-\bar{\boldsymbol{\sigma}}}\right)_* \Big(\mathbf{x}^{-\mathbf{w}_0 - i\bar{\boldsymbol{\vartheta}}}\, (\boldsymbol{\varrho}^{\rho}_B)_* \phi^{\rho}_B \Big),$$

a complex measure on $(0,\infty)$ whose variation is at most the positive directional law $\lambda_{\bar{\boldsymbol{\sigma}},\mathbf{w}_0}$, which integrates to the seam function at $\mathbf{w}_0$; it is *oscillating* when $\bar{\boldsymbol{\vartheta}} \neq 0$, and the line $\{\mathbf{w}_0 + i\bar{\boldsymbol{\vartheta}} + z\bar{\boldsymbol{\sigma}} : z \in \mathbb{R}\}$ is the *imaginary translate* by $\bar{\boldsymbol{\vartheta}}$ of the line through $\mathbf{w}_0$. Its *line function* is

$$\ell(z) = P_{W_B(\mathbf{w}_0+i\bar{\boldsymbol{\vartheta}}+z\bar{\boldsymbol{\sigma}})}(\mathbf{m}_B) = \int_0^\infty X^z\, d\lambda_{\bar{\boldsymbol{\sigma}},\mathbf{w}_0+i\bar{\boldsymbol{\vartheta}}}(X),$$

absolutely convergent for $\operatorname{Re} z$ in the open interval of the x with $\mathbf{w}_0 + x\bar{\boldsymbol{\sigma}} \in \Omega_B$, which contains 0, and continued meromorphically by (W1). A wall falls along $\bar{\boldsymbol{\sigma}}$ when its falling rate $-\dot{\kappa}_U$,

$\dot\kappa_U = \partial_{\bar{\boldsymbol\sigma}}\kappa_U$, is positive (Definition 31.5). The poles of ℓ with $\operatorname{Re} z \ge 0$ lie among the *candidate poles*

$$z = \big(\kappa_U(\mathbf{w}_0) + n + i\,\partial_{\bar{\boldsymbol\vartheta}}\kappa_U\big)/(-\dot\kappa_U), \qquad n \in \mathbb{N},$$

of the falling walls: on finitely many horizontal lines, with real parts in finitely many cosets of one lattice $N_0^{-1}\mathbb{Z}$, the falling rates being rational. Let Σ be the half-strip of the z with $\operatorname{Re} z \ge 0$ and $\operatorname{Im} z$ within 1 of the interval spanned by 0 and these lines. The *reach along* $\bar{\boldsymbol\sigma}$ at $\mathbf{w}_0 + i\bar{\boldsymbol\vartheta}$ is

$$r(\bar{\boldsymbol\sigma}; \mathbf{w}_0 + i\bar{\boldsymbol\vartheta}) = \inf\big\{M \ge 0 :\ \text{for every } \delta > 0 \text{ there are } C, n' \text{ with } |\ell(z)| \le C(1+|z|)^{n'} M^{\operatorname{Re} z}\big\},$$

the bound asked at every $z \in \Sigma$ at distance at least δ from the candidate poles; it is finite by (W2), and by the maximum modulus principle on circles about the candidates it does not change when the actual poles are used. A *wall series* is as in Definition 20.43, the η_i allowed to be complex and its condition read as $\sum_{\eta,j} |a_{\eta,j}| x'^{-\operatorname{Re}\eta} < \infty$ for every $x' > x_0$, x_0 its radius. At $\bar{\boldsymbol\vartheta} = 0$ the directional law is the *law along* $\bar{\boldsymbol\sigma}$. The same definitions apply to the merged seam function of Lemma 32.8(ii) on the pins of the merged shares, the merged values e^{y_G} in place of the seam coordinates and the source measure in place of the law.

The falling end of the directional law is $X \to \infty$, where the walls that fall along $\bar{\boldsymbol\sigma}$ make its moments diverge. In an end chart of Theorem 32.2 the Mellin power at the shares $\mathbf{z}$ is $\mathfrak{t}^{\mathbf{N}^{\mathsf T}\mathbf{z}}$, so the directional ratio is $\mathfrak{t}^{-\mathbf{d}}$, $\mathbf{d} = -\mathbf{N}^{\mathsf T}\bar{\boldsymbol\sigma}$ the falling rates of the walls of the chart, times a power of the tangential coordinates: the wall series of the directional law groups the terms of the chart by their exponents $(\kappa_j + n_j)/d_j$ along the direction, and the reach is the far boundary, in X, of the region on which the law equals that expansion. At width one with one table and factoring weights, normalized as in Proposition 28.11, the seam torus is a curve, $\vec{A}_B$ is the line of $\bar{\boldsymbol\sigma} = (-1, 1, -1, 1)$ in the shares $(a_{D_0}, a_{D_1}, b_{D_0}, b_{D_1})$, and the directional ratio is $x^*_{D_0}/x_{D_1}$, which is ϱ_B at the seam points (Proposition 28.11); every coordinate of the torus is a power of ϱ_B, so the directional law is a power of ϱ_B times the law of Definition 20.43, and by Theorems 32.10 and 20.44 the reach along $\bar{\boldsymbol\sigma}$ is the reach $\operatorname{reach}(B)$ of the bunch.

Theorem 32.10 (The reach along a direction is read on the law)**.** *Let $\bar{\boldsymbol\sigma}$, $\mathbf{w}_0$, $\bar{\boldsymbol\vartheta}$, the directional law $\lambda = \lambda_{\bar{\boldsymbol\sigma}, \mathbf{w}_0 + i\bar{\boldsymbol\vartheta}}$, its line function ℓ and its reach r be as in Definition 32.9.*

(i) On (r, ∞) the measure λ has a density which is a wall series of radius r. Its terms are the poles of ℓ with $\operatorname{Re} z > 0$: a pole η with the principal part $\sum_j (-1)^{j+1} j!\, a_{\eta,j}(z-\eta)^{-j-1}$ gives the terms $a_{\eta,j} X^{-\eta-1}(\log X)^j$, and there are no others.

(ii) If on some (x_0, ∞) the measure λ has a density which is a wall series of radius x_0, then $r \le x_0$; and for every $x' > x_0$ there is C with $|\ell(z)| \le C\delta^{-J-1} x'^{\operatorname{Re} z}$ at every z with $\operatorname{Re} z \ge 0$ at distance at least $\delta \le 1$ from the poles, whatever $\operatorname{Im} z$, J the largest power of the logarithm in the series.

(iii) So r is the least $x_0 \ge 0$ for which λ has on (x_0, ∞) a density which is a wall series of radius x_0. It does not change when $\mathbf{w}_0$ moves along $\bar{\boldsymbol\sigma}$, $r(c\bar{\boldsymbol\sigma}; \cdot) = r(\bar{\boldsymbol\sigma}; \cdot)^c$ for rational $c > 0$, and r is at least every point near which λ has no real-analytic density. At $\bar{\boldsymbol\vartheta} = 0$ the law λ is positive and carried by the closure of the values of $\mathbf{x}^{-\bar{\boldsymbol\sigma}}$ on the support of the law of the piece: $r \ge X_{\min}$, the least of these values, when it is positive, the least value of the directional ratio taking the place of the least ratio (Proposition 20.35); and no wall falls along $\bar{\boldsymbol\sigma}$ exactly when $\mathbf{x}^{-\bar{\boldsymbol\sigma}}$ is bounded on that support, and then $r = X_{\max}$, the largest. When the seam word has a Newton sum of full dimension, as for a piece of tables whose tables form a connected family (Theorem 31.4(ii)), $X_{\min} = (\sup \mathbf{V}_B^{\bar{\boldsymbol\sigma}})^{-1}$ and $X_{\max} = \sup \mathbf{V}_B^{-\bar{\boldsymbol\sigma}}$, the suprema of the monomials of the letter vector of Theorem 31.2 (Definition 31.1).

(iv) *At $\bar{\boldsymbol{\vartheta}} = 0$ let $\mathbb{L} = \{z_0 + kz_1 : \ k \in \mathbb{N}\}$, $z_1 > 0$ rational, be a progression at positive distance from the poles of ℓ, and put $r_{\mathrm{res}} = \limsup_\eta \max_j |a_{\eta,j}|^{1/\eta}$ over the poles and $r_{\mathbb{L}} = \limsup_k |\ell(z_0 + kz_1)|^{1/(z_0+kz_1)}$. Then $r = \max(r_{\mathrm{res}}, r_{\mathbb{L}})$: the reach is carried by the residues of the line or by its values on every progression.*

(v) *For every $\theta \geq 0$, r is the infimum of the $M \geq 0$ for which, for every $\delta > 0$, there are C and n' with $|\ell(z)| \leq C(1 + |z|)^{n'} M^{\operatorname{Re} z} e^{\theta |\operatorname{Im} z|}$ at every z with $\operatorname{Re} z \geq 0$ at distance at least δ from the candidate poles: the growth of the line function on its whole half-plane, at any allowance in the imaginary direction, is the reach.*

At width one the same argument, run on the law of a family at a node, reads the growth of the family on its law, and that of the bunch is its reach.

Corollary 32.11 (At width one the growth of a family is read on its law)**.** *In Section 20.7 let λ_B be the image of the base form ϕ_B under ϱ_B and λ_R the image of ϕ_R under $1/\varrho_R$. For $X \in \{B, R\}$ the growth* $\mathrm{growth}(X)$ *along the level d (Definition 20.33) is the least $x_0 \geq 0$ for which λ_X has on (x_0, ∞) a density that is a wall series of radius x_0. In particular* $\mathrm{growth}(B) = \mathrm{reach}(B)$*: the inequality* $\mathrm{reach}(B) \leq \mathrm{growth}(B)$ *of Theorem 20.34(i) is an equality, and Theorem 20.34(iii) closes a node on the lattices of both families when the two points beyond which their laws are their own wall series multiply to less than one.*

A closing of the share side moves the imaginary parts of the shares over a whole fibre, so its bounds read the seam function on every imaginary translate of a line as well as on the line itself.

Corollary 32.12 (The reach of a tube)**.** *Let $\bar{\boldsymbol{\sigma}}$ and $\mathbf{w}_0$ be as in Definition 32.9 and $V' \subseteq \vec{A}_B$ a subspace containing $\bar{\boldsymbol{\sigma}}$. For $\theta \geq 0$ let $g_{V'}(\bar{\boldsymbol{\sigma}}; \theta)$ be the infimum of the M for which there are C, n_1 and n_2 with*

$$\left|P_{W_B(\mathbf{w}_0 + \tau\bar{\boldsymbol{\sigma}} + i\bar{\boldsymbol{\vartheta}})}(\mathbf{m}_B)\right| \leq C\,\delta^{-n_2}(1 + \tau + |\bar{\boldsymbol{\vartheta}}|)^{n_1} M^\tau e^{\theta|\bar{\boldsymbol{\vartheta}}|_1} \qquad (\tau \geq 0,\ \bar{\boldsymbol{\vartheta}} \in V'),$$

δ the smaller of 1 and the distance from the hyperplanes of (W1), and let $r^\sharp_{V'}(\bar{\boldsymbol{\sigma}}; \mathbf{w}_0) = \lim_{\theta \downarrow 0} g_{V'}(\bar{\boldsymbol{\sigma}}; \theta)$ be the reach of the tube *over V'.*

(i) *$r(\bar{\boldsymbol{\sigma}}; \mathbf{w}_0 + i\bar{\boldsymbol{\vartheta}}) \leq r^\sharp_{V'}$ for every $\bar{\boldsymbol{\vartheta}} \in V'$; in particular $r(\bar{\boldsymbol{\sigma}}; \mathbf{w}_0) \leq r^\sharp_{V'}$, with equality when $V' = \mathbb{R}\bar{\boldsymbol{\sigma}}$.*

(ii) A certificate on the real fibres. *Let $\mathbf{v}_1, \ldots, \mathbf{v}_{n_{\mathcal{D}}-1}$ complete $\bar{\boldsymbol{\sigma}}$ to a basis of $\vec{A}_B$, and $y_i = \langle \mathbf{v}_i, \log \mathbf{x} \rangle$ on the torus. If the image of the measure $\mathbf{x}^{-\mathbf{w}_0}(\boldsymbol{\varrho}^\rho_B)_* \phi^\rho_B$ under $(\mathbf{x}^{-\bar{\boldsymbol{\sigma}}}, \mathbf{y})$, on the part where $\mathbf{x}^{-\bar{\boldsymbol{\sigma}}} > x_0$, is $\sum_{\eta,j} X^{-\eta-1}(\log X)^j dX \otimes \phi_{\eta,j}(d\mathbf{y})$, $j \leq J$, with finite signed measures $\phi_{\eta,j}$, the η in finitely many sets $\eta_i + \mathbb{N}$, and $\sum_{\eta,j} \|\phi_{\eta,j}\| x'^{-\eta} < \infty$ for every $x' > x_0$, then $g_{\vec{A}_B}(\bar{\boldsymbol{\sigma}}; 0) \leq x_0$, so that $r^\sharp_{\vec{A}_B} \leq x_0$: an expansion at the face over the real fibres certifies the tube, with no allowance for the phase.*

The certificate asks the expansion to hold over whole fibres of the directional ratio, with fixed measures on them, along one direction. Read in the coordinates in which the shares pair with the law linearly, expansions with fixed tangential measures at the falling ends certify the tube in every direction at once: in those coordinates a complex share multiplies the law by a factor of modulus one, and the continuation is made on the law itself.

Definition 32.13 (Log expansions of a law)**.** For a piece, with the space $\vec{A}_B$ of the directions of its shares of Definition 32.7 and its dual $\vec{A}^*_B$, the *log-ratio map* sends a point $\mathbf{x}$ of the seam torus

to the linear function $\mathbf{z} \mapsto \langle \mathbf{z}, \log \mathbf{x} \rangle$ on $\vec{A}_B$, written $\log \mathbf{x}|_{\vec{A}_B}$; for a real point $\bar{\mathbf{c}}$ of the pins at which the seam function converges, $\lambda_{\bar{\mathbf{c}}} = (\log \mathbf{x}|_{\vec{A}_B})_* \big(\mathbf{x}^{-\bar{\mathbf{c}}} (\boldsymbol{\varrho}_B^{\rho})_* \phi_B^{\rho}\big)$ is a finite positive measure on $\vec{A}_B^*$, and the seam function at $\bar{\mathbf{c}} + \mathbf{z}$ is $\int e^{-\langle \mathbf{z}, f \rangle}\, d\lambda_{\bar{\mathbf{c}}}(f)$ for $\mathbf{z} \in \vec{A}_B + i\vec{A}_B$ wherever the integral converges absolutely. A *log expansion* is the image of the complex measure

$$\sum_{\boldsymbol{\eta}, \mathbf{j}} \mathbf{p}^{\mathbf{j}} e^{-\langle \boldsymbol{\eta}, \mathbf{p} \rangle}\, d\mathbf{p} \otimes \phi_{\boldsymbol{\eta}, \mathbf{j}}(df) \qquad \text{on } [0, \infty)^k \times Y_Q$$

under $(\mathbf{p}, f) \mapsto f - \sum_{h \le k} p_h u_h$, where $u_1, \dots, u_k \in \vec{A}_B^*$ are linearly independent, $\boldsymbol{\eta}$ runs over the union of finitely many translates of $\mathbb{N}^k$ by positive vectors, $\mathbf{j} \le \mathbf{J}$, and the $\phi_{\boldsymbol{\eta}, \mathbf{j}}$ are complex measures on a compact set $Y_Q \subset \vec{A}_B^*$, its *inner face*, with $\sum \|\phi_{\boldsymbol{\eta}, \mathbf{j}}\| < \infty$. The law *has log expansions at* $\bar{\mathbf{c}}$ when $\lambda_{\bar{\mathbf{c}}}$ is the sum of finitely many log expansions Q and of a complex measure ϕ_0 carried by a compact set Y_0. Its *inner bound* along a direction $\bar{\boldsymbol{\sigma}} \in \vec{A}_B$ is the largest value of the directional ratio $e^{-\langle \bar{\boldsymbol{\sigma}}, f \rangle}$ on Y_0 and on the inner faces,

$$X_{\mathrm{in}}(\bar{\boldsymbol{\sigma}}) = \max \Big(\max_{f \in Y_0} e^{-\langle \bar{\boldsymbol{\sigma}}, f \rangle},\ \max_{Q} \max_{f \in Y_Q} e^{-\langle \bar{\boldsymbol{\sigma}}, f \rangle} \Big),$$

whose logarithm is convex in $\bar{\boldsymbol{\sigma}}$.

An end chart of Theorem 32.2 on a compact tangential source, whose tangential map and cut do not depend on $\mathfrak{t}$ and whose normal coordinates enter the log-ratio map through k linearly independent elements of $\vec{A}_B^*$, gives finitely many log expansions and a compact part: the log-ratio map is linear in $\log \mathfrak{t}$ and in the logarithms of the tangential coordinates; with $p_h = \log(R_h'/\mathfrak{t}_h)$ on the polydisc of the radii $R_h' < R_h$ the exponents are $\boldsymbol{\kappa} + \mathbf{n}$ and the coefficients $\widetilde{A}_{\mathbf{n}} R'^{\boldsymbol{\kappa} + \mathbf{n}}$, summable by Theorem 32.2(ii); where some $\mathfrak{t}_h$ lie in $[R_h', R_h)$ these join the tangential coordinates, the others keeping their expansions, summable uniformly by Cauchy's estimate on the closed polydisc; and where all of them do, the part is compact. A law with independent coordinates has such log expansions from the expansions of its factors at their ends.

Proposition 32.14 (A law with log expansions continues without phase)**.** *Let the law of a piece have log expansions at* $\bar{\mathbf{c}}$ *(Definition 32.13). Then for* $\mathbf{z} \in \vec{A}_B + i\vec{A}_B$ *off the hyperplanes* $\langle \mathbf{z}, u_h \rangle = \eta_h$ *of the log expansions,*

$$P_{W_B(\bar{\mathbf{c}} + \mathbf{z})}(\mathbf{m}_B) = \int e^{-\langle \mathbf{z}, f \rangle}\, d\phi_0(f) + \sum_{Q} \sum_{\boldsymbol{\eta}, \mathbf{j}} \prod_{h \le k} \frac{j_h!}{(\eta_h - \langle \mathbf{z}, u_h \rangle)^{j_h + 1}} \int_{Y_Q} e^{-\langle \mathbf{z}, f \rangle}\, d\phi_{\boldsymbol{\eta}, \mathbf{j}}(f),$$

continued: the seam function at $\bar{\mathbf{c}} + \cdot$ *is meromorphic on* $\vec{A}_B + i\vec{A}_B$ *with its poles on these hyperplanes, and there are* C *and* n *with*

$$\big| P_{W_B(\bar{\mathbf{c}} + \mathbf{z})}(\mathbf{m}_B) \big| \le C\, \delta^{-n} \max \Big(\max_{f \in Y_0} e^{-\langle \mathrm{Re}\, \mathbf{z}, f \rangle},\ \max_{Q} \max_{f \in Y_Q} e^{-\langle \mathrm{Re}\, \mathbf{z}, f \rangle} \Big),$$

δ *the smaller of* 1 *and the distance of* $\mathbf{z}$ *from these hyperplanes; the same holds, with another constant, for* δ *the smaller of* 1 *and the distance from the polar hyperplanes of the seam function alone. On the contour through a point* $\bar{\mathbf{c}} + \tau\bar{\boldsymbol{\sigma}}$, $\tau \ge 0$, *the bound is* $C\delta^{-n} X_{\mathrm{in}}(\bar{\boldsymbol{\sigma}})^{\tau}$, *with no factor in the imaginary parts and no power of* τ. *So, for a piece whose seam word has a Newton sum of full dimension and a rational* $\bar{\boldsymbol{\sigma}}$, $r(\bar{\boldsymbol{\sigma}}; \bar{\mathbf{c}}) \le r^{\sharp}_{\vec{A}_B}(\bar{\boldsymbol{\sigma}}; \bar{\mathbf{c}}) \le g_{\vec{A}_B}(\bar{\boldsymbol{\sigma}}; 0) \le X_{\mathrm{in}}(\bar{\boldsymbol{\sigma}})$, *and the growth of Theorem 31.4(iii) is* $g(\boldsymbol{\sigma}; 0) \le X_{\mathrm{in}}(\bar{\boldsymbol{\sigma}})$ *for every direction* $\boldsymbol{\sigma}$ *of the shares of Theorem 31.4(i) whose sums over the monomials are* $\bar{\boldsymbol{\sigma}}$.

The certificate of Corollary 32.12(ii) is one expansion along the direction itself, with fibre measures of any extent and no condition on the rest of the law: on the contours through the points of a ray of $\bar{\boldsymbol{\sigma}}$ the factor $\mathbf{x}^{-i\bar{\boldsymbol{\vartheta}}}$ has modulus one and only the values of the directional ratio enter, not the compactness of the faces. Neither certificate applies as stated where the tangential coordinates of a face move with the normal ones, as when the support of the law curves in its log-ratio coordinates, or where a cut of the fibres moves, as in Theorem 32.2: the measures on the fibres are then not fixed, and the imaginary translates are read one at a time by Theorem 32.10, or bounded by the ceilings of Theorem 32.15, which carry the phase of the letters on these lines through their constants.

Without such a certificate a tube can reach farther than every one of its lines. There are sector integrals in two shares, with a single wall and growth bounds, for which every line of the tube along the fall of the wall has a finite reach while the reach of the tube over all the directions of the shares is infinite: the factor $\mathbf{x}^{-i\bar{\boldsymbol{\vartheta}}}$ enters the Taylor coefficients of a letter at the falling face through the powers of $\bar{\boldsymbol{\vartheta}}$. The seam function of a piece can do the same: when its seam function on the pins is a Beta corner whose two arguments move independently on the pins, it has growth bounds only at positive θ, and on an imaginary translate along which one argument alone moves in the imaginary direction the Beta corner grows like a power of the imaginary part whose degree grows with the real parts, so that its tube reaches infinitely far while each of its lines has a finite reach. The sector letters of a piece of tables are never monomials in the falling variables, through which alone the factor $\mathbf{x}^{-i\bar{\boldsymbol{\vartheta}}}$ would enter without reaching the Taylor coefficients at the falling face. Theorem 32.16(i) is the limit $\theta \to 0$ of Theorem 31.4(iii); when the reach of the tube is infinite, the bound of that theorem at a positive θ, which pays for the phase, is the one that travels.

Theorem 32.15 (Ceilings, simple tops and fibres along a direction)**.** *Let the seam function of the piece converge at a real point of the pins with positive shares, let $\bar{\boldsymbol{\sigma}}$ and $\mathbf{w}_0$ be as in Definition 32.9, the walls being those of a fan of the seam word (Theorem 31.4(ii)), and for a sector π of it let $\varrho_{\pi,\bar{\boldsymbol{\sigma}}} = \prod_k q_k^{\dot{\kappa}_k}\, \mathbf{k}_\pi^{-\bar{\boldsymbol{\sigma}}}$ be the directional ratio in the sector (Definition 31.10), the sector letters L of $\mathbf{k}_\pi$ entering with the coordinates $\bar{\sigma}_L$ of $\bar{\boldsymbol{\sigma}}$ at their stations and $w_{0,L}$ of $\mathbf{w}_0$. The keyhole continuations along a direction $\boldsymbol{\sigma}$ depend on $\boldsymbol{\sigma}$ only through $\bar{\boldsymbol{\sigma}}$, and the falling variables of π are those with $\dot{\kappa}_k < 0$; for a piece of tables the sectors of the orders π of B may be taken.*

(i) No reach exceeds the ceiling. *For every keyhole continuation along $\bar{\boldsymbol{\sigma}}$, of ceiling $H_{\mathcal{O}}$, and every $\bar{\boldsymbol{\vartheta}} \in \vec{A}_B$, $r(\bar{\boldsymbol{\sigma}}; \mathbf{w}_0 + i\bar{\boldsymbol{\vartheta}}) \le H_{\mathcal{O}}$: the phase of the letters does not enter the reach.*

(ii) The values at the integers. *Let $\bar{\boldsymbol{\sigma}}$ be scaled so that every $\dot{\kappa}_k$ is an integer, and let the walls of the falling variables of every sector be off the integers at $\mathbf{w}_0$. An* integer keyhole continuation along $\bar{\boldsymbol{\sigma}}$ *is defined as in Definition 31.10 with every sector letter kept from vanishing except those L whose exponent $-w_{0,L} - m\bar{\sigma}_L$ at $\mathbf{w}_0 + m\bar{\boldsymbol{\sigma}}$ is a nonnegative integer for every large integer m, its ceiling defined in the same way; its keyhole contour, its tops and its simple tops, with their exponents* $\exp(p)$ *and coefficients $A(p)$, are those of Definition 20.50 with $\varrho_{\pi,\bar{\boldsymbol{\sigma}}}$ in place of ϱ_π, the sector form $\phi_{\pi,\mathbf{w}_0} = |\det(\mathbf{v}_{\pi,1}, \dots, \mathbf{v}_{\pi,|B|-1})| \prod_k q_k^{\kappa_k(\mathbf{w}_0)-1} \mathbf{k}_\pi^{-\mathbf{w}_0} dq$ in place of ϕ_π, the walls $\kappa_j(\mathbf{w}_0)$ of the sector in place of κ_j, and the faces $q_j = 0$ with $\dot{\kappa}_j = 0$ in place of the faces of the level variables. Then for every large integer m the seam function at $\mathbf{w}_0 + m\bar{\boldsymbol{\sigma}}$ is the integral of $\varrho_{\pi,\bar{\boldsymbol{\sigma}}}^m\, \phi_{\pi,\mathbf{w}_0}$ over the keyhole contour, and the growth at the integers* $\mathrm{growth}_{\mathbb{Z}}(\bar{\boldsymbol{\sigma}}; \mathbf{w}_0) = \limsup_m |P_{W_B(\mathbf{w}_0 + m\bar{\boldsymbol{\sigma}})}(\mathbf{m}_B)|^{1/m}$ *is at most the ceiling of every integer keyhole continuation along $\bar{\boldsymbol{\sigma}}$, and at most $r(\bar{\boldsymbol{\sigma}}; \mathbf{w}_0)$.*

(iii) Simple tops. *If an integer keyhole continuation along $\bar{\boldsymbol{\sigma}}$ of ceiling $H_{\mathcal{O}}$ has finitely many tops, all simple, and some $A_\zeta \neq 0$ (Theorem 20.51(iii)), then* $\mathrm{growth}_{\mathbb{Z}}(\bar{\boldsymbol{\sigma}}; \mathbf{w}_0) = H_{\mathcal{O}} \le r(\bar{\boldsymbol{\sigma}}; \mathbf{w}_0)$*; if moreover some keyhole continuation along $\bar{\boldsymbol{\sigma}}$ has the ceiling $H_{\mathcal{O}}$, then $r(\bar{\boldsymbol{\sigma}}; \mathbf{w}_0) = H_{\mathcal{O}}$.*

(iv) Fibres. *Let $\bar{\boldsymbol{\sigma}}$ be scaled so that its coordinates and every $\dot{\kappa}_k$ are integers. Call a box of a continuation along $\bar{\boldsymbol{\sigma}}$ a* fibre box *when on its sets Y the letters with $\bar{\sigma}_L \geq 0$ do not vanish, and those with $\bar{\sigma}_L < 0$ do not vanish at the points with a falling coordinate 0; its stationary bound, as in Definition 20.54 with $\varrho_{\pi,\bar{\boldsymbol{\sigma}}}$ in place of ϱ_π, is the supremum of $|\varrho_{\pi,\bar{\boldsymbol{\sigma}}}|$ over the points of these sets with no falling coordinate 0 at which some falling coordinates lie inside their discs and the derivatives of $\varrho_{\pi,\bar{\boldsymbol{\sigma}}}$ in them vanish, the points with only one such coordinate, of falling rate one, left out. For every continuation along $\bar{\boldsymbol{\sigma}}$ whose boxes are keyhole boxes or fibre boxes, of ceiling $H_{\mathcal{O}}$, with the stationary bound S of its fibre boxes, $r(\bar{\boldsymbol{\sigma}}; \mathbf{w}_0) \leq \max(H_{\mathcal{O}}, S)$.*

So the reach along a direction sits between the growth at the integers and the ceiling of every keyhole continuation along it, and the two meet at simple tops that do not cancel when a keyhole continuation along the direction has the same ceiling, as at width one; and, by Theorem 32.10, without any top it is the far boundary of the region on which the directional law is its own wall series. The phase of the letters, which Theorem 31.11 pays for at the points where the ceiling is read, does not enter the reach: on a line the imaginary parts stay bounded. It enters only through the transverse fibre of a closing, which Theorem 32.16 reads.

The integer scaling in (iv) is needed: a sector with one falling variable of falling rate one and a letter entering with a coordinate that is not an integer can have a fibre box of stationary bound 0 and a reach above its ceiling, the directional ratio not being single valued in the disc, so that Lemma 20.52 does not apply; scaled to integers, the stationary point that the bound left out is counted.

Theorem 32.16 (The closing past the walls is read along its direction)**.** *Read the glue as in Theorem 31.4(i), the partner in its monomials, for a piece with walls and growth bounds whose seam word has a Newton sum of full dimension. Let V be the space of the directions of the shares, of dimension n, the number of free shares, $\boldsymbol{\sigma} \in V$ a direction with rational coordinates, $\bar{\boldsymbol{\sigma}}$ its sums, $V' \subseteq \vec{A}_B$ the space of the sums of the directions in V, and $\mathbf{c}$ the real starting point, with $\bar{\mathbf{c}} \in \Omega_B$, off the null set of Theorem 31.2 taken with the polar hyperplanes of the seam function. Let h_Γ be the Gamma rate of Theorem 31.4(iii), so that the rate of that theorem, which holds for such a piece (Theorem 31.4, its seam function converging at the sums $\bar{\mathbf{c}} \in \Omega_B$ of the positive shares of the starting point), is $h_\theta(\boldsymbol{\sigma}) = h_\Gamma(\boldsymbol{\sigma}) + \log g(\boldsymbol{\sigma}; \theta) + \frac{2\theta^2}{\pi} \sum_{\sigma_l > 0} \sigma_l$, and let I be the integrand of the share side.*

(i) The tube bounds the closing. *If $h_\Gamma(\boldsymbol{\sigma}) + \log r^\sharp_{V'}(\bar{\boldsymbol{\sigma}}; \bar{\mathbf{c}}) < 0$, the closing along $\boldsymbol{\sigma}$ converges absolutely, its terms and the integrals left after them being $O\big(e^{\tau(h_\Gamma(\boldsymbol{\sigma}) + \log r^\sharp_{V'} + \epsilon)}\big)$ for every $\epsilon > 0$; the closing along $\boldsymbol{\sigma}$ is the closing along every direction of its chamber (Theorem 31.6), whose rates bound it as well. For the share side of Theorem 31.4(iv), with $\boldsymbol{\sigma}$ a direction of its shares with rational coordinates and $\mathbf{c}$ off the null set of that part, the closing along $\boldsymbol{\sigma}$ converges absolutely when $\sum_l \sigma_l \log|\sigma_l| + \log r^\sharp_B + \log r^\sharp_R < 0$, in this sentence $r^\sharp_B$ and $r^\sharp_R$ being the reaches of the tubes over the space of the directions of its shares (Corollary 32.12) of the seam functions of the piece and of the partner along $\boldsymbol{\sigma}$ at $\mathbf{c}$; its terms and the integrals left after them are then $O\big(e^{\tau(\sum_l \sigma_l \log|\sigma_l| + \log r^\sharp_B + \log r^\sharp_R + \epsilon)}\big)$ for every $\epsilon > 0$.*

(ii) One free share. *Let $n = 1$, and put $r = r(\bar{\boldsymbol{\sigma}}; \bar{\mathbf{c}})$ and $\ell(z) = P_{W_B(\bar{\mathbf{c}} + z\bar{\boldsymbol{\sigma}})}(\mathbf{m}_B)$. Then $r^\sharp_{V'} = r$, and for every $r' > r$ the terms are $O\big((1+\tau)^{n'} e^{\tau(h_\Gamma(\boldsymbol{\sigma}) + \log r')}\big)$; so the closing converges absolutely when $h_\Gamma(\boldsymbol{\sigma}) + \log r < 0$. Let $r > 0$, let $\mathbb{L}$ be the progression of the crossings of a falling share l_0, and let the data keep the poles apart: from some point on, $\mathbb{L}$ meets no pole of ℓ and no pole of another Gamma, and no pole of ℓ is a pole of a Gamma. If the poles*

of ℓ crossed by the ray are simple from some point on, or the values of ℓ on $\mathbb{L}$ carry the reach (Theorem 32.10(iv)), then for every $\epsilon > 0$ infinitely many terms have modulus at least $e^{\tau(h_\Gamma(\boldsymbol{\sigma})+\log r-\epsilon)}$: the rate $h_\Gamma(\boldsymbol{\sigma}) + \log r$ is exact, and the terms do not tend to zero when it is positive. Without either proviso, if those poles have order at most p, the same holds for all but at most $p-1$ of the partners obtained by multiplying the coefficients by $e^{\tau_0 v_l}$, $\tau_0 \in \mathbb{R}$, for a fixed $\mathbf{v}$ with $\langle \mathbf{v}, \boldsymbol{\sigma}\rangle = 1$, the rate of the partner of τ_0 being $h_\Gamma(\boldsymbol{\sigma}) - \tau_0 + \log r$. The same holds for the share side of Theorem 28.10(iii) with one free share and a partner whose seam function converges along the ray, with $\sum_l \sigma_l \log|\sigma_l| + \log\sup \mathbf{V}_R^{-\bar{\boldsymbol{\sigma}}}$ in place of $h_\Gamma(\boldsymbol{\sigma})$, the partners being the tinkered partners that multiply the room letters of each station D by $e^{\tau_0 v_D}$ (Definition 28.18); at a node of width one, where the share side has one free share, this rate is $\log\big(\operatorname{reach}(B)/\inf \varrho_R\big)$, the logarithm of the root rate of Theorem 20.39(ii).

(iii) Several free shares. *Let $n \geq 2$. Fix a complement $V_\perp$ of $\mathbb{R}\boldsymbol{\sigma}$ in V, a Lebesgue measure $d\boldsymbol{\vartheta}_\perp$ on it and $k_\sigma > 0$ with $d\boldsymbol{\vartheta} = k_\sigma\, dy\, d\boldsymbol{\vartheta}_\perp$ for $\boldsymbol{\vartheta} = y\boldsymbol{\sigma} + \boldsymbol{\vartheta}_\perp$, $d\boldsymbol{\vartheta}$ the measure of Definition 4.1. Let T_σ be the space of the* transverse tinkers, *the tinkers of the partner read in its monomials (Definition 28.18, with one multiplier e^{v_l} for each monomial in place of each coordinate of the seam vector), multiplying the coefficients read on V as $\xi_l \mapsto \xi_l e^{v_l}$, with $\langle \mathbf{v}, \boldsymbol{\sigma}\rangle = 0$, identified with the dual of $V_\perp$ and carrying the dual Lebesgue measure $d\mathbf{v}$. The crossings of the closing along $\boldsymbol{\sigma}$ are the same for every tinker, and at a crossing at the time τ^**

$$\int_{T_\sigma} e^{\langle \mathbf{v}, \mathbf{c}\rangle}\, \mathcal{R}_{\tau^*}\big(\boldsymbol{\xi} e^{\mathbf{v}}\big)\, d\mathbf{v} = -k_\sigma \operatorname*{Res}_{z=\tau^*} I(\mathbf{c} + z\boldsymbol{\sigma}),$$

$\mathcal{R}_{\tau^*}(\boldsymbol{\xi} e^{\mathbf{v}})$ the crossing term of the partner with the coefficients $\boldsymbol{\xi} e^{\mathbf{v}}$. Integrated over the transverse tinkers against the factor $e^{\langle \mathbf{v}, \mathbf{c}\rangle}$, the terms of the closing are $-k_\sigma$ times the residues of the integrand on the real line through $\mathbf{c}$ in the direction $\boldsymbol{\sigma}$; these are $O\big((1+\tau)^{n'} e^{\tau(h_\Gamma(\boldsymbol{\sigma})+\log r')}\big)$ for every $r' > r = r(\bar{\boldsymbol{\sigma}}; \bar{\mathbf{c}})$, and under the conditions of (ii) on that line infinitely many of them have modulus at least $e^{\tau(h_\Gamma(\boldsymbol{\sigma})+\log r-\epsilon)}$.

Theorem 32.17 (A closing with one free share is read on the law along it)**.** *Take, in Theorem 31.7, the share side of the kind (B), its bundles merged by Corollary 4.4, the bars marking sums over the bundles, and in this statement write*

$$I(\bar{\mathbf{a}}) = \frac{\prod_G \Gamma(\bar{a}_G)}{\prod_j \Gamma(s_j) \prod_j \Gamma(t_j)}\; P_{W_B^{\mathrm{m}}(\bar{\mathbf{a}})}(\mathbf{m}_B),$$

the products over the bundles and over the active letters, with the merged seam function of Lemma 32.8. Let the pins of the merged shares leave a fibre of dimension one, spanned by a rational direction $\bar{\boldsymbol{\sigma}}$, and let $\bar{\mathbf{c}}$ be a real point of the merged pins with positive coordinates at which the merged seam function converges. Let the merged law along $\bar{\boldsymbol{\sigma}}$, the law along $\bar{\boldsymbol{\sigma}}$ of the merged seam function (Definition 32.9), be the image of $\prod_G e^{-\bar{c}_G y_G}\lambda$ under $X = \prod_G e^{-\bar{\sigma}_G y_G}$, λ the source measure, its line function $\ell(\zeta) = P_{W_B^{\mathrm{m}}(\bar{\mathbf{c}}+\zeta\bar{\boldsymbol{\sigma}})}(\mathbf{m}_B)$ and its reach r, the least $x_0 \geq 0$ for which it has on (x_0, ∞) a density that is a wall series of radius x_0 (Definition 32.9, Theorem 32.10(iii)); and in this statement write $h_\Gamma^{\mathrm{m}}(\bar{\boldsymbol{\sigma}}) = \sum_G \bar{\sigma}_G \log|\bar{\sigma}_G|$, the Gamma rate of the merged share side, whose coefficients are inside the merged values.

(i) There is $k_P > 0$, depending only on the pins, with $P_{B\sqcup R}(\mathbf{m}) = \frac{k_P}{2\pi i}\int_{\operatorname{Re}\zeta=0} I(\bar{\mathbf{c}} + \zeta\bar{\boldsymbol{\sigma}})\, d\zeta$, and the crossing term (Lemma 31.3) at a crossing ζ^* of the ray is $-k_P \operatorname{Res}_{\zeta=\zeta^*} I(\bar{\mathbf{c}} + \zeta\bar{\boldsymbol{\sigma}})$: at the crossing $\bar{a}_f = -n$ of the falling share f, at which no other factor of I is polar, it is

$$k_P\, \frac{(-1)^n}{n!\,|\bar{\sigma}_f|}\, \frac{\prod_{G\neq f} \Gamma(\bar{a}_G)}{\prod_j \Gamma(s_j) \prod_j \Gamma(t_j)}\; P_{W_B^{\mathrm{m}}(\bar{\mathbf{a}})}(\mathbf{m}_B)$$

at $\bar{\mathbf{a}} = \bar{\mathbf{c}} + \zeta^*\bar{\boldsymbol{\sigma}}$*, and at a simple pole of the merged seam function at which no Gamma is polar it is* $-k_P \prod_G \Gamma(\bar{a}_G)/\big(\prod_j \Gamma(s_j)\prod_j \Gamma(t_j)\big)$ *there times* $\operatorname{Res}_{\zeta^*} \ell$*.*

(ii) For every $r' > r$ *there are* C *and* n' *such that the crossing terms at their times* τ*, and the integrals left at the times at a fixed distance from the crossings, are at most* $C(1+\tau)^{n'} e^{\tau h^{\mathrm{m}}_\Gamma(\bar{\boldsymbol{\sigma}})} r'^{\tau}$*.*

(iii) Let the ray $\bar{\mathbf{c}} + \tau\bar{\boldsymbol{\sigma}}$*,* $\tau \geq 0$*, cross its polar points simply: no crossing point of a falling merged share, one with* $\bar{\sigma}_G < 0$*, is a pole of the merged seam function or a crossing point of another falling share, and the poles of the merged seam function on the ray are simple. Then for each falling share* f *the crossing terms of* f *and those at the poles of the merged seam function have together the root rate* $e^{h^{\mathrm{m}}_\Gamma(\bar{\boldsymbol{\sigma}})} r$*: the upper limit of* $|\mathcal{R}|^{1/\tau}$ *over them is* $e^{h^{\mathrm{m}}_\Gamma(\bar{\boldsymbol{\sigma}})} r$*. The same holds when the data keep the poles apart only from some point on, as in Theorem 32.16(ii), read on* ℓ *and on the progression of the crossings of* f*, and the poles of* ℓ *crossed by the ray are simple from some point on or the values of* ℓ *on that progression carry the reach; without either proviso, if those poles have order at most* p*, it holds for all but at most* $p-1$ *of the partners obtained by multiplying the coefficients of the shares of each bundle* G *by* $e^{\tau_0 v_G}$*,* $\tau_0 \in \mathbb{R}$*, for a fixed* $\mathbf{v}$ *with* $\sum_G v_G \bar{\sigma}_G = 1$*, whose merged laws are constant multiples of the images of the merged law under* $X \mapsto e^{-\tau_0} X$*, with the root rates* $e^{h^{\mathrm{m}}_\Gamma(\bar{\boldsymbol{\sigma}}) - \tau_0} r$*.*

(iv) So the closing of the merged share side along $\bar{\boldsymbol{\sigma}}$*,* $P_{B \sqcup R}(\mathbf{m}) = \sum \mathcal{R}$ *over the crossings of the ray in their order, converges absolutely when* $e^{h^{\mathrm{m}}_\Gamma(\bar{\boldsymbol{\sigma}})} r < 1$*, and under the conditions of (iii) its terms do not tend to zero when* $e^{h^{\mathrm{m}}_\Gamma(\bar{\boldsymbol{\sigma}})} r > 1$*. No hypothesis on tops or on the phase of the letters enters, only the separations of the poles in (iii): the rate is read on the merged law along the direction. Where* X *is bounded on the support of the law of the piece,* r *is its largest value there, and when moreover the falling shares are alone in their bundles,* $h^{\mathrm{m}}_\Gamma(\bar{\boldsymbol{\sigma}}) + \log r$ *is the averaged rate* $\hat{h}_C$ *of Theorem 31.28; where* X *is unbounded,* $\hat{h}_C$ *is infinite and the averaged terms diverge past the walls, and (iii) carries the sharpness of that theorem past them, with the reach of the merged law in place of the largest value of* X*. When every bundle is a single share,* $\boldsymbol{\sigma} = \bar{\boldsymbol{\sigma}}$*, the merged seam function is the product of* $\boldsymbol{\xi}^{-\mathbf{a}}$ *and of the seam function at the sums over the monomials (Theorem 31.4(i)),* r *is* $e^{-\sum_l \sigma_l \log \xi_l}$ *times the reach of the piece along the sums of* $\boldsymbol{\sigma}$ *(Definition 32.9), and* $e^{h^{\mathrm{m}}_\Gamma(\bar{\boldsymbol{\sigma}})} r = e^{h_0(\boldsymbol{\sigma})}$*,* h_0 *the rate of Theorem 31.4(iii) at* $\theta = 0$*, whose growth* $g(\boldsymbol{\sigma}; 0)$ *is on a fibre of dimension one that reach: on such a fibre the rate of Theorem 31.4(iii) at* $\theta = 0$ *is exact under the conditions of (iii), and (iii) is Theorem 32.16(ii).*

The merged share side and the share side at the stations, before the stations of one excess are merged (Corollary 4.4), are two representations of one period, with two laws along their directions; completing the splits of a bundle can move the edge of the support at which the law stops being its own wall series. The merged law can stop being its own wall series at the image of a nearer edge of the support, where a level set of the merged seam letter ends the expansion of the law at its falling end, while the station closings, with more free shares, can read a farther edge: the merged closing can diverge where the station closing converges.

Corollary 32.18 (A law with log expansions bounds a closing of any fibre dimension)**.** *In Theorem 31.4(iii), with the starting point* $\mathbf{c}$ *off its null set, let the law of the piece have log expansions at the sums* $\bar{\mathbf{c}}$ *of* $\mathbf{c}$ *(Definition 32.13), with the inner bound* X_{in}*. The function* $h_\Gamma(\boldsymbol{\sigma}') + \log X_{\mathrm{in}}(\bar{\boldsymbol{\sigma}}')$ *is convex on the chamber* $C(\boldsymbol{\sigma})$ *of Definition 31.5. If its infimum* h' *on the chamber is negative, the closing along* $\boldsymbol{\sigma}$ *converges absolutely to* $P_{B \sqcup R}(\mathbf{m})$*, its terms and the integrals left after them being* $O(e^{\tau(h'+\epsilon)})$ *for every* $\epsilon > 0$*. The fibre may have any dimension, and no margin of coefficient*

factors and no phase enter: the rate is read on the compact part of the law and on the inner faces of its log expansions. In Theorem 31.4(iv), with $\mathbf{c}$ *off the null set of that part, if the laws of the piece and of the partner have log expansions at* $\mathbf{c}$*, with the inner bounds written* X^B_{in} *and* X^R_{in} *in this sentence, the same holds with* $\sum_l \sigma'_l \log|\sigma'_l| + \log X^B_{\mathrm{in}}(\boldsymbol{\sigma'}) + \log X^R_{\mathrm{in}}(\boldsymbol{\sigma'})$*, convex on the chamber* $C(\boldsymbol{\sigma})$*, in place of* $h_\Gamma(\boldsymbol{\sigma'}) + \log X_{\mathrm{in}}(\bar{\boldsymbol{\sigma}}')$*.*

So the counterparts of the reach theorems of width one hold along every rational direction. The tinkers of Definition 28.18 play two parts: all the tinkers of one partner separate the laws (Theorem 28.19), and the integral over the transverse tinkers of a closing, the partner read in its monomials, reads the reach of the real line (Theorem 32.16(iii)).

For a positive kernel the root rate of a crossing term is the exponential of the least Gamma rate of its chamber in every fibre dimension (Theorem 31.26), and averaging reads the log-support of the source measure (Theorem 31.7); Corollary 32.18 reads, past the walls, the compact part and the inner faces of the log expansions. It is an upper bound: with two or more free shares a crossing term is a fibre integral of positive dimension, whose size the law along one direction does not fix, and the best direction of a chamber can lose against the averaged closing of the same source (Theorem 31.8); the exact rate is then read on a joint word at a noncancelling simple top (Theorem 31.21). One partner does not read the real line: it averages over its transverse fibre, and its terms can fall below the rate of every real line of its chamber, the integral of the terms over the transverse tinkers then being carried by the other tinkered partners. Whatever the closing, the reach along the direction of the closing is at least the least value of the directional ratio on the support of the law, and at least every point near which the directional law, or after merging the merged law, has no real-analytic density (Theorem 32.10(iii)).

32.3 What the calculus of bunches settles

Remark 32.19 (What the calculus of bunches settles, and what it leaves open)*.* A closing of the glue along a direction of its share fibre is exact at every step and depends only on its chamber (Lemma 31.3, Theorem 31.6); Theorems 31.2, 31.4 and 31.11 give sufficient conditions for it, and the closings can be averaged over the source (Theorem 31.7). The cases that these conditions leave are settled as follows.

(i) *Crossing terms of positive dimension.* Along a rational ray, at simple nonresonant crossings and after a finite head, a crossing term kept with its falling shares integrated on their strips is, along its cohort, a scalar G_n times a finite sum $\sum_i \big(\mathsf{T}_{-n;(1)}[c_i]\,\phi_i\big)(Y_i)$ of joint Trailmoments of fixed functions on fixed compact domains, the joint word (Theorem 31.18): a falling Gamma becomes a positive share and one Beta variable (Lemma 31.14), a continued source strip a segment and circle integrals (Lemma 31.15), and nothing is extracted from the term. For a positive kernel its rate is the least Gamma rate of the chamber, in every fibre dimension and with no hypothesis on the tops (Theorem 31.26); averaged over a positive source it is the averaged rate $\hat{h}_C$ (Corollary 31.27), so a nonzero averaged rate decides by its sign whether the averaged terms tend to zero, with no condition on the bundles or the dimension (Theorem 31.28), and at $\hat{h}_C = 0$ Theorem 31.32 decides. The joint word has the root rate $r_G c_{\max}$ at noncancelling simple tops, r_G the root rate of the scalar and $c_{\max}$ the ceiling of the word (Theorem 31.21). Coincident crossings are packets of factors polar on one crossed hyperplane, assembled before a sign or a top is read (Theorem 31.30, Proposition 31.31); at the root rate one a positive moment sequence is decided by its law near the top (Theorem 31.32), and an expansion by its coefficients (Proposition 31.33).

(ii) *The phase.* A joint word is bounded by $|G_n| \sum_i \|\phi_i\| \, c_{\max}^n$ (Corollary 31.19): the fibre is completed before a modulus is taken, and the phase of the letters enters the coefficient functions, where it can cancel, and costs no term of the bound. It confines the radii of the procedure to the margins of the coefficient factors (Theorem 31.18, Remark 31.22). Read on the law, the phase costs nothing where the law has log expansions: in its log-ratio coordinates the shares pair with the law linearly, and the compact part and the inner faces of its log expansions bound the continued seam function on whole contours (Proposition 32.14). Where the tangential coordinates move with the normal coordinates at a falling end, the phase enters the coefficients of the expansion there, and a tube can reach infinitely far while each of its lines has a finite reach.

(iii) *Regions of equality and bounds at any width.* The regions on which a law equals its expansion at a falling end are certified from the sector letters, with the map from the motion of the shares to the exponents, the coefficients, the truncation bounds and exact boundary words (Theorems 32.2 and 32.4); the domain where a series converges and the region where it equals the law are kept apart (Proposition 32.6), and density charts are built at regular fibres (Proposition 32.5). The terms of a closing have at most the root rate $r_G c_{\max}$ of every joint word whose radii keep within the holomorphy of its source and the margins of its coefficient factors, $c_{\max}$ the ceiling of the word, and have that root rate when the word has a noncancelling simple top.

(iv) *The reach at any width.* Along every rational direction of the shares the reach is read on the law: it is the far boundary of the region on which the directional law, the law multiplied by $\mathbf{x}^{-\mathbf{w}_0}$ for the starting point $\mathbf{w}_0$ and read through the directional ratio, is its own wall series, whose exponents lie among the values $(\kappa_U(\mathbf{w}_0) + n)/(-\dot{\kappa}_U)$ of the walls divided by their falling rates, and it is at least every point at which that law is not analytic, the least value of the directional ratio among them (Theorem 32.10). The walls and the growth bounds that this uses hold for every seam function of a piece that converges at a real point and for its seam letters merged by bundles (Lemma 32.8), and at width one the same argument reads the growth of a family on its law, that of the bunch being its reach (Corollary 32.11). For a piece the reach is at most the ceiling of every keyhole continuation along the direction, with no phase, equal to it at simple tops that do not cancel when a keyhole continuation has the same ceiling, and bounded by fibres where letters vanish inside the keyholes, the direction scaled to integers (Theorem 32.15). A closing past the walls converges when the exponential of the Gamma rate times the reach of its tube is less than one, its terms then having at most that root rate (Theorem 32.16(i)); an expansion at the face over the real fibres bounds the reach of the tube along one direction and log expansions in every direction, with no allowance for the phase (Corollary 32.12, Proposition 32.14), and otherwise the tube can reach farther than every one of its lines; a law with log expansions bounds a closing of any fibre dimension by the rate read on the compact part and the inner faces of its log expansions (Corollary 32.18). With one free share, as at a node of width one, the tube is the line, and the terms attain the rate that the reach along the direction gives when the poles of the line and of the Gammas keep apart and the poles of the line are eventually simple or its values on a progression of crossings carry the reach (Theorem 32.16); the closing of a share side merged by its bundles to one free share, a series other than the station closings, has under the same conditions the root rate of Theorem 32.17(iii), read on the merged law along its direction, its terms not tending to zero beyond it, which carries the sharpness of Theorem 31.28 past the walls (Theorem 32.17). In every number of free shares the terms integrated over the tinkers of the partner transverse to the direction are the residues of the

real line, which attain its rate under the same conditions (Theorem 32.16), while the terms of one partner average over its transverse fibre and can fall below every real line of its chamber.

(v) *A gap at a family of tables.* A family of three tables whose seam has single stations has a chamber in which no direction certifies the closing while the averaged closing converges geometrically (Theorem 31.8); the gap is relative to the closings of one share side by the directions of its chamber (Remark 31.9).

At width one the reach is read on the law, as the point beyond which the law is its own wall series, and it is the ceiling of a keyhole continuation whose tops are simple and do not cancel (Theorems 20.44 and 20.51). At any width the first holds along every rational direction (Theorem 32.10), and the second along every rational direction for every piece, under the conditions of Theorem 32.15(ii) and (iii), and for joint words (Theorem 31.21). What a node of width one does not have is a transverse fibre. With two or more free shares the crossing terms of one partner integrate over the transverse fibre the imaginary translates of the line through its starting point. Theorem 32.16(i) bounds them by the reach of the tube when the exponential of the Gamma rate times that reach is less than one; a law with log expansions bounds the tube by the directional ratio on the compact part and the inner faces of its log expansions, and a closing of any fibre dimension with nothing paid for the phase (Corollary 32.18), while without log expansions the reach of the tube can be infinite though every line of the tube has a finite reach, and the bound that travels pays for the phase at a positive θ (Theorem 31.4(iii)). Theorem 32.16(iii) gives the integral of the terms over the transverse tinkers the rate of the real line, under the conditions of its part (ii) on that line; Theorem 31.21 gives the rate of one partner at the noncancelling simple tops of its joint words. The real line does not give the rate of one partner, whose terms can fall below every real line of its chamber, and the best direction of a chamber can lose against averaging (Theorem 31.8). Before the walls, under the hypotheses of Theorem 31.28, the rate of one partner is averaged over the source, and past them the closing of a share side merged by its bundles to one free share has, under the conditions of Theorem 32.17(iii), the rate read on the merged law along its direction. Two problems are open. The first is the rate past the walls of one partner whose joint words have no noncancelling simple top: at two or more free shares, where it asks for an averaged closing of the continued law, and at one free share when the data do not keep the poles apart or no proviso of Theorems 32.16(ii) and 32.17(iii) holds for that partner. The second is to read the growth $g(\boldsymbol{\sigma};\theta)$ on the law, as Theorem 32.10 reads the reach of a line. At $\theta = 0$ the reach of the line bounds it below and log expansions bound it above by their inner bound (Corollary 32.12, Proposition 32.14), and the two meet when, for every $\epsilon > 0$, the law has log expansions whose compact part and inner faces lie where the directional ratio is at most the reach plus ϵ; in general, and without log expansions, where it can be infinite at $\theta = 0$, it is known only through these bounds and those of Theorems 31.4(iii) and 31.11 and of Corollary 31.19, within the margins of the coefficient factors (Theorem 31.18). Degenerate and cancelling tops are open at width one as well.

Chapter 33

Price and complexity

A construction is a description of a family, and the exact theorems of Part V turn it into a description of the period; both have a price. The price of a construction is the length of its description, a repeated subtree described once and its multiplicity written in binary; the work of a word is the dimension of the integrals it asks for, an integral that recurs counted once. Repetition then costs what it should: M copies of a cell glued along a tree at a full lean, or closed in series at any exponents, or chained, have periods whose words cost the word of the cell and the binary length of M, and a departure from the repetition costs the cells that depart. The laws of cells (Chapter 23), the networks of holds (Chapters 25 and 26) and the finite interfaces (Chapter 27) are priced the same way: a law is computed once for each distinct subtree, a node of a network costs its periods at the two full leans whatever the number of bases of the whole table, and a polynomial Gamma moment of a repetition is the power of one finite matrix. What a value can contain is bounded the same way along a ray (Theorem 38.31).

33.1 Constructions and their price

Definition 33.1 (Construction)**.** A *construction* $\mathfrak{C}$ is a finite rooted tree with a family at each leaf, its marks, bases, weights, masses and exponents given, and at each inner node one of the operations: the direct sum of its subtrees; the substitution of its subtrees, each with a named hinge, into the marks of a core family named at the node, a mark left without a subtree being left in place (Definition 21.1); and the *powers* of a subtree $\mathfrak{C}_1$ with an integer M: $\mathfrak{C}_1^{\oplus M}$, M copies in direct sum; $\circ(\mathfrak{C}_1^{M})$, the series closure of M copies of the cell $\mathfrak{C}_1$ (Corollary 21.7(ii)); and $\mathfrak{C}_1^{\triangleright M}$, the chain of M copies glued along two named marks (Theorem 22.8). A subtree may be given by a reference to one already described. A construction builds one family, by Proposition 21.3 at each substitution.

Definition 33.2 (Price; work)**.** The *price* $\mathrm{price}(\mathfrak{C})$ of a construction is the number of bits of its description as written: for every leaf its marks, bases, weights, masses and exponents, the numbers written as rationals in binary; for every node its operation, its core and its attachments; for every power the $\lceil \log_2(M+1) \rceil$ bits of M; a subtree may be written once and referred to by an index wherever it recurs. The price of a word (Definition 1.1(vi)) is defined in the same way, and its *work* $\mathrm{work}(w)$ is the sum of the dimensions of its distinct integrals, an integral that recurs, under a power or an iterate in particular, counted once. The integration count of Definition 20.58 counts every occurrence: the work of w^M is that of w, and its integration count is M times that of w.

The work counts the distinct integrals a word is written with, and the price the length of what

has to be written down; neither counts the digits of an evaluated value, nor the cost of evaluating: a scalar power costs one exponentiation, a power of a $k \times k$ matrix costs $O(k^3 \log M)$ operations by repeated squaring, and an iterate $\mathcal{Q}^M$ of an operator costs M applications of $\mathcal{Q}$, nested integrals of M times its dimension, or $O(\log M)$ matrix products when $\mathcal{Q}$ leaves a finite-dimensional space of functions invariant. Every polynomial Gamma moment of degree D of a repetition (Chapter 27) is such a matrix power, a fixed row times a power of the transfer matrix $\mathbf{T}_D$ applied to the moment vector of the start (Theorem 27.5), and the period itself is reached through such moments with the certified stopping rule of Theorem 27.7, at a degree that depends on the accuracy asked.

Theorem 33.3 (Pricing by repetition)**.** *Let $\mathcal{A}$ be a family, a cell where a hinge is needed, described by a construction of price* $\mathrm{price}(\mathcal{A})$*, with the period $P_{\mathcal{A}}$ at its data, and let $M \geq 1$.*

(i) Direct sum. *The molecules of $\mathcal{A}^{\oplus M}$, $\mathcal{A}$ connected, are its M copies, and the product of their periods is $P_{\mathcal{A}}^{M}$ (Proposition 7.9; the period of the direct sum itself diverges on the balance wall, Proposition 8.16): price at most* $\mathrm{price}(P_{\mathcal{A}}) + \lceil \log_2(M+1) \rceil + O(1)$*, work that of $P_{\mathcal{A}}$.*

(ii) A tree of copies at a full lean. *For a table $\mathcal{A}$ at the exponents $(0,t)$, M copies glued along any tree at the masses $(\kappa, t-\kappa)$ on the two marks of every gluing have the word* $\Gamma_{1}^{2}\!\begin{bmatrix}\kappa, & t-\kappa \\ & t\end{bmatrix} \big(P_{\mathcal{A}}(\mathbf{m};0,t)/\Gamma_{1}^{2}\!\begin{bmatrix}\kappa, & t-\kappa \\ & t\end{bmatrix}\big)^{M}$ *(Corollary 26.11): price at most* $\mathrm{price}(P_{\mathcal{A}}) + \lceil \log_2(M+1) \rceil + O(1)$*, work that of $P_{\mathcal{A}}$, whatever the shape of the tree.*

(iii) A series closure. *The series closure of n_k copies of cells $\mathcal{A}_k$, $k \leq d$, at positive exponents of N tables on the balance wall has the word of Theorem 23.3,* $\prod_j (\Gamma(s_j)\Gamma(t_j))^{-1} \int \prod_j x_j^{s_j-1} \prod_{j \geq 2} y_j^{t_j-1} \prod_k \mathfrak{L}_k(x,y)^{n_k}\, dx\, dy$ *with the responses $\mathfrak{L}_k$ of the cells: price $O\big(\sum_k \mathrm{price}(\mathcal{A}_k)\big) + \sum_k \lceil \log_2(n_k+1) \rceil + O(N)$, the letters of a constructed cell being written through Theorem 21.4, and work at most $\sum_k |B_k| + 2N - 1$, B_k the marks of $\mathcal{A}_k$ besides its hinge, independent of the multiplicities and of the order of the cells.*

(iv) A chain. *$\mathcal{A}^{\triangleright M}$ has the word $(\mathcal{Q}^M P_0)(\mathbf{1})$ of Theorem 22.8, with the operator $\mathcal{Q}$ and the function P_0 of that theorem: price at most* $\mathrm{price}(\mathcal{A}) + \lceil \log_2(M+1) \rceil + O(1)$*, work at most $|\mathcal{E}_{\mathcal{A}}| - 1$; evaluated, the iterate unrolls to nested integrals of total dimension $M(|\mathcal{E}_{\mathcal{A}}| - 2) + 1$, that of the expanded period, unless $\mathcal{Q}$ leaves a finite-dimensional space of functions invariant; where the twist is pinned the word is* $P_{\mathcal{A}}^{M} / \Gamma_{1}^{2}\!\begin{bmatrix} m_{g_{\mathrm{in}}}, & m_{g_{\mathrm{out}}} \\ m_{g_{\mathrm{in}}} + m_{g_{\mathrm{out}}} & \end{bmatrix}^{M-1}$*, $m_{g_{\mathrm{in}}}, m_{g_{\mathrm{out}}}$ the masses of the two named marks $g_{\mathrm{in}}, g_{\mathrm{out}}$, of work $|\mathcal{E}_{\mathcal{A}}| - 1$ evaluated as well.*

(v) Integer joint moments *of a repeated transfer matrix, with Gamma laws on the marks or Dirichlet laws on the steps, have as word a fixed row times the power $\mathbf{A}^M$ of the one matrix of Theorem 22.10 times a fixed column, with rational entries at rational masses (Theorem 22.10): price at most that of the matrices of the cell plus $\lceil \log_2(M+1) \rceil + O(1)$, work zero.*

(vi) Blocks *read through their totals cost one stacked Gamma each,* $\Gamma_{1}^{|B_i|}\!\begin{bmatrix}\mathbf{m}|_{B_i} \\ m_{B_i}\end{bmatrix}$ *at the block B_i (Theorem 26.12): the work of the period of the family with blocks is that of the period of its core family, whatever the lengths of the blocks.*

(vii) A series repetition. *M copies of a series-balanced cell $\mathcal{A}$ at a series node against a cell $\mathcal{A}'$, at the exponents (s,t), have the word* $(\Gamma(s)\Gamma(t))^{-1} \int_0^\infty y^{t-1} f_{\mathcal{A}}(y)^M f_{\mathcal{A}'}(y)\, dy$*, with the transforms $f_{\mathcal{A}}, f_{\mathcal{A}'}$ of Theorem 24.2: price at most* $\mathrm{price}(\mathcal{A}) + \mathrm{price}(\mathcal{A}') + \lceil \log_2(M+1) \rceil + O(1)$*, work $|B| + |R| - 1$ for the marks B of $\mathcal{A}$ and R of $\mathcal{A}'$ besides the hinge, whatever M; at a*

series or parallel node of a hinge tree the multiplicities of equal subtrees enter as exponents (Proposition 23.18).

(viii) Series-parallel tables. *A table with a hinge tree of series and parallel nodes over marks has periods at the full leans that are stacked Gammas times monomials in the weights of its nodes, with one Gamma for each mark and two for each change of kind along an edge, and every period, at every lean and every twist, a fibre integral of dimension $n-1$ of an explicit stacked Gamma times an exponential of the loads, and a family of N such tables one of dimension $(2N-1)(n-1)$ (Corollaries 26.10 and 26.14): price linear in the size of the tree, work at most $n-1$, less one for each pooled pair (Proposition 26.15), and at most $(2N-1)(n-1)$ for the family, whatever the numbers of bases, which can be exponential in n.*

(ix) Polynomial Gamma moments of a repetition *have as word a fixed row times a power of the transfer matrix $\mathbf{T}_D$ applied to a fixed vector, with rational entries at rational data (Theorem 27.5): price that of the matrix of the chain cell plus $\lceil \log_2(M+1) \rceil + O(1)$, work zero.*

In the cases with a multiplicity M the expanded family has of the order of M times as many marks, and its period written as one integral over its simplex has the work of one less than its number of marks.

Theorem 33.4 (Repeated subtrees and departures)**.** *(i) In a construction, replacing identical subtrees, with matching hinges and data, by one subtree and references leaves the family built, the period and every exact word of Part V unchanged, and lowers the price by the price of the copies removed, less that of the references.*

(ii) In (ii), (iii) and (iv) of Theorem 33.3, replacing q of the M copies by cells $\mathcal{A}'_1, \dots, \mathcal{A}'_q$ changes the word to $\Gamma_1^2 \begin{bmatrix} \kappa, & t-\kappa \\ & t \end{bmatrix} \left(P_{\mathcal{A}} / \Gamma_1^2 \begin{bmatrix} \kappa, & t-\kappa \\ & t \end{bmatrix} \right)^{M-q} \prod_i \left(P_{\mathcal{A}'_i} / \Gamma_1^2 \begin{bmatrix} \kappa_i, & t-\kappa_i \\ & t \end{bmatrix} \right)$ at a full lean, to the product of $\mathfrak{L}_{\mathcal{A}}^{M-q}$ and of the responses of the new cells in a series closure, and to the composite of $\mathcal{Q}^{M-q}$ with the q operators of the new cells in a chain: the price grows by $\sum_i \operatorname{price}(\mathcal{A}'_i) + O(q \log M)$ and the work by at most the dimensions of the integrals of the new cells. A change of q leaves in a tree with at most h nodes on every path from its root to a leaf touches at most qh of its nodes.

Repetition is thus priced at the binary length of its count, as 2^M is written with M rather than with its digits, and the work follows the distinct subtrees. The construction is the certificate of the compression: a family given expanded, without its construction, can still be read for its bunches of width one, its prime nodes (Theorem 23.16) and its twins (Theorem 14.22), but finding its cheapest construction is a search. The prime nodes of the canonical hinge tree of a list are invariants of the list (Theorem 23.16); at a full lean its period is a product of stacked Gammas and the periods at the full leans of those nodes (Corollary 26.11, Theorem 26.5), and at every lean a fibre integral of their periods at the full leans, of dimension $n-1$ (Theorem 26.13); a prime node $\mathcal{H}_v$ on n_v marks with $|\mathcal{H}_v|$ bases has periods at the full leans of dimension $|\mathcal{H}_v| - n_v > 0$ on their share sides (Corollary 26.8). Symmetry is a second source of cheapness, distinct from repetition: a table assembled from a seed by a set of bijections (Proposition 11.6) is described by the seed and the bijections, and the table that is one circuit on n marks, prime for no n, is a series closure of single marks whose period is one integral over one scale of a product of n Grammas (Corollary 18.24), of work one whatever n; the list $\binom{\mathcal{E}}{r}$ with $2 \le r \le |\mathcal{E}| - 2$ is prime and cheap to describe, and its period at each full lean is one fibre integral of dimension $\binom{|\mathcal{E}|}{r} - |\mathcal{E}|$ on its share side (Corollary 26.8).

Part VI

The arithmetic of the output

Chapter 34

The motive of a family and the coaction along a tree

A family of lists at integer data whose proper walls are all at least one has as its period the period of a mixed motive: the relative cohomology of the toric variety of the braid fan, less the closures of the zero loci of its letters and of the linear letters, relative to its toric boundary. The walls are the orders of the form along the boundary divisors, and every boundary stratum is the product of the models of the steps of its flag. Brown's coaction acts on the motivic period, and birational changes of variables, Cremona among them, are identities of motivic periods. Along any tree of bunches the left factors of the coaction of weight at most k are sums of products of open periods of steps of at most $k+1$ marks; each step is attached to one vertex of the tree, its letters are letters of children of the tables there, and its open periods are rational combinations of constant terms of continued periods of families of lists on the step, hence of convergent periods of such families and of their derivatives in the masses. At a node of width c the bunch and its room meet only through the Skeleton values of the letters, at most c for each letter: every open period of a node step is a shape integral of rational functions against finite parts of scale integrals, constant terms of stacked Gammas times Bretas of one bunch at the joint spectrum, and at the root so is every left factor; at width one each Skeleton value is a quotient of hinge values and the share side separates the bunch from the room. Cells read through one hinge value split off as identities of motivic periods, whatever the widths of the bunches of the core; so do the cells of dual pairs at every pair of exponents, and at a full lean the motivic period of a list is a rational multiple of the product of those of its prime nodes. A pinned set of at least two marks at which every active table has width one splits off motivically.

34.1 The model

The motive of a family lives on the toric variety of the braid fan. Its charts are the sector cubes of Theorem 8.5(ii), and its boundary strata are indexed by chains of sets of marks.

Definition 34.1 (The model of a family)**.** Let $F = ((\mathcal{B}_j; s_j, t_j))_{j=1}^{N}$ be a family of lists on $\mathcal{E}$, $n = |\mathcal{E}| \geq 2$ (Definition 8.1), with integer exponents and integer masses $\mathbf{m}$ on its balance wall; it is *convergent* when $\kappa_S \geq 1$ for every $\varnothing \neq S \subsetneq \mathcal{E}$. Its *letters* are $\mathrm{Let}(F) = \{K_j : \ s_j \neq 0\} \cup \{\Psi_j : t_j \neq 0\}$; the *linear letters* are the $\alpha_J = \sum_{e \in J} \alpha_e$, $J \subseteq \mathcal{E}$, the basis polynomials of the lists $\binom{J}{1}$; and the *augmented letters* are $\mathrm{Let}^{+}(F) = \mathrm{Let}(F) \cup \{\alpha_J : \ J \subseteq \mathcal{E}, \ |J| \geq 2\}$. For an order $e_1, \ldots, e_n$ of

$\mathcal{E}$ put

$$\Omega_{\mathcal{E}} = \sum_{i=1}^{n} (-1)^{i-1} \alpha_{e_i}\, d\alpha_{e_1} \wedge \cdots \wedge \widehat{d\alpha_{e_i}} \wedge \cdots \wedge d\alpha_{e_n},$$

which another order changes by its sign; the *form* of F is

$$\omega_F = \alpha^{\mathbf{m}} \prod_j K_j^{-s_j} \Psi_j^{-t_j}\, \frac{\Omega_{\mathcal{E}}}{\alpha^{\mathcal{E}}},$$

a rational form of degree $n-1$ on $\mathbb{P}(\mathbb{Q}^{\mathcal{E}})$. Let $X_{\mathcal{E}}$ be the toric variety over $\mathbb{Q}$ of the *braid fan* in $\mathbb{R}^{\mathcal{E}}/\mathbb{R}\mathbf{1}$, whose rays are the images ρ_S of the $\mathbf{1}_S$, $\varnothing \neq S \subsetneq \mathcal{E}$, and whose cones are spanned by the rays of the chains $S_1 \subsetneq \cdots \subsetneq S_\ell$; D_S is the divisor of ρ_S, $D = \bigcup_S D_S$ the *boundary*, and the *positive cell* $\widetilde{\sigma}_{\mathcal{E}}$ is the closure in $X_{\mathcal{E}}(\mathbb{R})$ of the set $\widetilde{\sigma}^\circ_{\mathcal{E}}$ of the points of the torus with every $\alpha_e > 0$. An order $e_1, \dots, e_n$ of $\mathcal{E}$ gives the *chart* $U \cong \mathbb{A}^{n-1}$ of the cone of the chain $S_i = \{e_1, \dots, e_i\}$, $i < n$, with the coordinates $\varepsilon_i = \alpha_{e_i}/\alpha_{e_{i+1}}$, so that $\alpha_{e_j}/\alpha_{e_n} = \prod_{i \geq j} \varepsilon_i$. For a polynomial f on $\mathcal{E}$, $\widetilde{Y}_f$ is the closure in $X_{\mathcal{E}}$ of its zero locus in the torus. The *model* of F is the pair

$$V_F = X_{\mathcal{E}} \setminus \bigcup_{f \in \mathrm{Let}^+(F)} \widetilde{Y}_f, \qquad D_F = D \cap V_F,$$

with the relative cohomology $H_F = H^{n-1}(V_F, D_F)$.

Definition 34.2 (Flags and steps)**.** A *flag* of $\mathcal{E}$ is a chain $\mathfrak{f}: \varnothing = S_0 \subsetneq S_1 \subsetneq \cdots \subsetneq S_\ell \subsetneq S_{\ell+1} = \mathcal{E}$, $\ell \geq 0$. Its *steps* are the sets $Z_i = S_i \setminus S_{i-1}$, $1 \leq i \leq \ell+1$, as in Theorem 22.9, and its *dimension* is $\sum_i (|Z_i| - 1) = n - 1 - \ell$. In the model of a family F (Definition 34.1) its *stratum* is $D_{\mathfrak{f}} = D_{S_1} \cap \cdots \cap D_{S_\ell} \cap V_F$, the model V_F itself at $\ell = 0$. The *letters of the step* $(Z_i; \mathfrak{f})$ are the step letters at Z_i (Proposition 12.20) of the augmented letters of F that are not monomials: K of the step list of $\mathcal{B}_j$ at Z_i at the bottom of the chain for every $K_j \in \mathrm{Let}(F)$, Ψ of its step list at the top for every $\Psi_j \in \mathrm{Let}(F)$, and the α_J with $J \subseteq Z_i$, $|J| \geq 2$; for $\ell = 0$ the step lists at the one step $\mathcal{E}$ are the lists of F themselves. They form a set $\mathrm{Let}(Z_i; \mathfrak{f})$ of polynomials on Z_i, which depends on S_{i-1} and S_i alone. The *model of the step* is

$$V_{Z_i;\mathfrak{f}} = X_{Z_i} \setminus \bigcup_{g \in \mathrm{Let}(Z_i;\mathfrak{f})} \widetilde{Y}_g,$$

a point when $|Z_i| = 1$, with its toric boundary $\partial V_{Z_i;\mathfrak{f}}$.

Lemma 34.3 (Charts, strata and the letters in a chart)**.** *In Definition 34.1:*

(i) $X_{\mathcal{E}}$ is smooth and projective of dimension $n-1$, and the charts of the orders cover it. In the chart of the order $e_1, \dots, e_n$, $D_{S_i} \cap U = \{\varepsilon_i = 0\}$ for $i < n$ and $D_S \cap U = \varnothing$ for every other S; D is a divisor with simple normal crossings and smooth components, and $D_{S_1} \cap \cdots \cap D_{S_\ell}$ is not empty exactly when the S_i form a chain. In the chart $\widetilde{\sigma}_{\mathcal{E}} \cap U = [0, \infty)^{n-1}$, and the closure of the set of the points of $\widetilde{\sigma}^\circ_{\mathcal{E}}$ with $\alpha_{e_1} < \cdots < \alpha_{e_n}$, the sector *of the order, is the cube $[0,1]^{n-1}$; the sectors of the orders cover $\widetilde{\sigma}_{\mathcal{E}}$, two of them meeting in a set of measure zero.*

(ii) Let f be a letter K or Ψ of a list $\mathcal{B}$ on $\mathcal{E}$, or a linear letter α_J, of the degree δ, with the floor *$d_f(S)$: $d(S)$ for K, $d^*(S)$ for Ψ (Theorem 7.13), and 1 or 0 for α_J as $J \subseteq S$ or not. In the chart of an order,*

$$f(\alpha)/\alpha_{e_n}^{\delta} = \prod_{i<n} \varepsilon_i^{d_f(S_i)}\, \widetilde{f}(\varepsilon),$$

with $\widetilde{f}$ a polynomial with nonnegative integer coefficients and constant term 1, the sector letter of Theorem 8.5(ii); so $\widetilde{f} \geq 1$ where $\varepsilon \geq 0$. For $I \subseteq \{1, \dots, n-1\}$, the restriction of $\widetilde{f}$ to $\{\varepsilon_i = 0 : \ i \in I\}$ is the product, over the steps Z of the chain $(S_i)_{i \in I}$, of the polynomials that this rule attaches to the step letters of f at Z (Proposition 12.20) in the chart of X_Z of the order induced on Z, whose coordinates are the ε_k with $e_k, e_{k+1} \in Z$. Moreover $\widetilde{Y}_f \cap U = \{\widetilde{f} = 0\}$.

(iii) In the chart, with the walls κ_S of F,

$$\omega_F = \pm \prod_{i<n} \varepsilon_i^{\kappa_{S_i}-1} \prod_j \widetilde{K}_j^{-s_j} \widetilde{\Psi}_j^{-t_j} \, d\varepsilon_1 \wedge \cdots \wedge d\varepsilon_{n-1}.$$

Proposition 34.4 (The model)**.** *Let F be a family as in Definition 34.1.*

(i) $\widetilde{\sigma}_{\mathcal{E}}$ is compact, $\widetilde{\sigma}_{\mathcal{E}} \setminus \widetilde{\sigma}_{\mathcal{E}}^{\circ} \subseteq D$, and $\widetilde{\sigma}_{\mathcal{E}}$ misses $\widetilde{Y}_f$ for every letter f of a list on $\mathcal{E}$ and every linear letter; so $\widetilde{\sigma}_{\mathcal{E}} \subseteq V_F(\mathbb{R})$.

(ii) ω_F has the order $\kappa_S - 1$ along D_S for every $\varnothing \neq S \subsetneq \mathcal{E}$ and neither zeros nor poles on the points of the torus in V_F. So ω_F is a regular form on V_F exactly when F is convergent, and then its integral over $\widetilde{\sigma}_{\mathcal{E}}$, oriented so that it is positive, converges and is the period $P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$ (Theorem 8.7).

(iii) V_F is a smooth affine variety, D_F is a divisor in it with simple normal crossings and smooth components, and every stratum is smooth and affine. More generally $X_{\mathcal{E}} \setminus \bigcup_{g \in \mathcal{G}} \widetilde{Y}_g$ is affine for every finite set $\mathcal{G}$ of polynomials on $\mathcal{E}$ that contains the linear letters α_J, $|J| \geq 2$.

(iv) The stratum of a flag $\mathfrak{f}$ with the steps $Z_1, \dots, Z_{\ell+1}$ is isomorphic to $\prod_i V_{Z_i;\mathfrak{f}}$ (Definition 34.2), compatibly with the boundaries, and $\widetilde{\sigma}_{\mathcal{E}}$ meets it in $\prod_i \widetilde{\sigma}_{Z_i}$.

(v) For the tables of F and complex masses and exponents on the balance wall, wherever every proper wall has positive real part,

$$P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \sum_{\pi} \operatorname{cube}\big(\boldsymbol{\kappa}_\pi(\mathbf{m}); h_\pi\big), \qquad \boldsymbol{\kappa}_\pi(\mathbf{m}) = \big(\kappa_{S_i^\pi}(\mathbf{m})\big)_{i<n}, \quad h_\pi = \prod_j \widetilde{K}_j^{-s_j} \widetilde{\Psi}_j^{-t_j},$$

the sum over the orders π of $\mathcal{E}$, with the chains S_i^π and the sector letters of their charts, and cube *the cube integral of Lemma 8.4. The right side continues meromorphically along the balance wall, jointly in the exponents, with poles only on the hyperplanes $\kappa_S = -j$, $\varnothing \neq S \subsetneq \mathcal{E}$, $j \in \mathbb{N}$: it is the* continued period *of Theorems 8.5(iii) and 8.7.*

The walls are thus the orders of the form along the boundary, and convergence is regularity. The linear letters are removed so that the model is affine; they are the letters of the lists $\binom{J}{1}$, and the motivic period does not see them (Lemma 34.7).

34.2 Motivic periods

Definition 34.5 (Motivic periods; Galois conjugates; open spaces)**.** An object M of Brown's category of realizations over $\mathbb{Q}$ (F. Brown, *Notes on motivic periods*, Commun. Number Theory Phys. 11 (2017), 557–655, §3.1) has a Betti realization M_{B} and a de Rham realization M_{dR}; its *motivic periods* $[M, \gamma, \omega]^{\mathrm{mot}}$, $\gamma \in M_{\mathrm{B}}^\vee$ and $\omega \in M_{\mathrm{dR}}$, span the ring $\mathcal{P}^{\mathrm{mot}}$, bilinear in (γ, ω),

with $[M,\phi^{\mathrm{t}}\gamma',\omega]^{\mathrm{mot}} = [M',\gamma',\phi(\omega)]^{\mathrm{mot}}$ for every morphism $\phi : M \to M'$; its de Rham periods $[M,f,\omega]^{\mathrm{dR}}$, $f \in M_{\mathrm{dR}}^{\vee}$, span the ring $\mathcal{P}^{\mathrm{dR}}$; and the *coaction* $\Delta : \mathcal{P}^{\mathrm{mot}} \to \mathcal{P}^{\mathrm{mot}} \otimes \mathcal{P}^{\mathrm{dR}}$ is

$$\Delta[M,\gamma,\omega]^{\mathrm{mot}} = \sum_i [M,\gamma,e_i]^{\mathrm{mot}} \otimes [M,e_i^{\vee},\omega]^{\mathrm{dR}}$$

for a basis (e_i) of M_{dR} with the dual basis $(e_i^{\vee})$; the $[M,\gamma,e_i]^{\mathrm{mot}}$ are its *left factors*. For $\xi \in \mathcal{P}^{\mathrm{mot}}$ the space of its *Galois conjugates* is

$$\mathrm{C}(\xi) = \big\{(\mathrm{id}\otimes\varphi)\Delta\xi : \ \varphi \in \mathrm{Hom}_{\mathbb{Q}}(\mathcal{P}^{\mathrm{dR}},\mathbb{Q})\big\};$$

for an object M and $\gamma \in M_{\mathrm{B}}^{\vee}$, $L(M,\gamma) = \{[M,\gamma,\omega]^{\mathrm{mot}} : \ \omega \in M_{\mathrm{dR}}\}$; and $\mathcal{A}\cdot\mathcal{A}'$ is the span of the products of the elements of two subspaces. For a convergent family F (Definition 34.1) the *motivic period* is

$$P_F^{\mathrm{mot}} = [H_F, \widetilde{\sigma}_{\mathcal{E}}, \omega_F]^{\mathrm{mot}},$$

the positive cell, oriented so that $\Omega_{\mathcal{E}}/\alpha^{\mathcal{E}}$ is positive on $\widetilde{\sigma}_{\mathcal{E}}^{\circ}$, read as a class of relative homology, and the form as a class of relative de Rham cohomology; its period is $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ (Proposition 34.4(ii)). For a step $(Z;\mathfrak{f})$ of a flag of $\mathcal{E}$ (Definition 34.2) with $|Z| \geq 2$, its *open space* is the set of motivic periods

$$\mathrm{Open}(Z;\mathfrak{f}) = \Big\{ \big[H^{|Z|-1}(V_{Z;\mathfrak{f}}, \partial V_{Z;\mathfrak{f}}), \widetilde{\sigma}_Z, \eta\big]^{\mathrm{mot}} : \ \eta \text{ a regular form of degree } |Z|-1 \text{ on } V_{Z;\mathfrak{f}} \Big\},$$

$\widetilde{\sigma}_Z$ oriented as $\widetilde{\sigma}_{\mathcal{E}}$ is, and $\mathrm{Open}(Z;\mathfrak{f}) = \mathbb{Q}$ when $|Z| = 1$.

Lemma 34.6 (Galois conjugates)**.** *For $\xi,\xi' \in \mathcal{P}^{\mathrm{mot}}$, an object M and $\gamma \in M_{\mathrm{B}}^{\vee}$:*

(i) $\xi \in \mathrm{C}(\xi)$*;*

(ii) $\mathrm{C}([M,\gamma,\omega]^{\mathrm{mot}}) \subseteq L(M,\gamma)$*, and* $\Delta L(M,\gamma) \subseteq L(M,\gamma)\otimes\mathcal{P}^{\mathrm{dR}}$*;*

(iii) $\mathrm{C}(\xi+\xi') \subseteq \mathrm{C}(\xi)+\mathrm{C}(\xi')$*,* $\mathrm{C}(\xi\xi') \subseteq \mathrm{C}(\xi)\cdot\mathrm{C}(\xi')$*, and* $\mathrm{C}(q\,\xi) = \mathrm{C}(\xi)$ *for* $q \in \mathbb{Q}$*,* $q \neq 0$*.*

Lemma 34.7 (Birational invariance)**.** *For $i = 1,2$ let X_i be a smooth projective variety over $\mathbb{Q}$ of dimension m, $D_i \subset X_i$ a divisor with simple normal crossings and smooth components, $Y_i \subset X_i$ a closed set, $X_i^{\circ} = X_i \setminus Y_i$ and $D_i^{\circ} = D_i \setminus Y_i$. Let $\sigma_i \subset X_i(\mathbb{R})$ be compact, the closure of an oriented open semialgebraic set $\sigma_i^{\circ} \subseteq (X_i \setminus (D_i \cup Y_i))(\mathbb{R})$ of dimension m, with $\sigma_i \cap Y_i = \varnothing$ and $\sigma_i \setminus \sigma_i^{\circ} \subseteq D_i$, and let ω_i be a regular form of degree m on X_i°. If an isomorphism $\Phi : U_1 \to U_2$ of dense open sets $U_i \subseteq X_i \setminus (D_i \cup Y_i)$ with $\sigma_i^{\circ} \subseteq U_i(\mathbb{R})$ maps σ_1° onto σ_2° preserving the orientations and has $\Phi^*\omega_2 = \omega_1$, then*

$$\big[H^m(X_1^{\circ}, D_1^{\circ}), \sigma_1, \omega_1\big]^{\mathrm{mot}} = \big[H^m(X_2^{\circ}, D_2^{\circ}), \sigma_2, \omega_2\big]^{\mathrm{mot}}.$$

In particular, with Φ the identity, removing a larger closed set that misses σ_1 leaves the motivic period unchanged; the motivic period of a convergent family is the same in the model without the linear letters, $X_{\mathcal{E}} \setminus \bigcup_{f\in\mathrm{Let}(F)} \widetilde{Y}_f$; and two convergent families on $\mathcal{E}$ with one form have one motivic period.

Corollary 34.8 (Cremona between motivic periods)**.** *Let $F = ((\mathcal{B}_j; s_j, t_j))_j$ be a convergent family with the masses $\mathbf{m}$ and the total strength σ, and F^{c} the family of the same tables with the exponents (t_j, s_j) and the masses $2\sigma\mathbf{1} - \mathbf{m}$. Then F^{c} is convergent, its wall at S is the wall of F at $\mathcal{E} \setminus S$, and $P_{F^{\mathrm{c}}}^{\mathrm{mot}} = P_F^{\mathrm{mot}}$: Theorem 8.14 is an identity of motivic periods.*

34.3 Steps along a tree of bunches

The boundary strata are indexed by flags, and a stratum is a product over the steps of its flag (Proposition 34.4(iv)). A tree of bunches (Definition 20.7) assigns every step to one of its vertices.

Definition 34.9 (Attachment)**.** Let $\mathcal{T}$ be a tree of bunches of a family F (Definition 20.7) and $(Z;\mathfrak{f})$ a step of a flag of $\mathcal{E}$. Starting at the root, Z descends through vertices whose marks contain it:

(i) at a split vertex, if Z lies in one of its children it descends to that child; otherwise Z is *attached* there as a *node step*;

(ii) at a node v that is not a leaf, with its bunch B_v: if $Z \subseteq B_v$, Z is attached to v as a *bunch step*; if Z meets B_v and $M_v \setminus B_v$, as a *node step*; and if $Z \subseteq M_v \setminus B_v$, it descends to the room of v;

(iii) at a leaf, Z is attached as a *leaf step*.

Every step is attached to exactly one vertex.

Lemma 34.10 (The letters of an attached step)**.** *Let $\mathcal{T}$ be a tree of bunches of a family F as in Definition 34.1, and let the step $(Z;\mathfrak{f})$ be attached to the vertex v, with the marks M_v. Every letter of the step other than the linear letters is K or Ψ of the child, at a pattern of $M_v \setminus Z$ (Definition 12.1), of a table at v that carries that letter.*

Every family has trees of bunches: at every node that is not a leaf choose a bunch and pass to its room, which has fewer marks. For nonnegative exponents the Foreman tree is one of them (Definition 14.4); with nonnegative exponents merging equal children keeps every letter, so the record and the peel give the same tree, and it is fixed by the tables and the rays of the exponent pairs (Theorem 14.6). The statements below hold along every tree of bunches, and along the Foreman tree the vertex at which each step is attached, and the node form there, are fixed by the family.

34.4 The weights of the coaction

Lemma 34.11 (One form carries every period)**.** *Let V be a smooth affine variety over $\mathbb{Q}$ of dimension m and $D \subset V$ a divisor with simple normal crossings and smooth components. Every class of the relative de Rham cohomology $H^m_{\mathrm{dR}}(V,D)$ is the class of a regular form of degree m on V. So, for a convergent family F (Definition 34.1), $L(H_F,\widetilde{\sigma}_{\mathcal{E}})$ is the open space of the one step $\mathcal{E}$ of the flag $\varnothing \subsetneq \mathcal{E}$, and for every step, $L\big(H^{|Z|-1}(V_{Z;\mathfrak{f}},\partial V_{Z;\mathfrak{f}}),\widetilde{\sigma}_Z\big) = \mathrm{Open}(Z;\mathfrak{f})$.*

So the open space of the whole set of marks already holds every period of H_F on its cell, and a decomposition of the left factors into products over steps carries information only when it is graded. The steps enter through the weight filtration W of the de Rham realization, by Brown's weight-graded face maps.

Proposition 34.12 (Weight-graded faces)**.** *Let F be convergent (Definition 34.1), $k < n-1$ and $e \in W_k(H_F)_{\mathrm{dR}}$. Then*

$$[H_F,\widetilde{\sigma}_{\mathcal{E}},e]^{\mathrm{mot}} \in \sum_{\mathfrak{f}\ \textit{of dimension } k}\ \prod_{\textit{steps } Z\ \textit{of } \mathfrak{f}} \mathrm{Open}(Z;\mathfrak{f}).$$

Theorem 34.13 (Small steps along the tree)**.** *Let F be convergent, $\mathcal{T}$ a tree of bunches of F, and (e_i) a basis of $(H_F)_{\mathrm{dR}}$ adapted to the weight filtration W. For $k < n-1$ every left factor $[H_F, \widetilde{\sigma}_{\mathcal{E}}, e_i]^{\mathrm{mot}}$ of the coaction of P_F^{mot} with $e_i \in W_k$ satisfies*

$$[H_F, \widetilde{\sigma}_{\mathcal{E}}, e_i]^{\mathrm{mot}} \in \sum_{\mathfrak{f} \text{ of dimension } k} \ \prod_{\text{steps } Z \text{ of } \mathfrak{f}} \mathrm{Open}(Z; \mathfrak{f}).$$

Only steps of at most $k+1$ marks occur. Each is attached to exactly one vertex v of $\mathcal{T}$, and every letter of it other than the linear letters is K or Ψ of the child, at a pattern of $M_v \setminus Z$, of a table at v that carries that letter.

The theorem is read on Brown's affine model, which removes the linear letters α_J to make the complement affine. They are the letters of the lists $\binom{J}{1}$, and they enter the families of the steps below as tables. Each open period is a constant term of continued periods, and those constant terms are read on convergent data.

Proposition 34.14 (Laurent coefficients are read on convergent data)**.** *Let $F = ((\mathcal{B}_j; s_j, t_j))_{j=1}^N$ be a family of lists on $\mathcal{E}$ with integer exponents and integer masses $\mathbf{m}$ on its balance wall, and $\mathbf{v} \in \mathbb{Q}^{\mathcal{E}}$ with $v_{\mathcal{E}} = 0$ and $v_S \neq 0$ for every $\varnothing \neq S \subsetneq \mathcal{E}$. Then $\varepsilon \mapsto P_F(\mathbf{m} + \varepsilon\mathbf{v}; \mathbf{s}, \mathbf{t})$, the continued period (Proposition 34.4(v)), is meromorphic near $\varepsilon = 0$, and there are finitely many convergent families $F_k = ((\mathcal{B}_j; s_j^{(k)}, t_j^{(k)}))_j$ on the same tables, with $\mathbf{s}^{(k)} - \mathbf{s},\ \mathbf{t}^{(k)} - \mathbf{t} \in \mathbb{N}^N$ and integer masses $\mathbf{m}^{(k)}$ on their balance walls, and rational functions $R_k \in \mathbb{Q}(\varepsilon)$, with*

$$P_F(\mathbf{m} + \varepsilon\mathbf{v}; \mathbf{s}, \mathbf{t}) = \sum_k R_k(\varepsilon)\, P_{F_k}\big(\mathbf{m}^{(k)} + \varepsilon\mathbf{v}; \mathbf{s}^{(k)}, \mathbf{t}^{(k)}\big)$$

near $\varepsilon = 0$. So every coefficient of the Laurent expansion at $\varepsilon = 0$ is a rational combination of the absolutely convergent integrals

$$\partial_\varepsilon^l P_{F_k}\big(\mathbf{m}^{(k)} + \varepsilon\mathbf{v}; \mathbf{s}^{(k)}, \mathbf{t}^{(k)}\big)\Big|_{\varepsilon=0} = \int_{\Delta_{\mathcal{E}}} u^{\mathbf{m}^{(k)} - \mathbf{1}} \langle \mathbf{v}, \log u \rangle^l \prod_j K_j(u)^{-s_j^{(k)}} \Psi_j(u)^{-t_j^{(k)}}\, d\omega_{\mathcal{E}}(u),$$

$l \in \mathbb{N}$. If $\mathbf{s}, \mathbf{t} \geq 0$, every F_k has nonnegative exponents and positive masses.

Corollary 34.15 (Open periods from families of lists)**.** *Let $(Z; \mathfrak{f})$ be a step of a flag of $\mathcal{E}$ with $|Z| \geq 2$ and η a regular form of degree $|Z| - 1$ on $V_{Z;\mathfrak{f}}$. On the torus,*

$$\eta = \sum_t c_t\, \omega_{F_t}, \qquad c_t \in \mathbb{Q},$$

a finite sum over families F_t of lists on Z at integer data on their balance walls: the tables of F_t are the lists of the letters of the step, the step list for its K or its Ψ and $\binom{J}{1}$ for α_J, each carrying its letter with an exponent $k_{t,g} \in \mathbb{N}$, and the masses are some $\mathbf{a}_t \in \mathbb{Z}^Z$. For every $\mathbf{v} \in \mathbb{Q}^Z$ with $v_Z = 0$ and $v_S \neq 0$ for every $\varnothing \neq S \subsetneq Z$, each continued period $P_{F_t}(\mathbf{a}_t + \varepsilon\mathbf{v})$ (Proposition 34.4(v)) is meromorphic in ε near 0, and

$$\int_{\widetilde{\sigma}_Z} \eta = \sum_t c_t \operatorname*{CT}_{\varepsilon=0} P_{F_t}(\mathbf{a}_t + \varepsilon\mathbf{v}).$$

By Proposition 34.14 each constant term is a rational combination of convergent periods of families of lists on Z with nonnegative integer exponents and positive integer masses, values of the serif family (Proposition 8.12), and of their derivatives along $\mathbf{v}$ in the masses. So every element of $\mathrm{Open}(Z; \mathfrak{f})$ has such a number as its period, and by Theorem 34.13 every left factor of weight at most k has as its period a sum of products of such numbers over the steps of the flags of dimension k, whose letters are letters of children of the tables at the vertices where the steps are attached.

34.5 The node

Theorem 34.16 (The node form)**.** *Let F be convergent (Definition 34.1), $\mathcal{T}$ a tree of bunches of F, v a node of $\mathcal{T}$ that is not a leaf, with its bunch B_v of width c (Definition 20.7), and $(Z;\mathfrak{f})$ a node step of v (Definition 34.9), with $Z_B = Z \cap B_v$ and $Z_R = Z \cap (M_v \setminus B_v)$. Read the bunch side in scale and shape and the room side on its simplex, $\alpha_{Z_B} = \rho u$ with $\rho > 0$ and $u \in \Delta_{Z_B}$, and $\alpha_{Z_R} = u' \in \Delta_{Z_R}$ (Lemma 2.7).*

(i) Every letter g of the step is the basis polynomial of a list $\mathcal{N}_g$ on Z: the step list at the bottom for a letter K, the dual of the step list at the top for a letter Ψ (Proposition 7.2), and $\binom{J}{1}$, its marks outside J loops, for α_J. The width c_g of Z_B in $\mathcal{N}_g$ is at most c, and $c \geq 1$.

(ii) With d_g the floor of Z_B in $\mathcal{N}_g$ and the Skeleton values $\xi_{g,1}, \dots, \xi_{g,c_g}$ of $K_{\mathcal{N}_g}$ along Z_B at (u,u') (Definition 12.10),

$$g(\rho u, u') = \rho^{d_g}\, K_{\mathcal{N}_g|Z_B}(u)\, K_{\mathcal{N}_g/Z_B}(u') \prod_{i=1}^{c_g} \big(\rho + \xi_{g,i}(u,u')\big),$$

the leading coefficient being the top level of Z_B (Theorem 12.19); these Skeleton values, each with its letter, form the joint spectrum of Z_B at (u,u') (Definition 12.14).

(iii) For every regular form η of degree $|Z|-1$ on $V_{Z;\mathfrak{f}}$ there are finitely many terms t, with rational functions A_t on Δ_{Z_B} and B_t on Δ_{Z_R}, integers ν_t and letter exponents $k_{t,g} \in \mathbb{N}$, such that

$$\int_{\widetilde{\sigma}_Z} \eta = \int_{\Delta_{Z_B} \times \Delta_{Z_R}} \sum_t A_t(u)\, B_t(u')\, \mathrm{Sc}_t(u,u')\, d\omega_{Z_B}(u)\, d\omega_{Z_R}(u'),$$

the integrand absolutely integrable. Here $\mathrm{Sc}_t = 0$ when no letter with $k_{t,g} > 0$ has a Skeleton value, and otherwise

$$\begin{aligned} \mathrm{Sc}_t &= \mathrm{Reg} \int_0^\infty \rho^{\nu_t - 1} \prod_{g,i} \big(\rho + \xi_{g,i}\big)^{-k_{t,g}}\, d\rho \\ &= \operatorname*{CT}_{\kappa=\nu_t} \Gamma_{|J_t|}^{\,2} \begin{bmatrix} \kappa, & |\mathbf{w}_t| - \kappa \\ & \mathbf{w}_t \end{bmatrix} \mathsf{B}^{\{J_t\}}_{\mathbf{w}_t, |\mathbf{w}_t|-\kappa;\, I_{J_t}}\big(\boldsymbol{\xi}(u,u')\big), \end{aligned}$$

J_t indexing the Skeleton values $\xi_{g,i}$ of the letters with $k_{t,g} > 0$, each with the letter exponent $w_{t,(g,i)} = k_{t,g}$, so that $|\mathbf{w}_t| = \sum_g k_{t,g} c_g$: the finite part in ρ (Definition 1.5) is the constant term at ν_t of the stacked Gamma times the Breta of one bunch of Proposition 15.1, continued from the strip $0 < \mathrm{Re}\,\kappa < |\mathbf{w}_t|$. This is the node form *of η at v: the bunch and the room meet only through the joint spectrum, as the coefficients of Bretas of one bunch at the unit configuration.*

*(iv) (*Width one.*) If $c = 1$, every letter has at most one Skeleton value, the room's hinge value over the bunch's, $\xi_g = \gamma_R^g(u')/\gamma_B^g(u)$ with $\gamma_B^g = K_{\mathcal{N}_g|Z_B}/K_{\mathcal{N}_g/Z_R}$ and $\gamma_R^g = K_{\mathcal{N}_g|Z_R}/K_{\mathcal{N}_g/Z_B}$ (Corollary 19.5), positive. For κ in the strip, the share side (Corollary 15.5) writes the stacked Gamma times the Breta of the term t as an integral over $|J_t|-1$ shares of stacked Gammas times powers $\xi_g^{-b_g} = \gamma_R^g(u')^{-b_g} \gamma_B^g(u)^{\,b_g}$, the b_g affine in the shares and in κ, with real parts constant along the contour. On every such contour on which these stacked Gammas have arguments with positive real parts and*

$$\int_{\Delta_{Z_B}} |A_t| \prod_g (\gamma_B^g)^{\mathrm{Re}\, b_g}\, d\omega_{Z_B} < \infty, \qquad \int_{\Delta_{Z_R}} |B_t| \prod_g (\gamma_R^g)^{-\mathrm{Re}\, b_g}\, d\omega_{Z_R} < \infty,$$

the integral over $\Delta_{Z_B} \times \Delta_{Z_R}$ of $A_t B_t$ times the stacked Gamma times the Breta is the share integral of the stacked Gammas times $\int_{\Delta_{Z_B}} A_t \prod_g (\gamma_B^g)^{b_g} d\omega_{Z_B}$ times $\int_{\Delta_{Z_R}} B_t \prod_g (\gamma_R^g)^{-b_g} d\omega_{Z_R}$: the bunch and the room separate. When $0 < \nu_t < |\mathbf{w}_t|$, Sc_t is the convergent scale integral at $\kappa = \nu_t$, and the term itself separates.

(v) If the root of $\mathcal{T}$ is a node that is not a leaf, the period of every element of $L(H_F, \widetilde{\sigma}_{\mathcal{E}})$, every left factor of the coaction of P_F^{mot} among them, is given by the node form at the root.

(vi) At a split vertex and a node step Z of it that meets the child M_1, the same holds with $Z_B = Z \cap M_1$, $Z_R = Z \setminus M_1$ and $c = 1$: the letters other than the linear letters have width zero at Z_B, and only the α_J with J meeting Z_B and Z_R have a Skeleton value.

At width two or more the Skeleton values are the negatives of the roots of Skeleton polynomials of degree c_g, whose extreme coefficients are products of a bunch letter and a room letter and whose middle coefficients are sums over the patterns of their levels (Theorem 12.19); the node form reads them as the coefficients of a Breta of one bunch at any width, while hinge values are defined at width one only (Definition 19.2). For the period itself, $\eta = \omega_F$ at the root, the glue reads the bunch and the room through their two laws (Theorem 28.10(ii)), opened with one share per station (Theorem 28.10(iii)) or with one more pin for every direction a side does not see (Theorem 28.12); at width one in one table this is Theorem 19.13, and with one Skeleton value Corollary 19.14. Theorem 34.16 extends the node form from the period to every form on every node step, and so to every left factor; width one enters it only in (iv).

34.6 Pinned cells

Theorem 34.17 (Pinned cells split off motivically)**.** *Let $F = ((\mathcal{B}_j; s_j, t_j))_{j=1}^N$ be a convergent family (Definition 34.1) on $\mathcal{E} = L \sqcup R_1 \sqcup \cdots \sqcup R_q$, $q \geq 1$, $|R_i| \geq 2$, whose active tables are substituted table by table (Definition 21.1): $\mathcal{B}_j = \mathcal{H}_j\langle \mathcal{A}_{1j}, \ldots, \mathcal{A}_{qj} \rangle$, the marks of L left in place, with the cores $\mathcal{H}_j$, lists on $L \sqcup \{h_1, \ldots, h_q\}$, and the cells $\mathcal{A}_{ij}$, lists on $R_i \sqcup \{g_i\}$; here and below j runs over the active tables, the others carrying no letter. Let the active letters read every cell through one hinge value: for every i there is a function γ_i on Δ_{R_i} with $\gamma^K_{\mathcal{A}_{ij}} = \gamma_i$ whenever $s_j \neq 0$ and $\gamma^\Psi_{\mathcal{A}_{ij}} = \gamma_i$ whenever $t_j \neq 0$. Let $\kappa_i = \kappa_{R_i}$, the wall of the cell (Theorem 21.10), put $2\sigma = \sum_j (s_j + t_j)$, and fix integer loads a_{ij}, b_{ij} with $a_{ij} = 0$ when $s_j = 0$, $b_{ij} = 0$ when $t_j = 0$ and $\sum_j (a_{ij} + b_{ij}) = \kappa_i$.*

(i) $1 \leq \kappa_i \leq 2\sigma - 1$. The core family *$F_{\mathcal{H}} = ((\mathcal{H}_j; s_j, t_j))_j$ on $L \sqcup \{h_1, \ldots, h_q\}$, with the masses $\mathbf{m}|_L$ and κ_i at h_i, is convergent, and so is, for every i, the* pinned family *G_i on R_i, the load family at zero imbalance of Corollary 22.7: the tables $\mathcal{A}_{ij} \setminus g_i$ at $(a_{ij}, t_j - b_{ij})$ and $\mathcal{A}_{ij}/g_i$ at $(s_j - a_{ij}, b_{ij})$, with the masses $\mathbf{m}|_{R_i}$.*

(ii) The motivic period factors through the core:

$$P_F^{\mathrm{mot}} = P_{F_{\mathcal{H}}}^{\mathrm{mot}} \prod_{i=1}^{q} P_{G_i}^{\mathrm{mot}}, \qquad \mathrm{C}(P_F^{\mathrm{mot}}) \subseteq \mathrm{C}(P_{F_{\mathcal{H}}}^{\mathrm{mot}}) \cdot \prod_{i=1}^{q} \mathrm{C}(P_{G_i}^{\mathrm{mot}}).$$

(iii) The cell family *$F_i = ((\mathcal{A}_{ij}; s_j, t_j))_j$ on $R_i \sqcup \{g_i\}$, with the masses $\mathbf{m}|_{R_i}$ and $2\sigma - \kappa_i$ at g_i, is convergent, and*

$$P_{F_i}^{\mathrm{mot}} = \Gamma_{\begin{smallmatrix} 2 \\ 1 \end{smallmatrix}} \begin{bmatrix} \kappa_i, & 2\sigma - \kappa_i \\ & 2\sigma \end{bmatrix} P_{G_i}^{\mathrm{mot}},$$

the Beta corner a positive rational number.

(iv) The form, the period and the motivic period of G_i do not depend on the loads: its form is $\gamma_i^{-\kappa_i}\alpha^{\mathbf{m}|_{R_i}}\prod_j K_{\mathcal{A}_{ij}/g_i}^{-s_j}\Psi_{\mathcal{A}_{ij}\setminus g_i}^{-t_j}\,\Omega_{R_i}/\alpha^{R_i}$, and its period is the pinned shape integral of the cell (Theorem 22.5).

(v) Every $S \subseteq L$ has in $\mathcal{B}_j$ the width it has in $\mathcal{H}_j$ (Corollary 21.11): a bunch among the marks left in place keeps the width it has in the core, and no condition is placed on it.

One hinge value confines the set it reads to width at most one (Lemma 19.6), and the marks of a cell always form a set of width one (Proposition 21.3(i)); so it is the cells that have width one, and a bunch among the marks left in place has any width up to the number of the other marks and cells (Corollary 21.11). With q cells the letters read the room through q hinge values, one for each cell.

Corollary 34.18 (Dual pairs and full leans)**.** *Let $F = (\mathcal{B}; s, t)$ be a convergent family of one list (Definition 34.1).*

*(a) (*Dual pairs.*) Let $\mathcal{B} = \mathcal{H}\langle \mathcal{A}_1, \dots, \mathcal{A}_q\rangle$ as in Theorem 34.17, with every cell a dual pair (Definition 21.1). Then every cell is read through one hinge value at all integers s, t; the pinned family of the cell i has the form of the family $(\mathcal{B}|R_i;\ \kappa_i,\ s+t-\kappa_i)$ at the masses $\mathbf{m}|_{R_i}$, with $\kappa_i = m_{R_i} - (s+t)(r(R_i)-1)$; and*

$$P_F^{\mathrm{mot}} = P_{(\mathcal{H};s,t)}^{\mathrm{mot}} \prod_{i=1}^{q} P_{(\mathcal{B}|R_i;\,\kappa_i,\,s+t-\kappa_i)}^{\mathrm{mot}},$$

the core at the masses $\mathbf{m}|_L$ and κ_i at h_i.

*(b) (*Full leans.*) Let $t = 0$ or $s = 0$. Split $\mathcal{B}$ at a set of width one with at least two marks on each side into the substitution of its two cells (Proposition 21.3(iii)), and repeat at the nodes so obtained until no node has such a set. The nodes on at least four marks are then prime (Theorem 23.16), and those on two or three marks are the lists $\binom{S}{1}$ and $\binom{S}{|S|-1}$. Give each prime node $\mathcal{H}_v$ the family $F_v = (\mathcal{H}_v; s, t)$ with the masses of its marks and, at each marker, the wall of F at the marks on the other side of the split that made it. Every F_v is convergent, and*

$$P_F^{\mathrm{mot}} = c\prod_v P_{F_v}^{\mathrm{mot}}, \qquad c \in \mathbb{Q}_{>0};$$

so $\mathrm{C}(P_F^{\mathrm{mot}}) \subseteq \prod_v \mathrm{C}(P_{F_v}^{\mathrm{mot}})$, and a list without prime nodes has a rational motivic period at its full leans.

Part (b) is the motivic form of Corollary 26.11 and Theorem 26.5: the series and parallel nodes contribute stacked Gammas at integer arguments (Proposition 26.9), which are rational, and their motivic periods are these rationals. At a full lean the width of a bunch plays no part, and the two full leans of one list are exchanged by Cremona, as motivic periods (Corollary 34.8). In a prime list no set with two marks on each side splits off (Corollary 28.26(ii)), so the splitting of (b) ends at the prime nodes; their only cells are the complements of single marks, which at a full lean split off by one Beta corner and, with both letters active, exactly where the deletion and the contraction have one even letter (Corollary 28.26(iii),(iv)).

Theorem 34.19 (A pinned set splits off motivically)**.** *Let $F = ((\mathcal{B}_j; s_j, t_j))_j$ be a convergent family (Definition 34.1) with $s_j, t_j \geq 0$, and let S, $|S| \geq 2$, be pinned (Theorem 28.25) with width one in every active table, $S' = \mathcal{E} \setminus S$. Every active table is then the substitution of its cell of the bunch $\mathcal{B}_{j,S}^{+}$ into its cell of the room $\mathcal{B}_{j,S'}^{+}$ (Theorem 19.4, Proposition 21.3(iii)), the marks of S' left in*

place, and the active letters read the cell through the one hinge value $\gamma = \gamma^K_{j,S} = \gamma^\Psi_{j,S}$. *The core family of Theorem 34.17 is the room with its stand-in at* $\mathbf{1}$, $S'^{(\mathbf{1})}$ *(Theorem 28.10(i)), the family* $((\mathcal{B}^+_{j,S'}; s_j, t_j))_j$ *of the active tables with the masses* $(\mathbf{m}|_{S'}, \kappa_S)$*; the period of its pinned family* G *is* $c = \int_{\Delta_S} \phi^\rho_S$, *the total mass of the law of* S*; and*

$$P^{\mathrm{mot}}_F = P^{\mathrm{mot}}_{S'^{(\mathbf{1})}}\, P^{\mathrm{mot}}_G, \qquad \mathrm{C}(P^{\mathrm{mot}}_F) \subseteq \mathrm{C}(P^{\mathrm{mot}}_{S'^{(\mathbf{1})}}) \cdot \mathrm{C}(P^{\mathrm{mot}}_G) :$$

the identity $P_F = c\, P_{S'^{(\mathbf{1})}}$ *of Theorem 28.25 is an identity of motivic periods.*

Every period of a family glued on a set is the integral, against the law of the set, of the period of the partner with a stand-in for it (Theorem 28.10(i)). Where the law is a point the integral is one evaluation (Theorem 28.25); where the set is moreover a cell, the change of variables behind the evaluation is birational and the evaluation is an identity of motivic periods. No other set splits off, and a set of width two or more enters every period glued on it through a law that is not a point (Corollary 28.26(i)); at every node, of every width, the open periods of node steps have the node form of Theorem 34.16.

34.7 Rational data

At rational masses and exponents the form of a family is multivalued on its model, a section of a local system of finite order. On the Kummer cover that adjoins the roots of the coordinate ratios and of the letters it becomes a single-valued regular form, and the period of the family is a period of the cover.

Proposition 34.20 (Rational data on a Kummer cover)**.** *Let* $F = ((\mathcal{B}_j; s_j, t_j))_{j=1}^N$ *be a family of lists on* $\mathcal{E}$, $n = |\mathcal{E}| \geq 2$, *with masses* $\mathbf{m}$ *and exponents in* $\frac{1}{M}\mathbb{Z}$ *on its balance wall,* $M \geq 1$, *and* $\kappa_S > 0$ *for every nonempty proper* S. *Define* $\mathrm{Let}(F)$, V_F *and* D_F *as in Definition 34.1, the letters read as a set of polynomials, and for* $g \in \mathrm{Let}(F)$ *write* e_g *for the sum of the exponents* s_j *with* $K_j = g$ *and* t_j *with* $\Psi_j = g$, *and* δ_g *for its degree.*

(i) On the points of the torus in V_F,

$$\omega_F = \prod_{e \neq e_0} \Big(\frac{\alpha_e}{\alpha_{e_0}}\Big)^{m_e} \prod_{g \in \mathrm{Let}(F)} \Big(\frac{g}{\alpha_{e_0}^{\delta_g}}\Big)^{-e_g} \frac{\Omega_{\mathcal{E}}}{\alpha^{\mathcal{E}}},$$

a regular form times a branch of a function whose M*-th power is a regular unit: a section of a local system of rank one and order dividing* M.

(ii) Let $V_F^{(M)}$ *be the normalization of* V_F *in the algebra, a finite product of fields, obtained from its function field by adjoining the* M*-th roots* r_e *of* α_e/α_{e_0}, $e \neq e_0$, *and* w_g *of* $g/\alpha_{e_0}^{\delta_g}$, $g \in \mathrm{Let}(F)$, *and* $D^{(M)}$ *the preimage of* D_F. *In the chart of an order, with* $\eta_i^M = \varepsilon_i$ *and* $\widetilde{w}_g^M = \widetilde{g}$ *for the sector letters (Lemma 34.3),* $V_F^{(M)}$ *is smooth with the coordinates* η, $D^{(M)} = \{\prod_i \eta_i = 0\}$ *is a divisor with simple normal crossings, and the pullback of* ω_F *is*

$$\omega_F^{(M)} = \pm M^{n-1} \prod_{i<n} \eta_i^{M\kappa_{S_i}-1} \prod_{g \in \mathrm{Let}(F)} \widetilde{w}_g^{-Me_g}\, d\eta_1 \wedge \cdots \wedge d\eta_{n-1},$$

a single-valued form, regular on $V_F^{(M)}$.

(iii) The positive cell lifts to the closure $\widetilde{\sigma}_{\mathcal{E}}^{(M)}$ *of the set of the points over* $\widetilde{\sigma}_{\mathcal{E}}^{\circ}$ *at which every* r_e *and every* w_g *is real and positive, compact with its boundary in* $D^{(M)}$*, and*

$$P_F^{\mathrm{mot}} = \big[H^{n-1}\big(V_F^{(M)}, D^{(M)}\big),\ \widetilde{\sigma}_{\mathcal{E}}^{(M)},\ \omega_F^{(M)}\big]^{\mathrm{mot}}$$

is a motivic period whose period is $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$*. For* $M = 1$ *it is the motivic period of Definition 34.5.*

(iv) Over $\mathbb{Q}(\mu_M)$ *the group* $G = \mu_M^{\mathcal{E}\setminus e_0} \times \mu_M^{\mathrm{Let}(F)}$ *acts on* $V_F^{(M)}$ *by* $r_e \mapsto \zeta_e r_e$*,* $w_g \mapsto \zeta'_g w_g$*, and* $\phi^*\omega_F^{(M)} = \chi(\phi)\,\omega_F^{(M)}$ *with the character* $\chi(\zeta,\zeta') = \prod_e \zeta_e^{Mm_e}\prod_g \zeta_g'^{-Me_g}$*. So the de Rham class of* $\omega_F^{(M)}$ *lies in the* χ*-eigenspace of* $H^{n-1}_{\mathrm{dR}}(V_F^{(M)}, D^{(M)}) \otimes \mathbb{Q}(\mu_M)$*.*

So the periods of families at rational data are periods of mixed objects of the same kind as at integer data, read on a cover of the model of finite degree; the masses and the exponents enter as a character of its deck group, and the walls as the orders of the form along the boundary of the cover.

34.8 Separation by conjugates

A motivic period is not determined by its period alone, but it is determined by the periods of its Galois conjugates; for the motivic period of a family the conjugates below the top weight are values of families on the steps of its tree.

Theorem 34.21 (Motivic periods are separated by their conjugates)**.** *(i) The map* $\xi \mapsto (\mathrm{per}\otimes\mathrm{id})\Delta\xi$*, from* $\mathcal{P}^{\mathrm{mot}}$ *to* $\mathbb{C}\otimes_{\mathbb{Q}}\mathcal{P}^{\mathrm{dR}}$*, is injective. So a motivic period* ξ *is* 0 *exactly when every element of* $\mathrm{C}(\xi)$ *(Definition 34.5) has the period* 0*.*

(ii) Let F *be a convergent family (Definition 34.1) on* n *marks, and* (e_i) *a basis of* $(H_F)_{\mathrm{dR}}$ *adapted to the weight filtration. Then* $P_F^{\mathrm{mot}} = 0$ *exactly when*

$$\sum_i \mathrm{per}\,\big([H_F, \widetilde{\sigma}_{\mathcal{E}}, e_i]^{\mathrm{mot}}\big)\,\varphi\big([H_F, e_i^{\vee}, \omega_F]^{\mathrm{dR}}\big) = 0$$

for every $\mathbb{Q}$*-linear* $\varphi : \mathcal{P}^{\mathrm{dR}} \to \mathbb{Q}$*; for* $e_i \in W_k$*,* $k < n-1$*, the period of* $[H_F, \widetilde{\sigma}_{\mathcal{E}}, e_i]^{\mathrm{mot}}$ *is a sum of products, over the steps of flags of dimension* k*, of rational combinations of values of families of lists on the steps and of their derivatives in the masses, each step having at most* $k+1$ *marks and being attached to one vertex of any tree of bunches of* F*, with the letters of children of the tables at that vertex (Theorem 34.13, Corollary 34.15).*

So the separation of the motivic period of a family descends its tree: below the top weight its conjugates are read on the families of its steps, and only the left factors of top weight are read on the whole model.

Chapter 35

Positive words

The output of the theory is a value: a period, a Breta, a closing of fibre integrals, and such values are read arithmetically. A closing at rational data writes a value as a rational combination of Trailmoments of lattice inputs and rational heads (Proposition 5.13, Lemma 38.32); a sequence of such values that do not vanish, cleared by integers that grow more slowly than the values decay, shows that some Trailmoment it carries is irrational (Theorem 37.2, Chapter 44). What keeps a value from vanishing is positivity, and positive words are made in four ways: second jets of a period in its weights, even powers of the contrast of two bases, Beta ports on the pairs of a manufactured family, and Beta ports read against one mark with the room integrated. The jets and the contrasts are combinations of periods of the same family at shifted data on its balance wall, bounded by the period times a factor that their statements control; the port words of a manufactured family are combinations of its interests at shifted masses over one normalization, and the reads of the Beta ports are bounded by the read of the constant insertion.

35.1 Coefficient jets and basis contrasts

Theorem 35.1 (Positive coefficient jets)**.** *Let F have real exponents $s_j, t_j \geq 0$ and real masses on its balance wall, every proper wall positive. For an integer $n \geq 1$, the* depth*, the data $(n\mathbf{m}; n\mathbf{s}, n\mathbf{t})$ are again on the balance wall, with walls $n\kappa_S$; in this statement $\mathbb{E}$ is the expectation of $U \sim \mathrm{Breta}^{\circ}(F; n\mathbf{m}; n\mathbf{s}, n\mathbf{t})$. Choose* weight directions $\mathbf{b}_{j,T} \in \mathbb{Q}^k$*, one for each table j and basis $T \in \mathcal{B}_j$, and put*

$$\partial_{\mathbf{b}} K_j = \sum_{T \in \mathcal{B}_j} \mathbf{b}_{j,T}\, \alpha^{T}, \qquad \partial_{\mathbf{b}} \Psi_j = \sum_{T \in \mathcal{B}_j} \mathbf{b}_{j,T}\, \alpha^{\mathcal{E} \setminus T},$$

the derivatives of the letters of table j along the weights in these directions.

(i) For $v \in \mathbb{R}^k$ and small real ε, replace every table j by the two tables $(\mathcal{B}_j, \theta_j \pm \varepsilon\, v^{\mathsf{T}} \mathbf{b}_j)$, each with the exponents $(ns_j/2, nt_j/2)$. The period of this doubled family *at the masses $n\mathbf{m}$ is*

$$P_F(n\mathbf{m}; n\mathbf{s}, n\mathbf{t})\ \mathbb{E}\Big[\Big(\prod_j \Big(1 - \varepsilon^2 \Big(\frac{v^{\mathsf{T}} \partial_{\mathbf{b}} K_j}{K_j}\Big)^2\Big)^{-\frac{ns_j}{2}} \Big(1 - \varepsilon^2 \Big(\frac{v^{\mathsf{T}} \partial_{\mathbf{b}} \Psi_j}{\Psi_j}\Big)^2\Big)^{-\frac{nt_j}{2}}\Big)(U)\Big],$$

whose coefficient of ε^2 is $v^{\mathsf{T}} \mathbf{H}_n v$, with the jet matrix

$$\mathbf{H}_n = \frac{n}{2}\, P_F(n\mathbf{m}; n\mathbf{s}, n\mathbf{t})\ \mathbb{E}\Big[\sum_j \Big(s_j\, \frac{\partial_{\mathbf{b}} K_j\, \partial_{\mathbf{b}} K_j^{\mathsf{T}}}{K_j^2} + t_j\, \frac{\partial_{\mathbf{b}} \Psi_j\, \partial_{\mathbf{b}} \Psi_j^{\mathsf{T}}}{\Psi_j^2}\Big)(U)\Big].$$

$\mathbf{H}_n$ *is positive semidefinite, and positive definite when the directions* $\mathbf{b}_{j,T}$ *of the active tables span* $\mathbb{R}^k$.

(ii) For a rational positive semidefinite $k\times k$ *matrix* Q, $\operatorname{tr}(Q\mathbf{H}_n) > 0$ *exactly when* $\mathbf{b}_{j,T}^{\mathsf{T}} Q\, \mathbf{b}_{j,T} > 0$ *for some active table* j *and basis* T. *Completing squares writes* $Q = \sum_l c_l v_l v_l^{\mathsf{T}}$ *with rational* $c_l > 0$ *and rational* v_l, *and so writes* $\operatorname{tr}(Q\mathbf{H}_n) = \sum_l c_l\, v_l^{\mathsf{T}} \mathbf{H}_n v_l$ *as a sum of directional second jets with positive rational coefficients.*

(iii) In periods of F *(Theorem 27.9 at order two, the two copies of each table merged),*

$$\operatorname{tr}(Q\mathbf{H}_n) = \frac{n}{2} \sum_j \sum_{T,T'\in\mathcal{B}_j} \mathbf{b}_{j,T}^{\mathsf{T}} Q\, \mathbf{b}_{j,T'} \Big[s_j\, P_F\big(n\mathbf{m} + \mathbf{1}_T + \mathbf{1}_{T'};\, n\mathbf{s} + 2\mathbf{e}_j,\, n\mathbf{t}\big) + t_j\, P_F\big(n\mathbf{m} + \mathbf{1}_{\mathcal{E}\setminus T} + \mathbf{1}_{\mathcal{E}\setminus T'};\, n\mathbf{s},\, n\mathbf{t} + 2\mathbf{e}_j\big) \Big] :$$

every term stays on its balance wall, a basis insertion changes the wall of S *by* $|T\cap S| + |T'\cap S| - 2d_j(S) \geq 0$, *and a cobasis insertion by* $|S\setminus T| + |S\setminus T'| - 2d_j^*(S) \geq 0$.

(iv) Whenever (ii) gives positivity, $0 < \operatorname{tr}(Q\mathbf{H}_n) \leq n\, C(Q)\, P_F(n\mathbf{m}; n\mathbf{s}, n\mathbf{t})$, *with* $C(Q) = \frac{1}{2}\sum_j (s_j + t_j) \max_T \mathbf{b}_{j,T}^{\mathsf{T}} Q\, \mathbf{b}_{j,T}/\theta_{j,T}^2$.

(v) With the basis weights and the cobasis weights of every table taken as independent variables, the part of $\mathbf{H}_n$ *carried by* K_j *is the Hessian of* $P_F(n\mathbf{m}; n\mathbf{s}, n\mathbf{t})$ *in the basis weights of table* j, *paired with the directions* $\mathbf{b}_{j,T}$, *divided by* $2(ns_j + 1)$, *and the part carried by* Ψ_j *is the same in the cobasis weights divided by* $2(nt_j + 1)$. *On the share side of the period (Corollary 18.16) a weight derivative multiplies the integrand by minus the share divided by its weight, so every pin and every candidate pole hyperplane stays fixed.*

(vi) At the centre, $s_j = t_j$ *for every* j *and* $\mathbf{m} = \sigma\mathbf{1}$, *the doubled family is again at its centre, and the table's gauge* $\mathbf{1}$ *stays native (Proposition 8.21).*

A weight direction moves the two copies of a table apart symmetrically, so the period moves at second order only, by the expectation of a square under the Breta shape law: a jet of the period in its weights is a positive word. Under the basis law $\partial_{\mathbf{b}} K_j/K_j$ is the mean of the directions $\mathbf{b}_{j,T}/\theta_{j,T}$, $\mathbb{E}_{T\sim\mathbb{P}_{j,\alpha}}[\mathbf{b}_{j,T}/\theta_{j,T}]$, so the jet is the second moment, under the shape law, of the mean weight direction that the bases drawn at the shape carry. Table by table it is the period's own Hessian in the weights divided by $2(ns_j + 1)$ or $2(nt_j + 1)$, it is a finite combination of periods of the same family on the balance wall at data whose walls are no smaller, and it costs at most a factor linear in the depth against the period.

Lemma 35.2 (Rounding inside a rational subspace)**.** *Let* V *be the subspace of the real symmetric* $k\times k$ *matrices on which finitely many linear functionals* $Q \mapsto \operatorname{tr}(MQ)$, M *rational, vanish, spanned over* $\mathbb{R}$ *by integer symmetric matrices* $G_1, \dots, G_r$, *and let* $Q_* = \sum_j u_j G_j \in V$ *with* $Q_* \succeq \varepsilon I$, $\varepsilon > 0$. *For an integer* $\ell \geq 1$ *put* $Q = \sum_j \operatorname{round}(\ell u_j)\, G_j$ *and* $\beta = \frac{1}{2}\sum_j \big(\operatorname{tr} G_j^2\big)^{1/2}$. *Then* Q *is an integer matrix in* V *with* $Q \succeq (\ell\varepsilon - \beta)I$ *and* $\operatorname{tr} Q \leq \ell \operatorname{tr} Q_* + k\beta$; *for* $\ell > \beta/\varepsilon$ *it is positive definite.*

The jet word $\operatorname{tr}(Q\mathbf{H}_n)$ is linear in Q, so conditions on its coefficients of Trailmoments, such as the vanishing of chosen ones, define a rational subspace of matrices Q. A positive definite matrix in that subspace rounds to an integer one in the same subspace, and the jet word keeps its positivity and the vanishing of the chosen coefficients together at integer data.

Theorem 35.3 (Two bases generate positive contrast words of any depth)**.** *Let F have real data $(\mathbf{m};\mathbf{s},\mathbf{t})$ on its balance wall with every proper wall positive, with the pair coordinates $(\boldsymbol{\mu}_\perp;\boldsymbol{\sigma},\boldsymbol{\delta})$ (Definition 8.1) and the centred potential Φ° (Theorem 8.19). Let $T \neq T'$ be two bases of a table j, and for integers $n,h \geq 1$ let the* contrast word *be*

$$\frac{1}{2}\,P_F(n\mathbf{m};n\mathbf{s},n\mathbf{t})\;\mathbb{E}_{U\sim\mathrm{Breta}^\circ(F;n\mathbf{m};n\mathbf{s},n\mathbf{t})}\Big[\big(\mathbb{P}_{j,U}(T)-\mathbb{P}_{j,U}(T')\big)^{2h}+\big(\mathbb{P}^*_{j,U}(T)-\mathbb{P}^*_{j,U}(T')\big)^{2h}\Big]>0;$$

the two contrasts have modulus below one on the open orthant.

(i) The first half of the contrast word is

$$\frac{1}{2}\sum_{l=0}^{2h}(-1)^l\binom{2h}{l}\theta_{j,T}^{2h-l}\theta_{j,T'}^{l}\,P_F\big(n\mathbf{m}+(2h-l)\mathbf{1}_T+l\mathbf{1}_{T'};\,n\mathbf{s}+2h\mathbf{e}_j,\,n\mathbf{t}\big),$$

and the second is the same with $\mathbf{1}_{\mathcal{E}\setminus T}$, $\mathbf{1}_{\mathcal{E}\setminus T'}$ in the masses and $2h\mathbf{e}_j$ added to the cobasis exponents; every term is balanced with its walls weakly raised. The inversion $\alpha\mapsto\alpha^{-1}$ carries the second half at $(\mathbf{m};\mathbf{s},\mathbf{t})$ to the first half at $(2\sigma\mathbf{1}-\mathbf{m};\mathbf{t},\mathbf{s})$, the data of Theorem 8.14; at the centre the two halves are equal.

(ii) For rational $\eta>0$ and $h=\eta n$, along the integers n with $\eta n\in\mathbb{N}$, $\frac{1}{n}\log$ of the contrast word tends to

$$-\inf_{z\in\mathbf{1}^\perp}\Big(\Phi^\circ(z)-2\langle\boldsymbol{\mu}_\perp,z\rangle-2\eta\log\max\Big(\big|\mathbb{P}_{j,e^{2z}}(T)-\mathbb{P}_{j,e^{2z}}(T')\big|,\;\big|\mathbb{P}^*_{j,e^{2z}}(T)-\mathbb{P}^*_{j,e^{2z}}(T')\big|\Big)\Big);$$

the infimum exceeds the minimum of $\Phi^\circ-2\langle\boldsymbol{\mu}_\perp,\cdot\rangle$ on $\mathbf{1}^\perp$ and tends to infinity with η; that minimum is $-\lim_n\frac{1}{n}\log P_F(n\mathbf{m};n\mathbf{s},n\mathbf{t})$.

(iii) Let the exponents be nonnegative, and write $q=2h$ and $H_q(x,y)=\sum_{l=0}^{q}(-1)^l\binom{q}{l}(x)_{q-l}(y)_l$. When $s_j>0$, the first half is the share side of $P_F(n\mathbf{m};n\mathbf{s},n\mathbf{t})$ (Corollary 18.16) with its integrand multiplied by $H_q(a_{j,T},a_{j,T'})/\big(2(ns_j)_q\big)$, a the basis shares; when $t_j>0$, the second half is the same with $H_q(b_{j,T},b_{j,T'})/\big(2(nt_j)_q\big)$, b the cobasis shares: polynomial insertions that keep every pin and every pole hyperplane.

Two bases of one table give a contrast of modulus below one, which stays away from one on the compact sets where the Breta shape law concentrates; so its even powers are positive words that become exponentially small against the period, at a rate that grows without bound with the ratio of the power to the depth. At the centre with unit weights the basis law gives every basis the same chance at the table's gauge, where the law concentrates, and the contrast vanishes there. On the share side the contrast is a polynomial in the shares, so the contrast words of every depth keep the fibre, the pins and the poles of the period.

35.2 Manufactured tables and their port words

Definition 35.4 (Manufactured tables)**.** Let *seed letters* on $\mathcal{E}$ be polynomials $L_i(x)=\sum_{P\in\operatorname{supp}L_i}\theta_{i,P}\,x^P$, $i\in I$, with supports $\operatorname{supp}L_i\subseteq 2^{\mathcal{E}}$, weights $\theta_{i,P}>0$ and exponents $w_i\geq 0$; a table $(\mathcal{B}_j,\theta_j)$ of a family with exponents (s_j,t_j) gives the two seed letters K_j, with exponent s_j, and Ψ_j, with exponent t_j. Choose $\beta_i\in(0,1)$ and replace every mark e by a pair $\{e^+,e^-\}$ of new marks, on $\mathcal{E}^\pm=\{e^+,e^-:e\in\mathcal{E}\}$. The polynomials

$$\widetilde{K}_i(\alpha)=L_i(\mathbf{1})\prod_{e\in\mathcal{E}}(\alpha_{e^+}+\alpha_{e^-})-\beta_i\sum_P\theta_{i,P}\prod_{e\in P}\alpha_{e^+}\prod_{e\notin P}(\alpha_{e^+}+\alpha_{e^-}),$$

$$\widetilde{\Psi}_i(\alpha) = L_i(\mathbf{1}) \prod_{e\in\mathcal{E}} (\alpha_{e^+} + \alpha_{e^-}) - \beta_i \sum_P \theta_{i,P} \prod_{e\in P} \alpha_{e^-} \prod_{e\notin P} (\alpha_{e^+} + \alpha_{e^-})$$

are the basis and cobasis polynomials of a table on $\mathcal{E}^{\pm}$ of rank $|\mathcal{E}|$, whose bases $U^+ \cup (\mathcal{E}\backslash U)^-$, $U \subseteq \mathcal{E}$, take one mark of each pair, with the weights $\widetilde{\theta}_{i,U} = L_i(\mathbf{1}) - \beta_i \sum_{P\subseteq U} \theta_{i,P} \geq L_i(\mathbf{1})(1-\beta_i) > 0$; the seed weights are recovered from $\big(L_i(\mathbf{1}) - \widetilde{\theta}_{i,U}\big)/\beta_i = \sum_{P\subseteq U} \theta_{i,P}$ by inversion over the subsets. The *manufactured family* $\widetilde{F}$ has these tables with the exponents $(w_i, 0)$; for masses $\mathbf{m}$ on $\mathcal{E}^{\pm}$ its *pair walls* are $\kappa_{\{e^+,e^-\}} = m_{e^+} + m_{e^-} - |\mathbf{w}|$, $|\mathbf{w}| = \sum_i w_i$, and its *pair shapes* are $x_e = \alpha_{e^+}/(\alpha_{e^+} + \alpha_{e^-})$. For orders $\mathbf{n} \in \mathbb{N}^{\mathcal{E}}$, positive masses and positive pair walls, its *port word* is

$$M_{\widetilde{F},\mathbf{n}}(\mathbf{m}) = \frac{J_{\widetilde{F}}(\mathbf{m};\mathbf{w},\mathbf{0})}{\prod_e \Gamma\big(\kappa_{\{e^+,e^-\}}\big)}\ \mathbb{E}_{\alpha\sim \mathrm{Breta}(\widetilde{F};\mathbf{m};\mathbf{w},\mathbf{0})}\Big[\prod_{e\in\mathcal{E}} \Pi_{n_e}^{m_{e^+},m_{e^-}}(x_e)\Big],$$

and $M^*_{\widetilde{F},\mathbf{n}}(\mathbf{m})$ is the same at the exponents $(0, w_i)$, with $J_{\widetilde{F}}(\mathbf{m};\mathbf{0},\mathbf{w})$ and $\mathrm{Breta}(\widetilde{F};\mathbf{m};\mathbf{0},\mathbf{w})$. An *occupancy* is a family $\mathbf{o} = (o_{i,P})$ of integers $o_{i,P} \geq 0$, zero when $w_i = 0$, with the totals $|o_i| = \sum_P o_{i,P}$ and $|\mathbf{o}| = \sum_i |o_i|$, the *loads* $\mathrm{load}_e(\mathbf{o}) = \sum_i \sum_{P\ni e} o_{i,P}$, and the *coefficient*

$$\mathrm{cf}(\mathbf{o}) = \prod_i \Big[\frac{(w_i)_{|o_i|}}{L_i(\mathbf{1})^{w_i} \prod_P o_{i,P}!} \prod_P \Big(\frac{\beta_i\, \theta_{i,P}}{L_i(\mathbf{1})}\Big)^{o_{i,P}}\Big].$$

Theorem 35.5 (Interest of a manufactured family; the occupancy sum)**.** *In the pair scales and shapes,* $(\alpha_{e^+}, \alpha_{e^-}) = \rho_e(x_e, 1-x_e)$,

$$\widetilde{K}_i = \prod_e \rho_e\big(L_i(\mathbf{1}) - \beta_i L_i(x)\big), \qquad \widetilde{\Psi}_i = \prod_e \rho_e\big(L_i(\mathbf{1}) - \beta_i L_i(\mathbf{1}-x)\big).$$

Let the masses be positive and the pair walls positive.

(i) Every wall of $\widetilde{F}$ *at the exponents* $(w_i, 0)$ *is positive, and*

$$J_{\widetilde{F}}(\mathbf{m};\mathbf{w},\mathbf{0}) = \prod_e \Gamma\big(\kappa_{\{e^+,e^-\}}\big) \int_{[0,1]^{\mathcal{E}}} \prod_e x_e^{m_{e^+}-1}(1-x_e)^{m_{e^-}-1} \prod_i \big(L_i(\mathbf{1}) - \beta_i L_i(x)\big)^{-w_i}\, dx,$$

the integral convergent at all positive masses; the simplex integral $P_{\widetilde{F}}(\mathbf{m};\mathbf{w},\mathbf{0})$ *is* $\Gamma_{1\,|\mathcal{E}|}\begin{bmatrix}(\kappa_{\{e^+,e^-\}})_e \\ \sum_e \kappa_{\{e^+,e^-\}}\end{bmatrix}$ *times the same integral. Under* $\mathrm{Breta}(\widetilde{F};\mathbf{m};\mathbf{w},\mathbf{0})$ *the pair scales are independent,* $\rho_e \sim \mathrm{Gamma}_{\kappa_{\{e^+,e^-\}}}$*, and independent of the pair shapes, whose density on the cube is proportional to the integrand. So* $M_{\widetilde{F},\mathbf{0}}(\mathbf{m})$ *is the integral displayed, and* $M_{\widetilde{F},\mathbf{n}}(\mathbf{m})$ *is that integral with* $\prod_e \Pi_{n_e}^{m_{e^+},m_{e^-}}(x_e)$ *inserted; with* $L_i(\mathbf{1}-x)$ *in place of* $L_i(x)$ *the same holds for* $M^*_{\widetilde{F},\mathbf{n}}(\mathbf{m})$.

(ii) The integral is the series of nonnegative terms

$$M_{\widetilde{F},\mathbf{0}}(\mathbf{m}) = \sum_{\mathbf{o}} \mathrm{cf}(\mathbf{o}) \prod_e \Gamma_{2\,1}\begin{bmatrix} m_{e^+} + \mathrm{load}_e(\mathbf{o}),\ m_{e^-} \\ m_{e^+} + m_{e^-} + \mathrm{load}_e(\mathbf{o})\end{bmatrix}$$

over the occupancies.

Theorem 35.6 (The port word of a manufactured family)**.** *Let the masses be positive, the pair walls positive and* $\mathbf{n} \in \mathbb{N}^{\mathcal{E}}$*. Then*

$$M_{\widetilde{F},\mathbf{n}}(\mathbf{m}) = \sum_{\mathbf{o}} \mathrm{cf}(\mathbf{o}) \prod_{e} \binom{\mathrm{load}_e(\mathbf{o})}{n_e} \Gamma_{1}^{2}\begin{bmatrix} m_{e^+} + \mathrm{load}_e(\mathbf{o}), & m_{e^-} + n_e \\ m_{e^+} + m_{e^-} + \mathrm{load}_e(\mathbf{o}) + n_e \end{bmatrix}$$
$$= \frac{1}{\prod_e n_e!} \int_{[0,1]^{\mathcal{E}}} \prod_e x_e^{m_{e^+}+n_e-1}(1-x_e)^{m_{e^-}+n_e-1}\, \partial_x^{\mathbf{n}} \prod_i \big(L_i(\mathbf{1}) - \beta_i L_i(x)\big)^{-w_i}\, dx.$$

Every occupancy with $\mathrm{load}_e(\mathbf{o}) < n_e$ *for some* e *is annihilated, every surviving term is positive, every mixed derivative of* $\prod_i (L_i(\mathbf{1}) - \beta_i L_i(x))^{-w_i}$ *is nonnegative on the cube, and* $M_{\widetilde{F},\mathbf{n}}(\mathbf{m}) > 0$ *exactly when every mark* e *with* $n_e > 0$ *lies in a member of the support of a seed letter with* $w_i > 0$*. At integer masses the Beta ports have integer coefficients, and* $M_{\widetilde{F},\mathbf{n}}(\mathbf{m})$ *is an integer combination of the* $M_{\widetilde{F},\mathbf{0}}$ *at the masses shifted by* $(k_e, n_e - k_e)$ *on the pair of* e*,* $0 \le k_e \le n_e$*: of the interests of* $\widetilde{F}$ *at these masses, all of pair walls* $\kappa_{\{e^+,e^-\}} + n_e$*, over the one normalization* $\prod_e \Gamma(\kappa_{\{e^+,e^-\}} + n_e)$*.*

Theorem 35.7 (Suppression selected by incidence)**.** *In Theorem 35.6 write* $\mathrm{occ}(\mathbf{n}) = \min\{|\mathbf{o}| : \mathrm{load}_e(\mathbf{o}) \ge n_e$ *for every* $e\}$ *over the occupancies, and* $\beta = \max_i \beta_i < 1$ *over the seed letters with* $w_i > 0$*. Then*

$$0 \le M_{\widetilde{F},\mathbf{n}}(\mathbf{m}) \le \prod_e \Big[\Gamma_{1}^{2}\begin{bmatrix} m_{e^+}, & m_{e^-} \\ m_{e^+} + m_{e^-} \end{bmatrix} \frac{(m_{e^-})_{n_e}}{n_e!}\Big] \prod_i L_i(\mathbf{1})^{-w_i} \sum_{l \ge \mathrm{occ}(\mathbf{n})} \frac{(|\mathbf{w}|)_l}{l!}\, \beta^l.$$

For an integer demand $\mathbf{d} \in \mathbb{N}^{\mathcal{E}}$ *let* $\mathrm{fc}(\mathbf{d}) = \min\big\{\sum_{i,P} \lambda_{i,P} : \ \lambda \ge 0,\ \sum_{i,P} \lambda_{i,P} \mathbf{1}_P \ge \mathbf{d}\big\}$*, the* fractional cover *of the demand by the members of the supports of the seed letters with* $w_i > 0$*. Then* $\mathrm{occ}(q\mathbf{d}) = q\,\mathrm{fc}(\mathbf{d}) + O(1)$ *as* $q \to \infty$*, and* $\limsup_q \frac{1}{q} \log M_{\widetilde{F},q\mathbf{d}}(\mathbf{m}) \le \mathrm{fc}(\mathbf{d}) \log \beta < 0$ *for a nonzero demand that the supports cover. When the seed letters are the letters* K_j, Ψ_j *of the tables of a family, every surviving occupancy satisfies* $\sum_j \big(r_j(S)\,|o_{K_j}| + (|S| - d_j(S))\,|o_{\Psi_j}|\big) \ge \sum_{e \in S} n_e$ *for every* $S \subseteq \mathcal{E}$*,* $|o_{K_j}|$ *and* $|o_{\Psi_j}|$ *the total occupancies of the two letters of table* j*.*

Theorem 35.8 (Reflection of the port words of a manufactured family)**.** *The swap* $\alpha_{e^+} \leftrightarrow \alpha_{e^-}$ *on every pair,* $x_e \leftrightarrow 1 - x_e$*, swaps* $\widetilde{K}_i$ *with* $\widetilde{\Psi}_i$ *and* m_{e^+} *with* m_{e^-}*, and keeps every seed weight and every* β_i*: with* $\mathbf{m}'$ *the masses swapped on every pair,* $M_{\widetilde{F},\mathbf{n}}(\mathbf{m}) = (-1)^{|\mathbf{n}|} M^{*}_{\widetilde{F},\mathbf{n}}(\mathbf{m}')$*.*

A manufactured table turns any positive polynomials, the two letters of every table of a family among them, into a table whose bases are the transversals of the pairs. On the pair shapes its letter is the constant $L_i(\mathbf{1})$ less a copy of the seed scaled by β_i, so the port word is a series of nonnegative terms indexed by occupancies of the members of the seed, and a Beta port of order n_e on a pair keeps only the occupancies that load the mark at least n_e times. The port words are therefore positive exactly when the incidence of the supports can meet the demand, and they are suppressed at the exponential rate of the cheapest fractional cover of the demand: the incidence structure of the seed decides which port words survive and how small they are.

35.3 Mark relations with the room integrated

Definition 35.9 (Mark reads)**.** Select a mark with coordinate x, and let the coordinates α_R of its room range over a measure space with a density $\Omega(\alpha_R) \ge 0$. The letters (Section 3.2) in the selected mark are polynomials $L_i(x, \alpha_R)$ in x, $i = 1, \dots, h$, positive where x ranges, with exponents w_i; they are *linear* when $L_i = c_i(\alpha_R) + d_i(\alpha_R)\, x$ with $c_i > 0$ and $d_i \ge 0$, and a linear letter *sees*

the mark when $w_i d_i > 0$ on a set of positive measure. For $a, b > 0$ the *mark read* of an insertion $g(x, \alpha_R)$ on the box is

$$\langle g \rangle_{a,b;\mathbf{w}} = \int\!\!\int_0^1 g\, x^{a-1}(1-x)^{b-1} \prod_i L_i^{-w_i}\, dx\; \Omega(\alpha_R)\, d\alpha_R,$$

and for $a, \lambda > 0$ its read on the half-line is

$$\langle g \rangle^{\lambda}_{a;\mathbf{w}} = \int\!\!\int_0^\infty g\, x^{a-1} e^{-\lambda x} \prod_i L_i^{-w_i}\, dx\; \Omega(\alpha_R)\, d\alpha_R,$$

wherever these converge; at a fixed point of the room, $\Omega(\alpha_R)\, d\alpha_R$ is the Dirac measure there. A sequence of reads at the data $a_n + j$, b_n, $\mathbf{w}(n)$ and Ω_n keeps the depth n (Theorem 35.1) apart from the *moment index* j of the selected mark.

Theorem 35.10 (The mark relation)**.** *Let the letters be polynomial in the selected mark, with exponents w_i, and let $A(x, \alpha_R)$ be a polynomial in x with coefficients depending on the room.*

(a) On the box, for $a, b > 0$:

$$\Big\langle x(1-x)\,\partial_x A + \big(a - (a+b)x\big) A - x(1-x)\, A \sum_i w_i\, \partial_x \log L_i \Big\rangle_{a,b;\mathbf{w}} = 0.$$

(b) On the half-line, for $a, \lambda > 0$, whenever the reads converge:

$$\Big\langle x\,\partial_x A + (a - \lambda x) A - x\, A \sum_i w_i\, \partial_x \log L_i \Big\rangle^{\lambda}_{a;\mathbf{w}} = 0.$$

(c) On a restricted interval the difference of the flux at its two ends is retained, and a kernel coupled to x contributes its product-rule term.

Multiplying by $\prod_i L_i$ gives a polynomial numerator; on a box of several marks the relation holds in each coordinate with the others as room.

Theorem 35.11 (The moments of a selected mark close in a finite span)**.** *On a family select a mark e, $x = \alpha_e$, with room $R = \mathcal{E} - e$; splitting the bases and the cobases by e gives the two coefficients of every letter in x. Pull the letters free of x into the room, absorb pure powers of x into its mass, and write the remaining letters $L_i = c_i(\alpha_R) + d_i(\alpha_R)\, x$, $c_i, d_i > 0$, $i = 1, \dots, h$, with exponents w_i; read them on the half-line at a fixed point of the room (Definition 35.9), with $m, \lambda > 0$. With $\prod_i L_i = \sum_{k=0}^{h} p_k x^k$, $p_{-1} = 0$, $q_0 = 0$ and $q_k = \sum_i w_i d_i\, [x^{k-1}] \prod_{i' \neq i} L_{i'}$,*

$$\lambda p_h\, \langle x^{n+h+1} \rangle^{\lambda}_{m;\mathbf{w}} = \sum_{k=0}^{h} \big[(m+n+k)\, p_k - q_k - \lambda p_{k-1}\big]\, \langle x^{n+k} \rangle^{\lambda}_{m;\mathbf{w}},$$

a recurrence whose coefficients are polynomials in the room coordinates, with leading coefficient λp_h, $p_h = \prod_i d_i > 0$. For a mark f of the room,

$$\partial_{\alpha_f} \langle x^n \rangle^{\lambda}_{m;\mathbf{w}} = -\sum_i w_i \Big[(\partial_{\alpha_f} d_i)\, \langle x^{n+1} \rangle^{\lambda}_{m;\mathbf{w}+\mathbf{e}_i} + (\partial_{\alpha_f} c_i)\, \langle x^n \rangle^{\lambda}_{m;\mathbf{w}+\mathbf{e}_i} \Big],$$

and the moments with at most ℓ such derivatives lie in the span, over rational functions of the room, of $\{\langle x^k \rangle^{\lambda}_{m;\mathbf{w}+v} : 0 \le k \le h,\ v \in \mathbb{N}^h,\ |v| \le \ell\}$: at most $(h+1)\binom{h+\ell}{\ell}$ states.

Theorem 35.12 (Positive reads of the Beta ports)**.** *Let the letters be linear, $L_i = c_i + d_i x$, with exponents $w_i \geq 0$, let $a, b > 0$ and $q \in \mathbb{N}$, and let J be a set of letters, with $w_J = \sum_{i\in J} w_i$.*

(i) The Beta port of order q reads (Theorem 3.15(iii), integrated over the room)

$$\big\langle (-1)^q \Pi_q^{a,b} \big\rangle_{a,b;\mathbf{w}} = \sum_{|v|=q} \prod_i \frac{(w_i)_{v_i}}{v_i!} \Big\langle \big(x(1-x)\big)^q \prod_i \Big(\frac{d_i}{L_i}\Big)^{v_i} \Big\rangle_{a,b;\mathbf{w}} \in \Big[0, \frac{(|\mathbf{w}|)_q}{q!} \langle 1\rangle_{a,b;\mathbf{w}}\Big].$$

(ii) The part of this sum over the v supported in J lies in $\big[0, \frac{(w_J)_q}{q!}\langle 1\rangle_{a,b;\mathbf{w}}\big]$, and for $q > 0$ it is positive when some letter of J sees the mark.

(iii) At $q = 1$,

$$a\,\langle 1\rangle_{a,b;\mathbf{w}} - (a+b)\,\langle x\rangle_{a,b;\mathbf{w}} - \sum_{i\notin J} w_i \Big\langle \frac{x(1-x)\,d_i}{L_i} \Big\rangle_{a,b;\mathbf{w}} = \sum_{i\in J} w_i \Big\langle \frac{x(1-x)\,d_i}{L_i} \Big\rangle_{a,b;\mathbf{w}} \in \big[0,\, w_J \langle 1\rangle_{a,b;\mathbf{w}}\big].$$

Along a sequence at the data $a_n + j$, b_n, $\mathbf{w}(n)$ the bounds hold with $\langle 1\rangle_{a_n,b_n;\mathbf{w}(n)} \geq \langle 1\rangle_{a_n+j,b_n;\mathbf{w}(n)}$ in place of the read at the moment index j, uniformly in j.

Proposition 35.13 (The finite-band polynomial)**.** *In Theorem 35.12 write $L_{J^c} = \prod_{i\notin J} L_i$. The polynomial*

$$A = \big[a - (a+b)x\big] L_{J^c} + x(1-x)\Big(\partial_x L_{J^c} - L_{J^c} \sum_{i\notin J} \frac{w_i d_i}{L_i}\Big),$$

of degree at most $h - |J| + 1$ in x, has the read

$$\langle A\rangle_{a,b;\mathbf{w}} = \sum_{i\in J} w_i \Big\langle \frac{x(1-x)\,d_i\,L_{J^c}}{L_i} \Big\rangle_{a,b;\mathbf{w}},$$

positive when a letter of J sees the mark and the reads are finite. On the half-line, $A = a\,L_{J^c} + x\,\partial_x L_{J^c} - \lambda x L_{J^c} - x L_{J^c} \sum_{i\notin J} w_i d_i/L_i$ has $\langle A\rangle^{\lambda}_{a;\mathbf{w}} = \sum_{i\in J} w_i \big\langle x\,d_i\,L_{J^c}/L_i\big\rangle^{\lambda}_{a;\mathbf{w}}$.

Theorem 35.14 (A positive sequence of Beta ports on an interval of a selected mark)**.** *In a projective chart take a selected mark at a mass $m_e \in (0,1]$, restricted to an interval $0 < \lambda_0 < \alpha_e < \lambda_1$, and write $\alpha_e = \lambda_0 + (\lambda_1 - \lambda_0)x$, $x \in [0,1]$; its letters are linear in α_e with nonnegative coefficients, $L_i = c_i + d_i x$ with $d_i \geq 0$ and $c_i \geq \lambda_0 d_i/(\lambda_1 - \lambda_0)$, and exponents $w_i \geq 0$, the letters constant in x going into the room density, and the factor $\alpha_e^{m_e - 1}$ of the mass is counted among them as the letter $\lambda_0 + (\lambda_1 - \lambda_0)x$ at the exponent $1 - m_e$. So $x(1-x)\,d_i/L_i \leq (\sqrt{\lambda_1} - \sqrt{\lambda_0})/(\sqrt{\lambda_1} + \sqrt{\lambda_0})$ on $[0,1]$ for every letter. Let $\langle 1\rangle_{1,1;\mathbf{w}}$ be finite. By Theorem 35.12(i) at $a = b = 1$ and the bound of Theorem 3.15(iii), integrated over the room, for $n \in \mathbb{N}$,*

$$0 < \big\langle (-1)^n \Pi_n^{1,1} \big\rangle_{1,1;\mathbf{w}} \leq \frac{(|\mathbf{w}|)_n}{n!} \Big(\frac{\sqrt{\lambda_1} - \sqrt{\lambda_0}}{\sqrt{\lambda_1} + \sqrt{\lambda_0}}\Big)^n \langle 1\rangle_{1,1;\mathbf{w}},$$

the first inequality when a letter sees the mark, as the letter of the mass does when $m_e < 1$.

Theorem 35.15 (The finite-band recurrence in the order of the Beta ports)**.** *At a fixed point of the room let the letters be linear, $L_i = c_i + d_i x$ with $c_i > 0$ and $d_i \geq 0$, $i = 1, \dots, h$, with exponents $w_i(n)$ depending on $n \in \mathbb{N}$, let $a_n, b_n > 0$, and in this statement write $L = \prod_i L_i = \sum_k p_k x^k$ and*

$$A_n = \big(a_n - (a_n + b_n)x\big)\, L + x(1-x)\, \partial_x L - x(1-x)\, L \sum_i \frac{w_i(n)\, d_i}{L_i}.$$

For every polynomial g, $\big\langle L\, x(1-x)\, \partial_x g + A_n g \big\rangle_{a_n, b_n; \mathbf{w}(n)} = 0$ (Theorem 35.10(a) with the polynomial Lg). Expanding $L\, x(1-x)\, \partial_x g + A_n g$ at $g = (-1)^r \Pi_r^{a_n, b_n}$ in the Beta ports $(-1)^{r+s} \Pi_{r+s}^{a_n, b_n}$ by the finite rules of Theorem 3.15(v) gives the relation

$$\sum_{s=-h-1}^{h+1} \mathfrak{b}_{n,r,s} \left\langle (-1)^{r+s} \Pi_{r+s}^{a_n, b_n} \right\rangle_{a_n, b_n; \mathbf{w}(n)} = 0$$

of width at most $2h + 3$, whose coefficients, written $\mathfrak{b}_{n,r,s}$ in this statement, are rational in n and r when a_n, b_n and the $w_i(n)$ are, and polynomial in the room data. With $|\mathbf{w}(n)| = \sum_i w_i(n)$ and $p_h = \prod_i d_i$, the furthest forward coefficient is

$$\mathfrak{b}_{n,r,h+1} = \big[|\mathbf{w}(n)| - a_n - b_n - h - r\big]\, p_h\, (-1)^{h+1} \binom{a_n + b_n + 2r - 2}{r} \Big/ \binom{a_n + b_n + 2r + 2h}{r + h + 1}.$$

Lemma 35.16 (A rational eventual sign certificate)**.** *Let $Q_n(X) = n^d q_d(X) + \sum_{k<d} n^k q_k(X)$ with polynomials q_k, and let rationals $X_1 \geq X_{\max} > 0$ and $\delta > 0$ satisfy $q_d \geq \delta$ on $[0, X_1]$. With $B_k = \sum_i \big|[X^i] q_k\big|\, X_1^i$, $Q_n \geq \delta n^d / 2$ on $[0, X_{\max}]$ for every $n \geq \max\big(1, 2 \sum_{k<d} B_k / \delta\big)$. Composition of recurrences with variable coefficients keeps its shifts: with* Sh *the shift $n \mapsto n + 1$, $\big(\sum_j b_j(n)\, \mathrm{Sh}^j\big)\big(\sum_i a_i(n)\, \mathrm{Sh}^i\big) = \sum_{i,j} b_j(n)\, a_i(n + j)\, \mathrm{Sh}^{i+j}$.*

With the room held fixed, a mark is integrated alone against its letters, and the mark relation is the integration by parts that this allows: the flux of the density $x^{a-1}(1-x)^{b-1}$ times a polynomial vanishes at both ends of the box, and that of the Gamma density at both ends of the half-line. Two uses follow. Against the Gamma density a mark of a family closes its moments into a recurrence of bounded order whose coefficients are polynomials in the room, and the derivatives in the room stay in a finite span: one mark closes all its moments. Against a Beta port the same relation gives positive reads, sums of the ratios $x(1-x)d_i/L_i$ that a letter seeing the mark keeps positive and the total exponent bounds, and at every pair $a_n, b_n > 0$ the Beta ports $\Pi_r^{a_n, b_n}$ obey a recurrence of bounded width in their order r whose furthest coefficient is explicit: when every d_i is positive it vanishes at the one order $r = |\mathbf{w}(n)| - a_n - b_n - h$ at most.

Chapter 36

The critical-line law

Let $\mathcal{E}$ have two marks, and let F be the family of the one list $\binom{\mathcal{E}}{1}$, whose bases are its two singletons, at the exponents $(1,1)$ and the masses $\mathbf{1}$ (Theorem 36.2). Its period is one, $P_F(\mathbf{1};1,1)=1$. On the fibre of the atom formula on the balance wall (Corollary 18.16), one share per basis and letter, the pins leave one free share: the basis share and the cobasis share of one basis are equal, $a=b=\frac{1}{2}+iy$, and the fibre is the line $\operatorname{Re} a=\frac{1}{2}$, the critical line. The law of y, the imaginary part of that share, is the critical-line law $\mathbb{P}_{\mathrm{crit}}$ (Definition 36.1). Its characteristic function is a stacked Gamma, its moments are rational, and its negative moments, read as finite parts, are rational multiples of the odd Trailmoments of the lattice input on the coset $\frac{1}{2}+\mathbb{Z}$ (Theorem 36.2). A function R of the share, read against an odd derivative of $\mathbb{P}_{\mathrm{crit}}$ along the critical line, gives the critical-line word $\mathrm{crit}_k[R]$ (Definition 36.3): it carries one Trailmoment of odd index with a rational part, and it is positive whenever R is the Fourier transform of a positive measure (Theorem 36.8).

Definition 36.1 (The critical-line law)**.** The *critical-line law* is the probability law $\mathbb{P}_{\mathrm{crit}}(dy)=p_{\mathrm{crit}}(y)\,dy$ on $\mathbb{R}$ with

$$p_{\mathrm{crit}}(y)=\frac{1}{2\pi}\,\Gamma_4{}_0\big[\tfrac{1}{2}+iy,\ \tfrac{1}{2}+iy,\ \tfrac{1}{2}-iy,\ \tfrac{1}{2}-iy\big]=\frac{2\pi}{(e^{\pi y}+e^{-\pi y})^2},$$

the stacked Gamma of Lemma 5.16 on the line $\operatorname{Re} a=\frac{1}{2}$ divided by 2π.

Theorem 36.2 (The critical-line law and its moments)**.** *Let $\mathcal{E}$ have two marks and let F be the family of the one list $\binom{\mathcal{E}}{1}$, whose bases are its two singletons, at the exponents $(1,1)$ and the masses $\mathbf{1}$. On the fibre of Corollary 18.16 the basis and cobasis shares of one basis are equal, $a=b=\frac{1}{2}+iy$, the fibre integral is $P_F(\mathbf{1};1,1)=1$, and the imaginary part Y of the share has the law $\mathbb{P}_{\mathrm{crit}}$. In this statement $\mathbb{E}$ is the expectation of $Y\sim\mathbb{P}_{\mathrm{crit}}$.*

(i) $\mathbb{E}[e^{i\xi Y}]$ *is the Fourier read of Lemma 5.16(iii) at $t=\xi$; every odd moment of Y vanishes and every even moment is rational.*

(ii) For $j\geq 1$ the finite part at $y=0$ (Definition 1.5) of $\mathbb{E}[Y^{-2j}]$ is

$$\begin{aligned}\operatorname{Reg}\mathbb{E}\big[Y^{-2j}\big]&=(-1)^j\,2j\,(\mathsf{T}_{2j+1;(1)}[x]\,\mathbb{I}_{\frac{1}{2}+\mathbb{Z}})((0,\infty))\\&=(-1)^j\,2j\,(2^{2j+1}-1)\,(\mathsf{T}_{2j+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty)),\end{aligned}$$

the second line by the lattice relation (Theorem 5.12(i)) at the step $q=2$, the lattice $\frac{1}{2}\mathbb{Z}$ splitting into $\mathbb{Z}$ and $\frac{1}{2}+\mathbb{Z}$.

(iii) With $X=\frac{1}{2}+iY$, $\mathbb{E}[e^{tX}]=\dfrac{te^t}{e^t-1}=t+\dfrac{t}{e^t-1}$, and $d_{m+1}\,\mathbb{E}[X^m]\in\mathbb{Z}$ for every $m\in\mathbb{N}$.

The list $\binom{\mathcal{E}}{1}$ on two marks is the smallest table with a share that moves: at the centre the pins hold its basis and cobasis shares equal, on the critical line, and the period, one, is the integral of the law $\mathbb{P}_{\mathrm{crit}}$ of their imaginary part. Everything about that law is read off the stacked Gamma $\Gamma_{\substack{4\\0}}\big[a,\ a,\ 1-a,\ 1-a\big]$ of Lemma 5.16. Its characteristic function is the stacked Gamma $\Gamma_{\substack{2\\0}}\big[1+\frac{i\xi}{2\pi},\ 1-\frac{i\xi}{2\pi}\big]$, its moments are rational with denominators bounded by the clearing integers, and its negative moments, which diverge at the origin, have finite parts that are rational multiples of the odd Trailmoments of the lattice input on the coset $\frac{1}{2}+\mathbb{Z}$, and so of the counting input.

36.1 Critical-line words

Definition 36.3 (Critical-line words)**.** For an integer $k \geq 1$ and a function R on the line $\operatorname{Re} u = \frac{1}{2}$, the *critical-line word* of order k is

$$\mathrm{crit}_k[R] = -\frac{2}{(2k)!}\,\frac{1}{2\pi i}\int_{(1/2)} \frac{R(u)}{1-2u}\,\partial_u^{2k-1}\Gamma_{\substack{4\\0}}\big[u,\ u,\ 1-u,\ 1-u\big]\,du,$$

wherever it converges; the integrand is regular at $u=\frac{1}{2}$, where the odd derivative of the stacked Gamma, which is even about $\frac{1}{2}$, vanishes. On the line, $u=\frac{1}{2}+iy$,

$$\mathrm{crit}_k[R] = \frac{(-1)^k}{(2k)!}\int_{\mathbb{R}} R(\tfrac{1}{2}+iy)\,\frac{p_{\mathrm{crit}}^{(2k-1)}(y)}{y}\,dy.$$

Proposition 36.4 (Critical-line words of polynomials)**.** *For an integer $k \geq 1$ and a polynomial $R(u) = (1-2u)\,Q(u) + R(\frac{1}{2})$, with $\mathbb{E}$ the expectation of $Y \sim \mathbb{P}_{\mathrm{crit}}$,*

$$\begin{aligned}\mathrm{crit}_k[R] &= R(\tfrac{1}{2})\,(\mathsf{T}_{2k+1;(1)}[x]\,\mathbb{I}_{\frac{1}{2}+\mathbb{Z}})((0,\infty)) + \frac{2}{(2k)!}\,\mathbb{E}\big[Q^{(2k-1)}(\tfrac{1}{2}+iY)\big]\\ &= (2^{2k+1}-1)\,R(\tfrac{1}{2})\,(\mathsf{T}_{2k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty)) + \frac{2}{(2k)!}\,\mathbb{E}\big[Q^{(2k-1)}(\tfrac{1}{2}+iY)\big],\end{aligned}$$

the second line by Theorem 5.12(i), as in Theorem 36.2(ii).

Definition 36.5 (Rows; clearing)**.** A value written as $x = \sum_{i=1}^{m} A_i v_i - B$, a rational combination of fixed real numbers v_i, its *coordinates*, such as Trailmoments of the counting input, less a rational number B, its *rational part*, has the *row* $(A_1,\dots,A_m;B)$; a positive integer *clears* the row when it makes all these coefficients integers.

Corollary 36.6 (The rational part of an integer polynomial argument)**.** *For $P \in \mathbb{Z}[x]$ of degree D and $R(u) = P(2u)$, the rational part of $\mathrm{crit}_k[R]$ (Definition 36.5) is cleared by $\frac{(2k)!}{2}\,d_{\max(1,D-2k+1)}$.*

Proposition 36.7 (Binomial moments of the critical-line law)**.** *Let $X = \frac{1}{2}+iY$ with $Y \sim \mathbb{P}_{\mathrm{crit}}$, $\mathbb{E}$ its expectation, and $H_m = (\mathsf{T}_{1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,m])$.*

(i) For complex z with $|z|<1$, $\mathbb{E}\big[(1+z)^X\big] = (1+z)\log(1+z)/z$.

(ii) $\mathbb{E}\big[\binom{X}{0}\big] = 1$ and $\mathbb{E}\big[\binom{X}{i}\big] = \dfrac{(-1)^{i+1}}{i(i+1)}$ for $i \geq 1$.

(iii) For $i \geq 1$, $\mathbb{E}\Big[\dfrac{d}{du}\dbinom{u}{i}\Big|_{u=X}\Big] = 2(-1)^i\,\dfrac{H_{i-1}-1}{i(i+1)}$. So for every polynomial $Q = \sum_i q_i\binom{u}{i}$,

$$\mathrm{crit}_1\left[(1-2u)\,Q\right] = 2\sum_{i\geq 1} q_i\,(-1)^i\,\frac{H_{i-1}-1}{i(i+1)}.$$

In the binomial basis the critical-line word of a polynomial has explicit coefficients, harmonic numbers over $i(i+1)$, whose denominators a prime q divides only to bounded powers; this is the basis in which the clearings of the critical-line words of polynomials are counted, prime by prime.

Theorem 36.8 (Positive arguments for the critical-line word)**.** *For an integer $k \geq 1$ and real t, with $\mathbb{E}$ the expectation of $Y \sim \mathbb{P}_{\mathrm{crit}}$,*

$$\mathrm{crit}_k\left[e^{t(u-\frac{1}{2})}\right] = \frac{1}{(2k)!}\int_{|t|}^{\infty} x^{2k-1}\,\mathbb{E}\big[e^{ixY}\big]\,dx > 0,$$

$$\mathrm{crit}_k[1] = (\mathsf{T}_{2k+1;(1)}[x]\,\mathbb{I}_{\frac{1}{2}+\mathbb{Z}})((0,\infty)) = (2^{2k+1}-1)\,(\mathsf{T}_{2k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty)) \quad \textit{(Theorem 5.12(i)).}$$

If $R(\frac{1}{2}+iy) = \int e^{ity}\,\phi(dt)$ for a finite nonzero positive measure ϕ on $\mathbb{R}$, then $\mathrm{crit}_k[R] = \int \mathrm{crit}_k\left[e^{t(u-\frac{1}{2})}\right]\phi(dt) > 0$.

On the critical line the word reads its argument against an odd derivative of the density of the critical-line law divided by the imaginary part of the share, a kernel without a fixed sign. Its Fourier transform, the word of an exponential argument, is the integral beyond $|t|$ of the characteristic function times a power, a positive function, so an argument that is the Fourier transform of a positive measure has a positive word. This is how positive words carrying one odd Trailmoment are made.

Theorem 36.9 (A positive rational argument with one odd index)**.** *Let $M \in \mathbb{N}$ and $p(v) = \sum_{j=0}^{D} b_j v^j \in \mathbb{Q}[v]$, nonnegative on $[0,1]$ and not identically zero, and let*

$$R_{M,p}(u) = \sum_{j=0}^{D} b_j\Big(\frac{1}{u+M+j} + \frac{1}{1-u+M+j}\Big), \qquad R_{M,p}(\tfrac{1}{2}) = 4\sum_j \frac{b_j}{2M+2j+1} > 0.$$

Then for every $k \geq 1$

$$\begin{aligned}
\mathrm{crit}_k[R_{M,p}] &= \frac{2}{(2k)!}\int_0^1\!\!\int_0^1 \frac{v^M x^{-1/2}\,p(v)\,[-\log(vx)]^{2k}}{1-vx}\,dx\,dv \\
&= R_{M,p}(\tfrac{1}{2})\,(\mathsf{T}_{2k+1;(1)}[x]\,\mathbb{I}_{\frac{1}{2}+\mathbb{Z}})((0,\infty)) \\
&\qquad - 4\sum_j \frac{b_j}{2M+2j+1}\,(\mathsf{T}_{2k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((M+j,\infty)) \\
&= (2^{2k+1}-2)\,R_{M,p}(\tfrac{1}{2})\,(\mathsf{T}_{2k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty)) \\
&\qquad + 4\sum_j \frac{b_j}{2M+2j+1}\,(\mathsf{T}_{2k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,M+j]) > 0.
\end{aligned}$$

If $Cb_j \in \mathbb{Z}$ for every j, then $C\,d_{2M+2D+1}\,d_{M+D}^{2k+1}$ clears both rational coefficients; the Trailmoments of $\mathbb{I}_{\frac{1}{2}+\mathbb{Z}}$ are read in those of $\mathbb{I}_{\mathbb{Z}}$ by Theorem 5.12(i).

Corollary 36.10 (Arguments of two Beta corners)**.** *For $p(v) = (1-v)^q$, $q \in \mathbb{N}$, the argument of Theorem 36.9 is*

$$R_{M,(1-v)^q}(u) = \Gamma\begin{matrix}2\\1\end{matrix}\!\left[\begin{matrix}u+M,\ q+1\\ u+M+q+1\end{matrix}\right] + \Gamma\begin{matrix}2\\1\end{matrix}\!\left[\begin{matrix}1-u+M,\ q+1\\ 2-u+M+q\end{matrix}\right].$$

Its words are positive and carry one Trailmoment of the counting input, of the odd index $2k+1$, at every k. For fixed M, $\mathrm{crit}_k[R_{M,(1-v)^q}] \sim \frac{4\,\Gamma(M+1)}{(2k)!}\,q^{-M-1}(\log q)^{2k}$ as $q \to \infty$.

Proposition 36.11 (Poles at the half-integers)**.** *For integers $k \geq 1$ and $l \geq 0$,*

$$\frac{1}{2\pi i}\int_{(1/2)} \frac{1}{u-\frac{1}{2}-l}\sum_{m\in\mathbb{Z}}\frac{du}{(u+m)^{2k+1}} = -(\mathsf{T}_{2k+1;(1)}[x]\,\mathbb{I}_{\frac{1}{2}+\mathbb{Z}})((l,\infty)),$$

the integrand being regular on the line at $l = 0$; and for $l \geq 1$, with the critical-line word of Definition 36.3,

$$\operatorname{crit}_k\Big[\frac{1}{u-\frac{1}{2}-l}\Big] = -\operatorname{crit}_k\Big[\frac{1}{u-\frac{1}{2}+l}\Big] = -\frac{1}{l}\,(\mathsf{T}_{2k+1;(1)}[x]\,\mathbb{I}_{\frac{1}{2}+\mathbb{Z}})((0,l]).$$

So the critical-line word of a simple pole at a half-integer other than $\frac{1}{2}$ is a head of the lattice input on the coset $\frac{1}{2}+\mathbb{Z}$, a rational number, and with Proposition 36.4 the word is read on every polynomial plus simple poles at these points. The rational arguments of Theorem 36.9 have their simple poles at the integers; the half-integers give heads and tails on the coset $\frac{1}{2}$.

Proposition 36.12 (The decay of the word of an exponential argument)**.** *For an integer $k \geq 1$ and $t > 0$, with the polynomial $c_k(t) = \sum_{l=0}^{2k} \frac{(2k)!}{l!}\,2^{2k-l+1}\,t^l$,*

$$\frac{e^{-t/2}}{(2k)!}\,c_k(t) \leq \operatorname{crit}_k\left[e^{t(u-\frac{1}{2})}\right] \leq \frac{e^{-t/2}}{(2k)!\,(1-e^{-t})}\,c_k(t).$$

A rational argument whose positive measure is the exponential profile of a polynomial nonnegative on $[0,1]$ gives a positive word with one odd Trailmoment of the counting input and a rational part cleared by $d_{2M+2D+1}d_{M+D}^{2k+1}$. The words of exponential arguments decay like $e^{-t/2}$ times a polynomial of degree $2k$, so the words of the arguments of two Beta corners decay like a power of their exponent q: they are positive, carry one Trailmoment and are controlled, the raw material of the relation blocks of Chapter 44.

Chapter 37

The gap and the shape words

A value read at rational data has a row, its coefficients on Trailmoments of the counting input and a rational part (Definition 36.5). The gap theorem turns a sequence of nonzero values whose rows are cleared by integers that grow more slowly than the values decay into irrationality, and the shape words supply such sequences. They are integrals over a cube against one letter; opened by one share they close on the stacked Gamma $\Gamma_{0}^{4}\big[a,\ a,\ 1-a,\ 1-a\big]$ of Lemma 5.16, so their rows are explicit, cleared by powers of the clearing integers d_n and carried by the Trailmoments $(\mathsf{T}_{s;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$ of index at most one more than the number of shapes. Beta ports inserted on one shape keep the words positive while they move the row, filters built from recurrences remove unwanted coordinates, and Beta ports whose order grows with the depth trade a slower decay for a selected coordinate.

37.1 Clearing and the gap

Lemma 37.1 (The growth of the clearing integers)**.** *For integers $n \geq 0$ and $s \geq 1$, d_n^s is the least positive integer D with $D\,(\mathsf{T}_{s;(1)}[x]\,f\,\mathbb{I}_{\mathbb{Z}})((0,n]) \in \mathbb{Z}$ for every integer density f, and*

$$\limsup_{n\to\infty} \frac{\log d_n}{n} \leq c_{\mathrm{lcm}} = \frac{14}{25}\log 2 + \frac{9}{25}\log 3 + \frac{1}{5}\log 5 = 1.10555\ldots < 1.106.$$

Theorem 37.2 (The gap)**.** *Let $v_1, \ldots, v_m$ be real, and let real numbers $x_n = \sum_i A_{n,i} v_i - B_n$, with $A_{n,i}, B_n \in \mathbb{Q}$, have positive integers D_n clearing all these coefficients, with $0 < |D_n x_n| \to 0$.*

(i) Some v_i is irrational.

(ii) For $m = 1$, $A_{n,1} \neq 0$ for all large n.

The hypothesis $x_n \neq 0$ holds in particular when x_n is the value of a word with a strictly positive read.

An integer of modulus below one is zero; nothing else is used. What the theory contributes is the two other hypotheses: positivity, which keeps the cleared values from vanishing, and rows whose clearing integers grow more slowly than the values decay.

37.2 Shape words with polynomial insertions

Definition 37.3 (Shape words)**.** For integers $n \geq 0$ and $k \geq 2$ let $L = \bar{x}_0 + x_0 x_1 \cdots x_k$ on the cube $[0,1]^{k+1}$ with coordinates $x_0, \ldots, x_k$. The *shape word* of depth n with k shapes of a polynomial

insertion $P \in \mathbb{Q}[x_0,\dots,x_k]$ is

$$I_n(k;P)=\int_{[0,1]^{k+1}} P(x)\,\frac{\prod_{i=0}^{k}(x_i\bar{x}_i)^n}{L^{n+1}}\,dx=\int_{[0,1]^{k+1}} P\,f_k^n\,\frac{dx}{L},\qquad f_k=\frac{\prod_{i=0}^{k}x_i\bar{x}_i}{L},$$

with the *base* f_k. For a monomial x^p, $p=(p_0,\dots,p_k)$, the *share function* is

$$g_{n,p}(a)=\frac{(n!)^{k-2}\,(1-a)_n^2\,(a)_{p_0}}{(n+1)_{p_0}\prod_{i=1}^{k}(a+p_i)_{n+1}},$$

and for $P=\sum_p\big([x^p]P\big)x^p$ it is $g_{n,P}=\sum_p\big([x^p]P\big)\,g_{n,p}$, with the coefficients $c_{n,h,s}(P)$ of its principal parts $c_{n,h,s}(P)(a+h)^{-s}$ at the poles $a=-h$ and the *column sums* $C_{n,s}(P)=\sum_h c_{n,h,s}(P)$. The *port factor* is $\mathfrak{a}_k=x_0\,x_1\bar{x}_1\,x_2\cdots x_k/L$, and $M_k(\eta)=\sup_{(0,1)^{k+1}} f_k\mathfrak{a}_k^{\eta}$ for $\eta\ge 0$.

Theorem 37.4 (Shape words: the one-share closing)**.** *Let P have degree at most D, with $p_0\le(k-2)(n+1)$ on every monomial x^p of P.*

(i) Share side. *For a monomial, on $0<\operatorname{Re}a=c<n+1$,*

$$\begin{aligned}I_n(k;x^p)&=\frac{1}{2\pi i}\int_{(c)}\Gamma\,{}_2^2\!\left[\begin{matrix}a,\ n+1-a\\ n+1\end{matrix}\right]\Gamma\,{}_2^2\!\left[\begin{matrix}a+p_0,\ n+1-a\\ n+1+p_0\end{matrix}\right]\prod_{i=1}^{k}\Gamma\,{}_2^1\!\left[\begin{matrix}a+p_i,\ n+1\\ a+p_i+n+1\end{matrix}\right]da\\&=\frac{1}{2\pi i}\int_{(c)}\Gamma\,{}_4^0\big[a,\ a,\ 1-a,\ 1-a\big]\ g_{n,p}(a)\,da.\end{aligned}$$

(ii) Closing. $I_n(k;P)=-\sum_{m\ge1}g'_{n,P}(m)$ *(Lemma 5.16(i)). Every pole of $g_{n,P}$ lies among $0,-1,\dots,-n-D$ with order at most k; the integers $1,\dots,n$ are zeros of order at least two of each $g_{n,p}$; $g_{n,p}(a)=O(|a|^{-2})$.*

(iii) The row. $C_{n,1}(P)=0$ *and*

$$\begin{aligned}I_n(k;P)&=\sum_{h=0}^{n+D}\sum_{s=1}^{k}s\,c_{n,h,s}(P)\,(\mathsf{T}_{s+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((h,\infty))\\&=\sum_{s=2}^{k}s\,C_{n,s}(P)\,(\mathsf{T}_{s+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))-\sum_{h,s}s\,c_{n,h,s}(P)\,(\mathsf{T}_{s+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,h]).\end{aligned}$$

Proposition 37.5 (An integer certificate for inserted words)**.** *In Theorem 37.4 let P have integer coefficients. Then $(n+1)_D\,d_{n+D}^{k-s}\,c_{n,h,s}(P)\in\mathbb{Z}$, and $(n+1)_D\,d_{n+D}^{k+1}$ clears every coefficient of the row, its rational part included.*

Theorem 37.6 (Integer-valued insertion clearing)**.** *In Theorem 37.4 let P have integer coefficients, let $p_{\max}$ be its largest exponent of a shape x_i, $i\ge1$, and $p_{0,\max}$ its largest exponent of x_0, and let $b_P=\operatorname{lcm}\big\{\binom{n+j}{j}:\ j$ an exponent of x_0 in $P\big\}$. Then $b_P\,d_{\max(n+p_{\max},\,p_{0,\max})}^{k-s}\,c_{n,h,s}(P)\in\mathbb{Z}$ and $b_P\,d_{\max(n+p_{\max},\,p_{0,\max})}^{k+1}$ clears the whole row, and b_P divides $d_{n+p_{0,\max}}$; insertions free of x_0 are cleared by $d_{n+p_{\max}}^{k+1}$ whatever their degrees. For $k\ge3$ the insertion x_0^n retains the top coordinate:*

$$C_{n,k}(x_0^n)=(-1)^{n(k+1)}\binom{2n}{n},\qquad\big[(\mathsf{T}_{k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))\big]\,I_n(k;x_0^n)=k\,(-1)^{n(k+1)}\binom{2n}{n}.$$

Theorem 37.7 (The exact maximum under a growing Beta port)**.** *Fix $k \ge 2$, with the base f_k and the port factor $\mathfrak{a}_k$ of Definition 37.3, so that $I_n(k;P) = \int P f_k^n \, dx/L$. For $q \in \mathbb{N}$,*

$$I_n\big(k; (-1)^q \Pi_q^{n+1,n+1}(x_1)\big) = \binom{n+q}{q} \int_{[0,1]^{k+1}} f_k^n \, \mathfrak{a}_k^q \, \frac{dx}{L} > 0.$$

For every real $\eta \ge 0$, $f_k \mathfrak{a}_k^\eta$ has a unique maximum on the open cube: with a the unique root in $0 < a < 1/(2+\eta)$ of

$$(1-2a)\big(1-(2+\eta)a\big)(1+\eta a)^{k-1} = (1+\eta)^k a^{k+2},$$

it is at $x_1 = a$, $x_2 = \cdots = x_k = \frac{(1+\eta)a}{1+\eta a}$, $x_0 = \frac{(1+\eta)a}{1-a}$, with value

$$M_k(\eta) = \frac{(1-a)^{k-2}}{(1+\eta a)^{k-1}} \, (1-2a)^{1+\eta} \, \big(1-(2+\eta)a\big),$$

and $0 < I_n\big(k; (-1)^q \Pi_q^{n+1,n+1}(x_1)\big) \le \binom{n+q}{q} M_k(q/n)^n \, I_0(k;1)$.

Proposition 37.8 (The root rate of the shape words)**.** *For $k \ge 2$:*

(i) $0 < I_n(k;1) \le M_k(0)^n \, I_0(k;1)$ (Theorem 37.7 at $q = 0$);

(ii) $\lim_n I_n(k;1)^{1/n} = M_k(0)$, where

$$M_k(0) = \max_{(0,1)^{k+1}} f_k = \max_{0<a<1} \frac{a^k (1-a)^k}{(1+a^{k/2})^2} \in \Big[\frac{4^{-k}}{(1+2^{-k/2})^2}, \; 4^{-k}\Big].$$

The maximum over a is at the root $a \in (0, \frac{1}{2})$ of $a^{k/2+1} + 2a = 1$, the root of Theorem 37.7 at $\eta = 0$. For every $k \ge 2$, $-\log M_k(0) > (k+1)\, c_{\mathrm{lcm}}$, so that $d_n^{k+1} I_n(k;1) \to 0$.

Theorem 37.9 (An irrational Trailmoment of the counting input)**.** *The shape word $I_n(2;1)$ is positive, and with $a_l = (-1)^l \binom{n}{l}\binom{n+l}{l}$, the coefficient of x^l in $(-1)^n \Pi_n^{1,1}(x)$ (Theorem 3.15(v)), and $b_l = 2a_l \sum_{j \ne l} \frac{a_j}{j-l}$,*

$$\begin{aligned} I_n(2;1) &= \sum_{l=0}^{n} \Big(2a_l^2 \, (\mathsf{T}_{3;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((l,\infty)) + b_l \, (\mathsf{T}_{2;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((l,\infty)) \Big) \\ &= 2\big(A_n \, (\mathsf{T}_{3;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((0,\infty)) - B_n \big), \\ A_n &= \sum_l a_l^2 \in \mathbb{Z}, \qquad d_n^3 B_n \in \mathbb{Z}, \end{aligned}$$

$$B_n = \sum_l a_l^2 \, (\mathsf{T}_{3;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((0,l]) + \sum_l a_l \, (\mathsf{T}_{2;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((0,l]) \sum_{j \ne l} \frac{a_j}{j-l},$$

$I_n(2;1) \le 2\, (\mathsf{T}_{3;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((0,\infty)) \, (\sqrt{2}-1)^{4n}$, and $(\mathsf{T}_{3;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((N,\infty)) \notin \mathbb{Q}$ for every integer cut $N \ge 0$.

A shape word is the cube against one letter, and one share opens the letter: the Beta corners of the shapes and of x_0 leave a single line integral of stacked Gammas, the stacked Gamma ${}_0\Gamma_4\big[a,\ a,\ 1-a,\ 1-a\big]$ times a rational share function, which closes on the positive integers. The share function has poles of order at most k at the nonpositive integers, so the row carries the Trailmoments of the counting input of index at most $k+1$ with rational parts cleared by powers

of d_{n+D}, and the coefficients of the simple poles sum to zero because the share function decays quadratically. At two shapes the row has one coordinate besides the rationals, the decay $(\sqrt{2}-1)^{4n}$ beats the clearing d_n^3, and the gap gives the irrationality of $(\mathsf{T}_{3;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((N,\infty))$ at every integer cut N. With more shapes the decay still beats the clearing, but the row carries several coordinates, and the filters and the growing Beta ports select one (Proposition 37.18, Theorem 37.19).

37.3 Rows

Proposition 37.10 (The row of a closing in rational terms)**.** *Let a closing give $x_n = \sum_{t\ge t_0} r_n(t)$, the sum over the integers $t \ge t_0$, with $r_n(t) = \sum_{k,s} \tilde{c}_{n,k,s}(t+k)^{-s} = O(t^{-2})$, $\tilde{c}_{n,k,s} \in \mathbb{Q}$, integer pole positions and $h_k = t_0 + k - 1 \ge 0$. With $\tilde{C}_{n,s} = \sum_k \tilde{c}_{n,k,s}$,*

$$x_n = \sum_{k,s} \tilde{c}_{n,k,s}\,(\mathsf{T}_{s;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((h_k,\infty)) = \sum_{s\ge 2} \tilde{C}_{n,s}\,(\mathsf{T}_{s;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty)) - B_n,$$

$$B_n = \sum_{k,s} \tilde{c}_{n,k,s}\,(\mathsf{T}_{s;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,h_k]),$$

the index-one Trailmoments regularized, and $D_n = \operatorname{lcm}_{k,s}\left(\operatorname{den}(\tilde{c}_{n,k,s})\,d_{h_k}^{s}\right)$ clears the row.

Proposition 37.11 (The primitive row)**.** *For a nonzero rational pair (A,B), a common clearing integer D and $g = \gcd(DA,DB)$, the pair $g^{-1}(DA,DB) \in \mathbb{Z}^2$ is, up to sign, independent of D and of every nonzero rational rescaling of (A,B), and with $(a,b) = g^{-1}(DA,DB)$, $av - b = (D/g)(Av - B)$ for every real v.*

Corollary 37.12 (The top-index criterion)**.** *Let $k \ge 3$, and suppose there are integer polynomials P_n of degree at most a fixed D with $C_{n,s}(P_n) = 0$ for $2 \le s < k$ and $I_n(k;P_n) > 0$ for all large n, P_n possibly changing sign on the cube. If the sums $\|P_n\|_1$ of the absolute values of the coefficients of P_n satisfy*

$$\limsup_n \frac{1}{n}\log\|P_n\|_1 < -\log M_k(0) - (k+1)\limsup_n \frac{1}{n}\log d_n,$$

then $(\mathsf{T}_{k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((N,\infty)) \notin \mathbb{Q}$ for every integer cut $N \ge 0$.

A closing in rational terms has a row whose clearing is read off its pole positions and orders, and a row is a primitive integer pair up to the clearing. With k shapes the row of $I_n(k;P)$ carries $(\mathsf{T}_{3;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty)),\dots,(\mathsf{T}_{k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$; an insertion that kills the lower column sums and keeps the word positive at a cost below the margin between the decay and the clearing separates $(\mathsf{T}_{k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$. The insertion may change sign: positivity is asked of the word, not of the insertion.

37.4 The Beta port ladder and the filters

Theorem 37.13 (The Beta port ladder of the shape words)**.** *For the shape word with $k \ge 2$ shapes at depth $n \ge 1$ write its letter as $L = \bar{x}_0 + x_0x_2\cdots x_k\,x_1$, and in this statement write $P_r = (-1)^r\Pi_r^{n+1,n+1}(x_1)$, $g_{n,r} = g_{n,P_r}$ and $g_n = g_{n,0}$, the share function of the insertion 1 (Definition 37.3).*

(i) $0 < I_n(k;P_r) \le \binom{n+r}{r} I_n(k;1)$ *(Theorem 37.7, the port factor being at most one).*

(ii) $g_{n,r}(a) = \binom{n+r}{r}\dfrac{(n+1-a)_r}{(n+1+a)_r}\,g_n(a)$ *with* $g_n(a) = \dfrac{(n!)^{k-2}(1-a)_n^2}{(a)_{n+1}^k}$, *and with* $b = n+r+1$, $(r+1)(a+b)\,g_{n,r+1}(a) = b\,(b-a)\,g_{n,r}(a)$.

(iii) For a function φ *on the integers and a finite set* $\mathcal{M}$ *of positive integers write* $S_{n,r}[\varphi] = \sum_{m\in\mathcal{M}} g_{n,r}(m)\varphi(m)$ *and* $S'_{n,r}[\varphi] = -\sum_{m\in\mathcal{M}} g'_{n,r}(m)\varphi(m)$, *the sums over the common finite set* $\mathcal{M}$, *with functions of the summation variable* m *inside the brackets. Then, with* $b = n+r+1$,

$$(r+1)\,S'_{n,r+1}\big[(m+b)\varphi\big] = b\,S'_{n,r}\big[(b-m)\varphi\big] + (r+1)\,S_{n,r+1}[\varphi] + b\,S_{n,r}[\varphi].$$

(iv) $\dfrac{g_{n+1,r}(a)}{g_{n,r}(a)} = \dfrac{(n+1)^{k-3}(n+r+1)(n+1-a)(n+r+1-a)}{(a+n+1)^{k-1}(a+n+r+1)}$, *and with* $U(m) = (m+n+1)^{k-1}(m+n+r+1)$ *and* $V(m) = (n+1)^{k-3}(n+r+1)(n+1-m)(n+r+1-m)$,

$$S_{n+1,r}[U\varphi] = S_{n,r}[V\varphi], \qquad S'_{n+1,r}[U\varphi] - S_{n+1,r}[U'\varphi] = S'_{n,r}[V\varphi] - S_{n,r}[V'\varphi].$$

(v) For $0 \le r \le h$ *the insertions* P_r *have degree at most* h, *their rows are cleared by* d_{n+h}^{k+1} *(Theorem 37.6), and their positive reads cost at most* $\binom{n+h}{h}$ *times the base word* $I_n(k;1)$.

(vi) In the selected mark x_1 *the furthest forward coefficient of Theorem 35.15, for the one letter* L *of exponent* $n+1$, *is nonzero on the open cube.*

Proposition 37.14 (The insertion index supplies auxiliary states)**.** *Fix* $k \ge 3$ *and* $n \ge 1$ *and, in this statement, write* $P_r = (-1)^r \Pi_r^{n+1,n+1}(x_1)$, *an insertion of the shape word with* k *shapes. As functions of* r, $C_{n,k}(P_r) \in \mathbb{Q}[r]$ *and* $C_{n,k-1}(P_r) = -2\,(\mathsf{T}_{1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,n+r])\,C_{n,k}(P_r) + q_n(r)$ *with* $q_n \in \mathbb{Q}(r)$. *Consequently a scalar finite shift recurrence over* $\mathbb{Q}(r)$ *annihilating* $C_{n,k-1}(P_r)$ *for all large* r *also annihilates* $C_{n,k}(P_r)$.

Proposition 37.15 (The shape step is a two-state operator relation)**.** *For* $k \ge 2$ *and* $n \ge 0$ *let* g_n *be the share function of the insertion* 1, $g_n(a) = (n!)^{k-2}(1-a)_n^2/(a)_{n+1}^k$, *and for integer cuts* $0 \le N_0 < N_1$ *write* $S_n[\varphi] = \sum_{N_0<m\le N_1} g_n(m)\varphi(m)$ *and* $S'_n[\varphi] = -\sum_{N_0<m\le N_1} g'_n(m)\varphi(m)$. *Then*

$$\begin{aligned} S_{n+1}\big[(m+n+1)^k\varphi\big] &= (n+1)^{k-2}\,S_n\big[(m-n-1)^2\varphi\big], \\ S'_{n+1}\big[(m+n+1)^k\varphi\big] &= k\,S_{n+1}\big[(m+n+1)^{k-1}\varphi\big] + (n+1)^{k-2}\,S'_n\big[(m-n-1)^2\varphi\big] \\ &\quad - 2(n+1)^{k-2}\,S_n\big[(m-n-1)\varphi\big], \end{aligned}$$

and the same holds over all $m > N_0$ *whenever the sums converge one by one: for bounded* φ, *when* $(k-2)(n+1) > 1$ *in the first identity and* $(k-2)(n+1) > 0$ *in the second.*

Proposition 37.16 (A polynomial filter from a bounded local recurrence)**.** *Let unwanted closing coefficients satisfy* $c_{n,j} = \ell(n)\,y_{n,j}$ *and* $y_{n+1,j} = \mathbf{A}(n)\,y_{n,j}$, $1 \le j \le r$, *with state vectors* $y_{n,j}$ *of a fixed length* h, *a* $1\times h$ *matrix* $\ell(n)$ *and an* $h\times h$ *matrix* $\mathbf{A}(n)$ *over* $\mathbb{Q}(n)$. *Write* $\mathbf{A} = \widehat{\mathbf{A}}/q$ *and* $\ell = \hat{\ell}/s$ *with integer polynomial matrices* $\widehat{\mathbf{A}}$, $\hat{\ell}$ *and integer polynomials* q, s, *put* $\mathbf{A}^{[0]} = I$, $\mathbf{A}^{[i]}(n) = \mathbf{A}(n+i-1)\cdots\mathbf{A}(n)$, $Q(n) = \prod_{t=0}^{h-1} q(n+t)\prod_{t=0}^{h} s(n+t)$ *and the* $1\times h$ *matrices* $\mathbf{r}_i(n) = Q(n)\,\ell(n+i)\,\mathbf{A}^{[i]}(n)$, $0 \le i \le h$. *If the* $\mathbf{r}_i$ *span* $\mathbb{Q}(n)^{1\times h}$ *and* $a_i(n)$ *is* $(-1)^i$ *times the determinant of the* $h\times h$ *matrix stacking the* $\mathbf{r}_{i'}$, $i' \ne i$, *in order, then the* a_i *are integer polynomials, not all zero, and*

$$\sum_{i=0}^{h} a_i(n)\,c_{n+i,j} = 0 \qquad (1 \le j \le r)$$

away from the integer zeros of the denominators; a target sequence x_n is retained at n exactly when $\sum_i a_i(n)\,x_{n+i} \neq 0$. With $D_{\mathbf{A}} = \max(\deg \widehat{\mathbf{A}}, \deg q)$, $D_s = \deg s$ and $D_\ell = \deg \hat{\ell}$: $\deg a_i \leq h(hD_{\mathbf{A}} + hD_s + D_\ell)$. For two states, with $\ell = (1,0)$ and $\mathbf{A} = (\beta_{il})$, the filter is $\beta_{12}c_{n+2} - (\beta_{11}^{+}\beta_{12} + \beta_{12}^{+}\beta_{22})c_{n+1} + \beta_{12}^{+}\det \mathbf{A}(n)\,c_n = 0$, $\beta_{il}^{+} = \beta_{il}(n+1)$; for one state, $q(n)c_{n+1} = p(n)c_n$ gives the filter $q(n)\,\mathrm{Sh} - p(n)$, Sh the shift $n \mapsto n+1$.

Proposition 37.17 (The finite jet recurrence)**.** *If a state has the recurrence $U_{n+1}(\varepsilon) = \mathbf{A}(n,\varepsilon)\,U_n(\varepsilon)$, regular at $\varepsilon = 0$, then with $U_n(\varepsilon) = \sum_j U_{n,j}\varepsilon^j$ and $\mathbf{A}(n,\varepsilon) = \sum_j \mathbf{A}_j(n)\varepsilon^j$, $U_{n+1,j} = \sum_{i=0}^{j} \mathbf{A}_i(n)\,U_{n,j-i}$ for $0 \leq j \leq J$: a lower block-triangular recurrence for the jets of order at most J, with diagonal blocks $\mathbf{A}_0(n)$.*

Proposition 37.18 (A recurrence filters the positive word)**.** *Let $x_n = \int X^n\,d\mu$ with $0 < X \leq X_{\max} < 1$ on the support of a finite positive measure μ, and $x_n = \sum_{j=1}^{r} \tilde{C}_{n,j}v_j - B_n$ with $\tilde{C}_{n,j}, B_n \in \mathbb{Q}$. Let $a_0(n), \dots, a_h(n) \in \mathbb{Z}[n]$, $Q_n(X) = \sum_i a_i(n)X^i$ and $\tilde{x}_n = \sum_i a_i(n)\,x_{n+i}$, and suppose that for all large n, $\sum_i a_i(n)\tilde{C}_{n+i,j} = 0$ for $j \neq j_*$ and Q_n has one sign on the support of μ, strictly on a set of positive measure. Then $\tilde{x}_n = \int X^n Q_n\,d\mu = A_n v_{j_*} - \sum_i a_i(n)B_{n+i}$ with $A_n = \sum_i a_i(n)\tilde{C}_{n+i,j_*}$, and $0 < |\tilde{x}_n| \leq O(n^{\max_i \deg a_i})\,X_{\max}^n \mu(\mathbb{R})$. If positive integers $D_{n,h}$ clear the rows of $x_n, \dots, x_{n+h}$, and $\limsup_n \frac{1}{n}\log D_{n,h} < -\log X_{\max}$, then $v_{j_*} \notin \mathbb{Q}$ and $A_n \neq 0$ for all large n. The sign of Q_n on $(0, X_{\max}]$ is certified when $Q_n(X) = \sum_{l=0}^{h} \beta_l(n)X^l(X_1 - X)^{h-l}$ for a rational $X_1 > X_{\max}$ with all $\beta_l(n) \geq 0$ and one of them positive.*

The Beta ports of one shape move the row of a shape word along a ladder: the share function of the Beta port of order $r+1$ is that of order r times a rational factor, so the sums over a common finite set of integers satisfy finite operator relations in the order of the Beta ports and in the depth. Unwanted coordinates whose coefficients follow a bounded local recurrence in the depth are annihilated by a filter with integer polynomial coefficients, read off the determinants of that recurrence, and jets in a regulator follow a block-triangular recurrence with the same diagonal. A filter applied to a positive word stays positive as long as its polynomial keeps one sign on the support of the word's measure, which a nonnegative expansion in the products $X^l(X_1 - X)^{h-l}$ certifies, and then the filtered word separates the coordinate it keeps, at the cost of clearing the rows of $h+1$ consecutive values.

37.5 Growing Beta ports

Theorem 37.19 (An arithmetic budget for growing Beta ports)**.** *For $k \geq 2$, $\eta > 0$ and $q_n = \lfloor \eta n \rfloor$, in this statement write $\ell_k(\eta) = \log M_k(\eta) + (1+\eta)\log(1+\eta) - \eta\log\eta$. Then*

$$\lim_n \frac{1}{n}\log I_n\big(k; (-1)^{q_n}\Pi_{q_n}^{n+1,n+1}(x_1)\big) = \ell_k(\eta),$$

$$\limsup_n \frac{1}{n}\log\Big(d_{n+q_n}^{k+1}\, I_n\big(k; (-1)^{q_n}\Pi_{q_n}^{n+1,n+1}(x_1)\big)\Big) \leq \ell_k(\eta) + (k+1)(1+\eta)\,c_{\mathrm{lcm}}.$$

The integer $d_{n+q_n}^{k+1}$ clears the whole row, which stays on the coordinates $(\mathsf{T}_{3;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$, …, $(\mathsf{T}_{k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$ and a rational part, and the coefficient of $(\mathsf{T}_{k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$ is

$$k\binom{n+q_n}{q_n}\sum_{j=0}^{n}(-1)^{jk}\binom{n}{j}^k\binom{n+j}{n}^2\frac{(n+1+j)_{q_n}}{(n+1-j)_{q_n}},$$

positive for even k.

Corollary 37.20 (A growing Beta port with a certified gap)**.** *For every $k \geq 2$ there is a rational $\eta_0 > 0$ such that $\ell_k(\eta) + (k+1)(1+\eta)\, c_{\mathrm{lcm}} < 0$ for every rational $\eta \in (0, \eta_0]$ (Theorem 37.19), the root of Theorem 37.7 at each such η being certified as a root of an integer polynomial in a rational interval. So with $q_n = \lfloor \eta n \rfloor$ the positive words $I_n\big(k; (-1)^{q_n} \Pi_{q_n}^{n+1,n+1}(x_1)\big)$ satisfy*

$$\limsup_n \frac{1}{n} \log \Big(d_{n+q_n}^{k+1}\, I_n\big(k; (-1)^{q_n} \Pi_{q_n}^{n+1,n+1}(x_1)\big)\Big) < 0,$$

on the fixed coordinates $(\mathsf{T}_{3;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$, …, $(\mathsf{T}_{k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$ and a rational part, with a positive coefficient of $(\mathsf{T}_{k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$ when k is even.

A Beta port whose order grows in proportion to the depth pulls the word toward the port factor: the word decays at the maximum value $M_k(\eta)$ of $f_k \mathfrak{a}_k^{\eta}$, the binomial of the Beta port adds its entropy $(1+\eta)\log(1+\eta) - \eta \log \eta$, and the clearing grows to $d_{n+q_n}^{k+1}$. Where the sum is negative the cleared words tend to zero on a fixed set of coordinates, and for even k the top coordinate keeps a positive coefficient. For every number of shapes the margin is positive at small rational ratios, by continuity from the base word (Proposition 37.8), each certified by an explicit algebraic root, and the cleared positive words decay exponentially on the coordinates $(\mathsf{T}_{3;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty)), \ldots, (\mathsf{T}_{k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$ with a rational part.

Part VII

Rays

Chapter 38

Rays, native gauges and tiers

A ray moves the data of a family along an integral direction. Along it the values of every insertion obey two relations, integration by parts in every mark and the shift by the stride, wherever the integrals converge and, when the walls of the direction are positive, at every strength as identities of meromorphic functions; these relations make the values a holonomic sequence: they satisfy a recurrence of order at most the dimension of the ray. The complex points at which the direction is native, the native gauges of the ray, carry formal solutions of the relations and bound the dimension from below, and the frame of any recurrence is a power times a stacked Gamma. Every ray with real origin is one function, carried by a pencil, with a branch at the native gauge of its direction, and on the centre ray of a family every sign is a candidate native gauge; a ray along a wall carries the product of the rays of its two faces. What a value can contain is bounded: finitely many values span every value along a ray, and a closing in rational terms carries Trailmoments of index at most the largest order of its poles (Theorem 38.31, Lemma 38.32). A ray is a line of the data space of its family, and its module is the module of the family (Chapter 47) restricted to that line (Proposition 47.5).

38.1 The relations along a ray

Definition 38.1 (Ray, stride, insertions, values)**.** Let F be a family on $\mathcal{E}$. A *ray* of F is the sequence of data $(\mathbf{m}_0 + k\mathbf{m}_1;\ \mathbf{s}_0 + k\mathbf{s}_1;\ \mathbf{t}_0 + k\mathbf{t}_1)$, $k \in \mathbb{N}$, the points at the integer times of the half-line from its *origin* $(\mathbf{m}_0; \mathbf{s}_0, \mathbf{t}_0)$, which is complex, along its *direction* $(\mathbf{m}_1; \mathbf{s}_1, \mathbf{t}_1)$, which is integral, $\mathbf{m}_1 \in \mathbb{Z}^{\mathcal{E}}$ and $s_{1j}, t_{1j} \in \mathbb{N}$, both on the balance wall; the walls along it are $\kappa_{0,S} + k\kappa_{1,S}$, with $\kappa_{0,S}$ and $\kappa_{1,S}$ the walls of the origin and of the direction. On the chart $y_{e_0} = 0$ of a fixed mark e_0, with $dy = \prod_{e \neq e_0} d\alpha_e/\alpha_e$, the *stride* and the *origin form* are

$$f = \alpha^{\mathbf{m}_1} \prod_j K_j^{-s_{1j}} \Psi_j^{-t_{1j}}, \qquad \omega_0 = \alpha^{\mathbf{m}_0} \prod_j K_j^{-s_{0j}} \Psi_j^{-t_{0j}}\, dy,$$

f a rational function of degree 0. The *letter complement* of F is $X_F = \{\alpha \in (\mathbb{C}^\times)^{\mathcal{E}}/\mathbb{C}^\times : K_j(\alpha)\Psi_j(\alpha) \neq 0 \text{ for every } j\}$, and the insertions along the ray are its regular functions, the algebra $\mathbb{C}[X_F]$, which is generated by the monomials α^v, $v \in \mathbb{Z}^{\mathcal{E}}$ with $v_{\mathcal{E}} = 0$, and the chances of the bases under the basis and cobasis laws, $\alpha \mapsto \mathbb{P}_{j,\alpha}(T) = \theta_{j,T}\alpha^T/K_j(\alpha)$ and $\alpha \mapsto \mathbb{P}^*_{j,\alpha}(T) = \theta_{j,T}\alpha^{\mathcal{E}\setminus T}/\Psi_j(\alpha)$, $T \in \mathcal{B}_j$. The *values* along the ray are $\langle g\rangle_k = \int_{y_{e_0}=0} g\, f^k \omega_0$ for $g \in \mathbb{C}[X_F]$, and over a compact real $(n-1)$-dimensional chain D in X_F, $\langle g\rangle_{k;D} = \int_D g\, f^k \omega_0$. The *defects* of the

origin and of the direction are the masses less the usages,

$$c_e^{(i)} = m_{i,e} - \sum_j \big(s_{ij} R_{j,e} + t_{ij} R_{j,e}^*\big), \qquad i = 0, 1,$$

with the occupation $R_{j,e}$ and the dual occupation $R_{j,e}^*$ of table j (Theorem 7.16).

Lemma 38.2 (Insertions)**.** *(i) $\mathbb{C}[X_F]$ is closed under every ∂_{y_e}: $\partial_{y_e}\alpha^v = v_e\alpha^v$, $\partial_{y_e}\mathbb{P}_{j,\alpha}(T) = (\mathbf{1}_T(e) - R_{j,e})\,\mathbb{P}_{j,\alpha}(T)$ and $\partial_{y_e}\mathbb{P}^*_{j,\alpha}(T) = (\mathbf{1}_{\mathcal{E}\setminus T}(e) - R^*_{j,e})\,\mathbb{P}^*_{j,\alpha}(T)$; the occupations and the defects lie in $\mathbb{C}[X_F]$.*

(ii) The stride lies in $\mathbb{C}[X_F]$, and $c_e^{(1)} = \partial_{y_e}\log f$, $c_e^{(0)} + k\,c_e^{(1)} = \partial_{y_e}\log(f^k\omega_0/dy)$.

(iii) Every value $\langle g\rangle_k$ is a finite combination, with products of weights as coefficients, of periods P_F at data $(\mathbf{m}_0 + k\mathbf{m}_1 + v;\ \mathbf{s}_0 + k\mathbf{s}_1 + \mathbf{a};\ \mathbf{t}_0 + k\mathbf{t}_1 + \mathbf{b})$ on the balance wall, $v \in \mathbb{Z}^{\mathcal{E}}$ and $\mathbf{a}, \mathbf{b} \in \mathbb{N}^N$.

Theorem 38.3 (The relations along a ray)**.** *If $\kappa_{1,S} > 0$ for every nonempty proper S, then for every insertion g the value $\langle g\rangle_k$ converges for all large k, and for every mark e*

$$\big\langle \big(c_e^{(0)} + k\,c_e^{(1)} + \partial_{y_e}\big)g\big\rangle_k = 0, \qquad \langle fg\rangle_k = \langle g\rangle_{k+1}.$$

In Theorem 38.3 the first relation is integration by parts in the mark e against the form $f^k\omega_0$, whose logarithmic derivative is the defect; the second is the definition of the stride. Proposition 38.5 carries both to every strength: wherever the integrals converge, whatever the walls of the direction, and, when these walls are positive, as identities of meromorphic functions of k. Both act on the insertions, which are closed under the derivatives, so the values of all insertions along a ray form one module over the operators in k, and every relation among insertions modulo these two is a recurrence among values.

38.2 Native gauges carry solutions

Definition 38.4 (Native gauges of a ray; the dimension)**.** A *native gauge* of a ray is a point α_c of X_F at which the direction is native, $c^{(1)}(\alpha_c) = 0$: a native gauge of the direction at a complex point (Definition 8.17); its *native value* is $f(\alpha_c)$, and it is *nondegenerate* when the Hessian of $\log f$ in y modulo $\mathbb{C}\mathbf{1}$ is nonsingular there. Near a nondegenerate native gauge there are holomorphic coordinates $v \in \mathbb{C}^{n-1}$ with $\log f = \log f(\alpha_c) - \frac{1}{2}\sum_i v_i^2$; the image D_c of a real ball $\{v \in \mathbb{R}^{n-1} : |v| \le \varepsilon\}$ is a *steepest-descent disc*. The *relation space* $\mathcal{L} \subseteq \mathbb{C}[X_F] \otimes \mathbb{C}(k)$ is the $\mathbb{C}(k)$-span of the elements $(c_e^{(0)} + k\,c_e^{(1)} + \partial_{y_e})g$, and the *dimension* of the ray is $\dim_{\mathbb{C}(k)}\big(\mathbb{C}[X_F] \otimes \mathbb{C}(k)\big)/\mathcal{L}$.

Proposition 38.5 (The relations at every strength)**.** *Let a ray of a family F be given. For an insertion $g = \alpha^u \prod_j K_j^{-a_j}\Psi_j^{-b_j}$ with $u \in \mathbb{Z}^{\mathcal{E}}$, $\mathbf{a}, \mathbf{b} \in \mathbb{N}^N$ and $u_{\mathcal{E}} = \sum_j (a_j r_j + b_j r_j^*)$, such insertions spanning $\mathbb{C}[X_F]$, write $\kappa_U(g) = u_U - \sum_j \big(a_j d_j(U) + b_j d_j^*(U)\big)$ for the walls of its data $(u; \mathbf{a}, \mathbf{b})$ (Definition 8.1).*

(i) Whatever the walls of the direction, at every complex k with $\operatorname{Re}\kappa_{0,U} + \kappa_U(g) + \operatorname{Re}(k)\,\kappa_{1,U} > 0$ for every nonempty proper U the values $\langle g\rangle_k$ and $\big\langle (c_e^{(0)} + k\,c_e^{(1)} + \partial_{y_e})g\big\rangle_k$ converge absolutely, and the second is 0 for every mark e. So if polynomials $p_0, \dots, p_h \in \mathbb{C}[k]$, an insertion g' and finite combinations G_e of insertions of the above kind, with coefficients in $\mathbb{C}(k)$, satisfy

$$\sum_{j=0}^{h} p_j(k)\, f^j g' = \sum_{e\in\mathcal{E}} \big(c_e^{(0)} + k\,c_e^{(1)} + \partial_{y_e}\big)G_e,$$

an explicit element of the relation space $\mathcal{L}$ (Definition 38.4), a certificate *of the recurrence, then $\sum_j p_j(k)\langle g'\rangle_{k+j} = 0$ at every k off the poles of those coefficients at which the values $\langle g'\rangle_{k+j}$ converge absolutely and the condition above holds for every insertion in the G_e.*

(ii) If $\kappa_{1,S} > 0$ for every nonempty proper S, every value $\langle g\rangle_k$ continues to a meromorphic function of $k \in \mathbb{C}$, whose poles have order at most $n-1$ and lie among the k with $\kappa_{0,U} + \kappa_U(g) + k\,\kappa_{1,U} \in \{0, -1, -2, \dots\}$ for some nonempty proper U. For every element $\sum_l r_l(k)\, g_l$ of $\mathcal{L}$ the continuation of $\sum_l r_l(k)\langle g_l\rangle_k$ vanishes identically, and $\langle fg\rangle_k = \langle g\rangle_{k+1}$ identically. So a recurrence $\sum_j p_j(k)\langle g\rangle_{k+j} = 0$ that follows from the relations, its element $\sum_j p_j(k) f^j g$ lying in $\mathcal{L}$, holds as an identity of meromorphic functions of k, and at every k at which its terms converge.

Theorem 38.6 (A native gauge carries a solution)**.** *Let α_c be a nondegenerate native gauge of a ray and D_c a steepest-descent disc through it.*

(i) As $k \to \infty$,

$$\langle g\rangle_{k;D_c} \sim f(\alpha_c)^k\, k^{-(n-1)/2} \sum_{i\geq 0} a_i(g)\, k^{-i},$$

where $a_0(g) = (2\pi)^{(n-1)/2}(\omega_0/dv)(\alpha_c)\, g(\alpha_c)$ with $(\omega_0/dv)(\alpha_c) \neq 0$, and each $a_i(g)$ is a finite combination of Taylor coefficients of $g\,\omega_0/dv$ and of $\log f$ at α_c. Further $\langle fg\rangle_{k;D_c} = \langle g\rangle_{k+1;D_c}$, and $\big\langle (c_e^{(0)} + k\, c_e^{(1)} + \partial_{y_e})g\big\rangle_{k;D_c}$ is at most a constant times $|f(\alpha_c)|^k e^{-k\varepsilon^2/2}$; so the expansions satisfy both relations to all orders.

(ii) For a finite set C of distinct nondegenerate native gauges α_c, the maps $A^{(c)} : \mathbb{C}[X_F] \otimes \mathbb{C}(k) \to \mathbb{C}((1/k))$, $g \mapsto \sum_l a_l^{(c)}(g)\, k^{-l}$, extended $\mathbb{C}(k)$-linearly, vanish on $\mathcal{L}$ and are linearly independent over $\mathbb{C}((1/k))$.

(iii) The dimension of the ray is at least the number of its nondegenerate native gauges.

Corollary 38.7 (The symbol)**.** *Let g be an insertion and $p_0, \dots, p_h \in \mathbb{C}[k]$, not all zero, with $\sum_j p_j(k)\, f^j g \in \mathcal{L}$. Under the hypothesis of Theorem 38.3, $\sum_j p_j(k)\, \langle g\rangle_{k+j} = 0$ for all large k. With d the largest degree of the p_j and c_j the coefficient of k^d in p_j, the* symbol $\sum_j c_j \lambda^j$ *vanishes at the native value of every nondegenerate native gauge α_c with $g(\alpha_c) \neq 0$. So h is at least the number of distinct native values of such native gauges.*

Proposition 38.8 (The top and the bottom of a certificate)**.** *Let g be an insertion and $\sum_{j=0}^h p_j(k)\, f^j g = \sum_e \big(c_e^{(0)} + k\, c_e^{(1)} + \partial_{y_e}\big) G_e$ a certificate (Proposition 38.5(i)) in which the $p_j \in \mathbb{C}[k]$ have the largest degree $d \geq 1$ and every $G_e = \sum_{i<d} k^i\, G_e^{[i]}$ is a polynomial in k of degree less than d with coefficients $G_e^{[i]} \in \mathbb{C}[X_F]$. With c_j the coefficient of k^d in p_j and the symbol $\chi(\lambda) = \sum_j c_j \lambda^j$ (Corollary 38.7),*

$$\chi(f)\, g = \sum_e c_e^{(1)}\, G_e^{[d-1]}, \qquad \sum_{j=0}^h p_j(0)\, f^j g = \sum_e \big(c_e^{(0)} + \partial_{y_e}\big) G_e^{[0]}.$$

So χ vanishes at the native value of every native gauge α_c of the ray with $g(\alpha_c) \neq 0$, nondegenerate or not, and for the origin 0 the bottom piece $\sum_j p_j(0) f^j g$ is the divergence $\sum_e \partial_{y_e} G_e^{[0]}$.

Proposition 38.9 (The native value bounds the order)**.** *Let a ray of a family have $\kappa_{1,S} > 0$ for every nonempty proper S. Then $\langle 1\rangle_k \neq 0$ for all large k, positive when the origin is real, and $\langle 1\rangle_{k+1}/\langle 1\rangle_k \to f(\alpha^\star)$, the native value of the native gauge $\alpha^\star$ of the direction on $\mathbb{R}^{\mathcal{E}}_{>0}$, which is the*

largest value of f there. If $\sum_{j=0}^{h} p_j(k)\,\langle 1\rangle_{k+j} = 0$ for all large k, with $p_j \in \mathbb{Q}[k]$ not all zero, then the symbol vanishes at $f(\alpha^\star)$: $f(\alpha^\star)$ is algebraic, $h \geq [\mathbb{Q}(f(\alpha^\star)) : \mathbb{Q}]$, and every conjugate of $f(\alpha^\star)$ is a root of the symbol. In particular, when $f(\alpha^\star)$ is irrational the values $\langle 1\rangle_k$ satisfy no recurrence of order one over $\mathbb{Q}(k)$, and when it is transcendental none at all.

Proposition 38.10 (The conjugates of the native value of the direction)**.** *Let a ray of a family whose weights lie in a subfield $\Bbbk$ of $\mathbb{C}$ have $\kappa_{1,S} > 0$ for every nonempty proper S, and let $\alpha^\star$ be the native gauge of its direction on the positive orthant, $\alpha^\star_{e_0} = 1$. Then the coordinates of $\alpha^\star$ are algebraic over $\Bbbk$, and for every embedding τ of $\Bbbk(\alpha^\star)$ in $\mathbb{C}$ over $\Bbbk$ the point $\tau(\alpha^\star)$ is a nondegenerate native gauge of the ray, of native value $\tau\big(f(\alpha^\star)\big)$. So every conjugate of $f(\alpha^\star)$ over $\Bbbk$ is the native value of a nondegenerate native gauge, the dimension of the ray is at least $[\Bbbk(\alpha^\star) : \Bbbk]$, and the symbol of every recurrence for $\langle 1\rangle_k$ that follows from the relations vanishes at every conjugate of $f(\alpha^\star)$.*

Proposition 38.11 (The frame of a recurrence is a power times a stacked Gamma)**.** *Let $\sum_{j=0}^{h} p_j(k)\,x_{k+j} = 0$ for $k \geq k_0$, with $p_j \in \mathbb{C}[k]$ and p_0, p_h without zeros at the integers $k \geq k_0$, and let $x^{(1)}, \dots, x^{(h)}$ be solutions. Their* frame *$C_k = \det\big[x^{(i)}_{k+l}\big]_{1\leq i\leq h,\ 0\leq l<h}$ satisfies $C_{k+1} = (-1)^h \frac{p_0(k)}{p_h(k)}\,C_k$, and writing $\frac{p_0(k)}{p_h(k)} = c\,\frac{\prod_{i=1}^{\deg p_0}(k-a_i)}{\prod_{i=1}^{\deg p_h}(k-b_i)}$,*

$$C_k = C_{k_0}\big((-1)^h c\big)^{k-k_0}\,\Gamma_{\substack{\deg p_0\\ \deg p_h}}\begin{bmatrix} k-a_1,\ \dots \\ k-b_1,\ \dots \end{bmatrix}\Big/\Gamma_{\substack{\deg p_0\\ \deg p_h}}\begin{bmatrix} k_0-a_1,\ \dots \\ k_0-b_1,\ \dots \end{bmatrix}.$$

The tier *of a sequence over a field $\Bbbk \subseteq \mathbb{C}$ is the least order of a recurrence with coefficients in $\Bbbk[k]$ and $p_0 p_h \neq 0$ that it satisfies for large k; a sequence of tier one is a power times a stacked Gamma, and so is every frame.*

Proposition 38.12 (The growth of the frame)**.** *In Proposition 38.11 let $C_{k_0} \neq 0$, let d_0 and d_h be the degrees of p_0 and p_h, and let c be the quotient of their leading coefficients. As $k \to \infty$,*

$$\log|C_k| = k\log|c| + (d_0 - d_h)(k\log k - k) + O(\log k).$$

When $d_0 = d_h$ is the largest degree of the p_j, the symbol $\sum_j c_j\lambda^j$ (Corollary 38.7) has the degree h and $c_0 \neq 0$, the product of its roots is $(-1)^h c$, and $|C_k|^{1/k} \to |c|$.

A native gauge of a ray is a complex point at which the direction uses every mark exactly as its masses ask, the complex counterpart of the native gauge of a family. Through it a steepest-descent disc carries a value that satisfies both relations up to exponentially small terms, and its asymptotic expansion is a formal solution; distinct native gauges give independent solutions, so their number bounds the dimension, and their native values are roots of the symbol of every recurrence that follows from the relations. On the real orthant the native gauge of the direction governs the growth of the values, and an irrational native value forbids a recurrence of order one. Whatever the order, the frame of a recurrence is a power times a stacked Gamma: the sequences of tier one are the bottom of the hierarchy of sequences that the relations produce.

38.3 The centre ray of a family

Definition 38.13 (The centre ray)**.** Let F be a family of N tables on $n \geq 2$ marks, and let strengths $\sigma_j \in \mathbb{N}$, not all zero, make it connected: every nonempty proper S has $c_j(S) > 0$ for

some j with $\sigma_j > 0$ (Definition 8.1); put $\boldsymbol{\sigma} = (\sigma_j)_j$ and $\sigma = \sum_j \sigma_j$. The *centre ray* of F at the strengths $\boldsymbol{\sigma}$ is its ray with origin 0 and direction $(\sigma\mathbf{1}; \boldsymbol{\sigma}, \boldsymbol{\sigma})$. Its stride is

$$f = \alpha^{\sigma\mathbf{1}} \prod_j \big(K_j \Psi_j\big)^{-\sigma_j} = \prod_j \big(K_j(e^{y}) K_j(e^{-y})\big)^{-\sigma_j},$$

its values are $\langle 1\rangle_k = \int_{y_{e_0}=0} f^k \, dy = P_F(k\sigma\mathbf{1}; k\boldsymbol{\sigma}, k\boldsymbol{\sigma})$, $k \geq 1$, and its direction walls are $\kappa_{1,S} = \sum_j \sigma_j c_j(S) > 0$ (Proposition 8.21).

Theorem 38.14 (A ray is one function)**.** *Let a ray of a family on $n \geq 2$ marks have real origin and $\kappa_{1,S} > 0$ for every nonempty proper S, let $\alpha^\star$ be the native gauge of its direction on $\mathbb{R}^{\mathcal{E}}_{>0}$, with $\alpha^\star_{e_0} = 1$ (Theorem 8.19), and let $k_0 \geq 0$ be an integer with $\kappa_{0,S} + k_0 \kappa_{1,S} > 0$ for every nonempty proper S.*

(i) $0 < f \leq f(\alpha^\star)$ on $\mathbb{R}^{\mathcal{E}}_{>0}$, with equality only at $\alpha \propto \alpha^\star$, and $f \leq C' e^{-c'\|y\|}$ on the chart for some $c', C' > 0$; every value $\langle 1\rangle_k$, $k \geq k_0$, converges and is positive.

(ii) For $|q| < f(\alpha^\star)^{-1}$ the generating function $G(q) = \sum_{k \geq k_0} \langle 1\rangle_k q^{k-k_0}$ is

$$G(q) = \int_{y_{e_0}=0} \frac{f^{k_0}\omega_0}{1 - qf} = \int_{y_{e_0}=0} \frac{\alpha^{\mathbf{m}_0 + k_0\mathbf{m}_1} \prod_j K_j^{-s_{0j} - (k_0-1)s_{1j}} \Psi_j^{-t_{0j} - (k_0-1)t_{1j}}}{\prod_j K_j^{s_{1j}} \Psi_j^{t_{1j}} - q\,\alpha^{\mathbf{m}_1}} \, dy,$$

$$G^{(l)}(q) = l! \int_{y_{e_0}=0} \frac{f^{k_0+l}\omega_0}{(1-qf)^{l+1}},$$

and the positive integral converges for every real $q < f(\alpha^\star)^{-1}$: the whole ray is carried by the pencil $\prod_j K_j^{s_{1j}} \Psi_j^{t_{1j}} - q\,\alpha^{\mathbf{m}_1}$.

(iii) For $k \geq k_0$ and $h \geq 1$,

$$\det\big[\langle 1\rangle_{k+i+i'}\big]_{i,i'=0}^{h-1} = \frac{1}{h!} \int \prod_{a=1}^{h} f(y_a)^k \, \frac{\omega_0}{dy}(y_a) \prod_{a<b} \big(f(y_a) - f(y_b)\big)^2 \prod_a dy_a > 0,$$

and G is not a rational function of q.

On the centre ray of a family (Definition 38.13) one may take $k_0 = 1$, and $\alpha^\star = \mathbf{1}$.

Theorem 38.15 (The branch at the native gauge of the direction)**.** *For a ray as in Theorem 38.14, with its generating function G and the native gauge $\alpha^\star$ of its direction, put $A = f(\alpha^\star)^{-1}$, $\varepsilon = 1 - q/A$ and $a = \frac{n-1}{2}$, and let H be the Hessian of $-\log f$ at $\log \alpha^\star$ on the chart,*

$$H = \Big(\sum_j \big(s_{1j}\, \kappa_{j,\alpha^\star}(X_e, X_{e'}) + t_{1j}\, \kappa_{j,(\alpha^\star)^{-1}}(X_e, X_{e'}) \big) \Big)_{e,e' \neq e_0},$$

the covariances of the indicators under the basis laws and the cobasis laws at $\alpha^\star$ (Definition 7.17, Theorem 7.16); it is positive definite. As $q \uparrow A$ there are functions U, V holomorphic at $\varepsilon = 0$ with

$$G(q) = U(\varepsilon) + \varepsilon^{a-1} V(\varepsilon) \quad (n \text{ even}), \qquad G(q) = U(\varepsilon) + \varepsilon^{a-1} \log\varepsilon \, V(\varepsilon) \quad (n \text{ odd}),$$

$$V(0) = \frac{\Gamma(1-a)\,(2\pi)^a\,(f^{k_0-1}\omega_0/dy)(\alpha^\star)}{A\sqrt{\det H}} \quad (n \text{ even}),$$

$$V(0) = \frac{(-1)^a (2\pi)^a\,(f^{k_0-1}\omega_0/dy)(\alpha^\star)}{\Gamma(a)\,A\sqrt{\det H}} \quad (n \text{ odd}).$$

The derivatives $G^{(l)}(A)$ are finite exactly for $l < a-1$, and

$$G(q) = \sum_{l<a-1} \frac{G^{(l)}(A)}{l!}\big(q-A\big)^l + V(0)\,\varepsilon^{a-1}\big(1 \text{ or } \log\varepsilon\big) + O\big(\varepsilon^{\lceil a-1\rceil}\big).$$

On the centre ray of a family, with $k_0 = 1$, $A = \prod_j K_j(\mathbf{1})^{2\sigma_j}$, the density $f^{k_0-1}\omega_0/dy$ is 1, and $H = 2\sum_j \sigma_j\big(\kappa_{j,\mathbf{1}}(X_e, X_{e'})\big)_{e,e'\neq e_0}$, the covariances under the weight laws.

Proposition 38.16 (The native gauges of a centre ray)**.** *On the centre ray of a family at the strengths $\boldsymbol{\sigma}$ (Definition 38.13) the defects of the direction are*

$$c_e^{(1)}(\alpha) = \sum_j \sigma_j\big(R_{j,e}(\alpha^{-1}) - R_{j,e}(\alpha)\big),$$

so a point α of X_F is a native gauge of the ray exactly when the occupations weighted by the strengths agree at α and at α^{-1}, $\sum_j \sigma_j R_j(\alpha) = \sum_j \sigma_j R_j(\alpha^{-1})$. Its native value is $\prod_j \big(K_j(\alpha)K_j(\alpha^{-1})\big)^{-\sigma_j}$.

Theorem 38.17 (Native gauges at the signs)**.** *For the centre ray of a family at the strengths $\boldsymbol{\sigma}$ (Definition 38.13), on the chart $\alpha_{e_0} = 1$, with the family word $W = \prod_j K_j^{-\sigma_j}\Psi_j^{-\sigma_j}$ at the exponents $(\boldsymbol{\sigma}, \boldsymbol{\sigma})$, so that $f = \alpha^{\sigma\mathbf{1}}W$:*

(i) $f(\alpha^{-1}) = f(\alpha)$; the points fixed by $\alpha \mapsto \alpha^{-1}$ are the 2^{n-1} signs $\eta \in \{\pm1\}^{\mathcal{E}}$, $\eta_{e_0} = 1$; every native gauge of the centre ray is a sign or is paired with its image, a native gauge of the same native value.

(ii) A sign with $K_j(\eta) = \sum_T \theta_{j,T}\eta^T \neq 0$ for every j is a native gauge, of native value $\prod_j K_j(\eta)^{-2\sigma_j}$. In the chart $\alpha_e = \eta_e e^{y_e}$, $y_{e_0} = 0$, the Hessian of $-\log f$ at $y = 0$ is $2\sum_j \sigma_j\big(\kappa_{j,\eta}(X_e, X_{e'})\big)_{e,e'\neq e_0}$, with $\kappa_{j,\eta}$ the covariances of the indicators under the signed measure $\mathbb{P}_{j,\eta}(T) = \theta_{j,T}\eta^T/K_j(\eta)$ of total mass one at the sign.

(iii) The critical polynomials $\sigma W^{-1} - \alpha_e\partial_e W^{-1}$, $e \neq e_0$, vanish identically modulo $\alpha_e^2 = 1$, and $W^{-1} \equiv \alpha^{\sigma\mathbf{1}}\prod_j K_j^{2\sigma_j}$ there. In $\mathbb{Q}(\boldsymbol{\theta})[\alpha_e : e \neq e_0]/(\alpha_e^2 - 1)$, $\mathbb{Q}(\boldsymbol{\theta})$ the field of the weights, localized at $\prod_j K_j$, the idempotents $2^{1-n}\prod_{e\neq e_0}(1+\eta_e\alpha_e)$ of the signs with $K_j(\eta) \neq 0$ for every j form a basis, and multiplication by $W^{-1}/\alpha^{\sigma\mathbf{1}}$ acts on the idempotent of η by $\prod_j K_j(\eta)^{2\sigma_j}$.

Theorem 38.18 (Weights that separate the signs)**.** *Let a family of N tables on $n \geq 2$ marks be connected at the strengths $\sigma_j \in \mathbb{N}$, of total σ, with its centre ray (Definition 38.13). There are weights $\theta_{j,T} \in \big\{1, \dots, 2^{n-1}\big((2n-1)N + (2^{n-1}-1)\sigma\big) + 1\big\}$ for which every sign has $K_j(\eta) \neq 0$ for every j and is a nondegenerate native gauge of the centre ray, and the 2^{n-1} native values $\prod_j K_j(\eta)^{-2\sigma_j}$ are distinct. For such weights the dimension of the centre ray is at least 2^{n-1}, and every recurrence for $\langle 1\rangle_k$ that follows from the relations (Corollary 38.7) has order at least 2^{n-1}.*

Along a ray with real origin the whole sequence of values is one function of the pencil parameter, holomorphic up to the reciprocal of the native value of the direction. The determinants $\det\big[\langle 1\rangle_{k+i+i'}\big]$ of the values are positive integrals of squared differences, so the generating function is not rational; at the native gauge of the direction it branches, with the exponent set by the number of marks and the coefficient by the value of $f^{k_0-1}\omega_0/dy$ there and the determinant of the covariances of the basis and cobasis laws. The centre ray of a family is its period at the centre read at every multiple of its strengths; its native gauge is the table's gauge, where it branches at

$\prod_j K_j(\mathbf{1})^{2\sigma_j}$ with the covariances of the weight laws. Every sign is a candidate native gauge, the signed measures $\mathbb{P}_{j,\eta}$ playing the part of the weight laws, and with weights chosen to separate the signs every recurrence that the relations produce for the centre ray of a family on n marks has order at least 2^{n-1}.

38.4 What a wall carries

Lemma 38.19 (Where native gauges can reach a wall)**.** *Let B be a proper bunch with room $R \ni e_0$, $\alpha_B = \rho u$, and in this statement write $K_j^{[l]} = K_{j,B}^{(d_j(B)+l)}(u, \alpha_R)$ and $\Psi_j^{[l]} = \Psi_{j,B}^{(d_j^*(B)+l)}(u, \alpha_R)$, so that $K_j = \rho^{d_j(B)} \sum_l \rho^l K_j^{[l]}$ and $\Psi_j = \rho^{d_j^*(B)} \sum_l \rho^l \Psi_j^{[l]}$ (Theorem 16.25), with the bottom letters $K_j^{[0]}$ and $\Psi_j^{[0]}$.*

(i) At every native gauge α of a direction $(\mathbf{m}_1; \mathbf{s}_1, \mathbf{t}_1)$ with $s_{1j}, t_{1j} \geq 0$, $m_{1,B} = \sum_j \big(s_{1j} \sum_T |T \cap B|\, \mathbb{P}_{j,\alpha}(T) + t_{1j} \sum_T |B \setminus T|\, \mathbb{P}^*_{j,\alpha}(T)\big)$: the direction's mass on B is its usage of B.

(ii) Let native gauges of such directions $\mathbf{v}_i \to \mathbf{v}$ have bunch scales $\rho_i \to 0$ and $(u_i, \alpha_{R,i}) \to (u^*, \alpha_R^*)$ in the torus, with $\kappa_{1,B}(\mathbf{v}) > 0$. Then some bottom letter vanishes at (u^*, α_R^*), and if only one does, its gradient in (u, α_R) vanishes there as well: the product $\prod_j K_j^{[0]} \Psi_j^{[0]}$ of the bottom letters vanishes at (u^*, α_R^*) together with its gradient in (u, α_R).

So the native gauges of a family leave for the wall of a bunch only at singular points of the zero set of the product of its bottom letters.

Theorem 38.20 (A ray along a wall carries its faces)**.** *Let B be a proper bunch with room $R \ni e_0$ on whose bottom levels the weights factor, and let a ray have its direction on the wall, $\kappa_{1,B} = 0$, and $\operatorname{Re} \kappa_{0,B} > 0$. With $\alpha_B = \rho u$, and writing in this statement $K_j^{[l]} = K_{j,B}^{(d_j(B)+l)}(u, \alpha_R)$ and $\Psi_j^{[l]} = \Psi_{j,B}^{(d_j^*(B)+l)}(u, \alpha_R)$ as in Theorem 16.25,*

$$f = f_B(u)\, f_R(\alpha_R) \big(1 + \rho\, h_1 + O(\rho^2)\big), \qquad h_1 = -\sum_j \Big(s_{1j} \frac{K_j^{[1]}}{K_j^{[0]}} + t_{1j} \frac{\Psi_j^{[1]}}{\Psi_j^{[0]}}\Big),$$

where f_B and f_R are the strides along the ray of the faces F^B and F^R of Theorem 16.25, and $\omega_0 = \rho^{\kappa_{0,B}-1} d\rho \wedge \omega_0^B \wedge \omega_0^R\, (1 + O(\rho))$ with the origin forms of the faces. Let α_c^B and α_c^R be nondegenerate native gauges of the rays of the faces with $h_1(\alpha_c^B, \alpha_c^R) \neq 0$, let $\operatorname{Re}\big(e^{i\vartheta} h_1\big) < 0$ near (α_c^B, α_c^R), and let $D = e^{i\vartheta}[0, \rho_1] \times D_B \times D_R$ with steepest-descent discs D_B, D_R of the faces. Then the values $\langle g \rangle_{k;D}$ satisfy both relations up to terms exponentially smaller than $|f_B(\alpha_c^B) f_R(\alpha_c^R)|^k$, and

$$\langle 1 \rangle_{k;D} = \Gamma(\kappa_{0,B}) \big(-k\, h_1(\alpha_c^B, \alpha_c^R)\big)^{-\kappa_{0,B}} \langle 1 \rangle_{k;D_B}^{F^B} \langle 1 \rangle_{k;D_R}^{F^R} \big(1 + O(1/k)\big),$$

with $\langle 1 \rangle_{k;D_B}^{F^B}$ and $\langle 1 \rangle_{k;D_R}^{F^R}$ the values of the rays of the faces over their discs (Theorem 38.6), and the power taken continuously along $e^{i\vartheta}(0, \infty)$.

Definition 38.21 (The whole cluster port)**.** On a bunch scale ρ take letters with *lower coefficients* $\boldsymbol{\lambda}_i \in \mathbb{C}^{r_i}$,

$$L_i(\rho, \boldsymbol{\lambda}_i) = \sum_{l < r_i} \lambda_{i,l}\, \rho^l + \rho^{r_i} C_i(\rho), \qquad C_i(0) \neq 0,$$

with exponents w_i, and a word $\rho^{\kappa-1} G(\rho) \prod_i L_i^{-w_i}$, with G and the C_i holomorphic on a neighbourhood of $[0, \infty)$, each $|C_i|$ bounded below by a positive constant there, and the word integrable at

∞; put $\kappa^\flat = \kappa - \sum_i r_i w_i$. Fix $b > 0$ with every C_i zero-free on $|\rho| \le b$; for $\boldsymbol{\lambda}$ in a small polydisc each L_i has exactly r_i roots in $|\rho| < b$, the *cluster*, none on $|\rho| = b$ and none on $[b, \infty)$. The *cluster port* of the word is its integral over the *cluster contour*, which comes in along the half-line $[b, \infty)$ of the scale, goes once around $|\rho| = b$ and goes out on the new sheet:

$$\operatorname{Port}_\kappa \Big[G \prod_i L_i^{-w_i} \Big](\boldsymbol{\lambda}) = \frac{1}{2\pi i} \Big[(e^{2\pi i \kappa^\flat} - 1) \int_b^\infty \rho^{\kappa-1} G \prod_i L_i^{-w_i}\, d\rho + \oint_{|\rho|=b} \rho^{\kappa-1} G \prod_i L_i^{-w_i}\, d\rho \Big].$$

Theorem 38.22 (Relations of the whole cluster port)**.** *(i) One turn around $|\rho| = b$ multiplies the word by $e^{2\pi i \kappa^\flat}$; the cluster port does not depend on b, is holomorphic in all the lower coefficients jointly on the polydisc, and the contour has no end at which the word is nonzero, so every integral of a ρ-derivative over it vanishes.*

(ii) On the stratum $\boldsymbol{\lambda} = 0$ the word is $\rho^{\kappa^\flat - 1} h$, with the stratum word $h = G \prod_i C_i^{-w_i}$*, and*

$$\operatorname{Port}_\kappa \Big[G \prod_i L_i^{-w_i} \Big](0) = \frac{e^{2\pi i \kappa^\flat} - 1}{2\pi i}\, \operatorname{Reg} \int_0^\infty \rho^{\kappa^\flat - 1} h\, d\rho \quad (\kappa^\flat \notin \mathbb{Z}),$$

$$\operatorname{Port}_\kappa \Big[G \prod_i L_i^{-w_i} \Big](0) = [\rho^{-\kappa^\flat}]\, h \quad (\kappa^\flat \in \mathbb{Z}_{\le 0}), \qquad \operatorname{Port}_\kappa \Big[G \prod_i L_i^{-w_i} \Big](0) = 0 \quad (\kappa^\flat \in \mathbb{Z}_{>0}).$$

(iii) For multi-indices $\mathbf{a}_i$, with $A_i = |\mathbf{a}_i|$ and $D = \sum_i \sum_l (r_i - l)\, a_{i,l}$, the derivative $\partial_{\boldsymbol{\lambda}}^{\mathbf{a}}$ of the cluster port at $\boldsymbol{\lambda} = 0$ is $\prod_i (-1)^{A_i} (w_i)_{A_i}$ times the value of (ii) for the stratum word $G \prod_i C_i^{-w_i - A_i}$ at the index $\kappa^\flat - D$; at $\kappa^\flat = 0$ it is $\prod_i (-1)^{A_i} (w_i)_{A_i} \cdot \frac{1}{D!}\, \partial_\rho^D \big[G \prod_i C_i^{-w_i - A_i} \big]_{\rho = 0}$.

Proposition 38.23 (Small lower coefficients on one parameter)**.** *Let $C_1, \dots, C_p$ be bounded below by a positive constant on $[0, \infty)$, G and the C_i holomorphic near 0 and continuous on $[0, \infty)$, $\xi_1, \dots, \xi_p \in \mathbb{C} \setminus (-\infty, 0]$, $\operatorname{Re} \kappa > 0$ and $\kappa^\flat = \kappa - |\mathbf{w}| \notin \mathbb{Z}$, with $\rho^{\kappa-1} G \prod_i (\rho C_i)^{-w_i}$ integrable at ∞ together with every $\rho^{\kappa^\flat - |\mathbf{a}| - 1} G \prod_i C_i^{-w_i - a_i}$, $\mathbf{a} \in \mathbb{N}^p$.*

(i) For small $\lambda > 0$,

$$\int_0^\infty \rho^{\kappa-1} G(\rho) \prod_i \big(\lambda \xi_i + \rho\, C_i(\rho) \big)^{-w_i} d\rho = A(\lambda) + \lambda^{\kappa^\flat} B(\lambda)$$

with A, B holomorphic at 0,

$$A(\lambda) = \sum_{\mathbf{a} \in \mathbb{N}^p} \prod_i \binom{-w_i}{a_i} (\lambda \xi_i)^{a_i}\, \operatorname{Reg} \int_0^\infty \rho^{\kappa^\flat - |\mathbf{a}| - 1} G \prod_i C_i^{-w_i - a_i}\, d\rho,$$

$$B(0) = G(0) \int_0^\infty u^{\kappa-1} \prod_i \big(\xi_i + u\, C_i(0) \big)^{-w_i}\, du,$$

the last integral continued in κ and $\mathbf{w}$; where every $\operatorname{Re} w_i > 0$ it is

$$\prod_i C_i(0)^{-w_i}\, \Gamma_{\!\!\stackrel{2}{p}} \begin{bmatrix} \kappa, & |\mathbf{w}| - \kappa \\ & \mathbf{w} \end{bmatrix} \mathsf{B}^{\{J\}}_{\mathbf{w}, |\mathbf{w}| - \kappa;\, I_J} \big((\xi_i / C_i(0))_i \big), \qquad J = \{1, \dots, p\}$$

(Proposition 15.1). The analytic part opens with the finite part of the stratum word along the whole scale, and the branch part with $G(0)$ times the scale integral of the letters linearized at the wall.

(ii) When G and the C_i are holomorphic on a neighbourhood of $[0,\infty)$, the cluster port of Definition 38.21 for these letters, $r_i = 1$ with the lower coefficients $\lambda\xi_i$, is $\frac{e^{2\pi i\kappa^\flat}-1}{2\pi i}A(\lambda)$.

At a wall the ray splits: the stride is the product of the strides of the two faces up to a first-order correction in the scale of the bunch, and integrating that scale against the correction contributes one Gamma of the origin wall, so a ray along a wall carries the product of the native values of its faces. The native gauges of a family reach a wall only where the product of its bottom letters is singular. When the bottom letters of a bunch are perturbed by lower coefficients, the scale integral is read on the cluster contour, which surrounds the whole cluster of roots at once: the cluster port is holomorphic in the lower coefficients, its value on the stratum where they vanish is the finite part of the stratum word, and its derivatives there are the finite parts of the stratum words with raised exponents. With small lower coefficients on one parameter the scale integral splits into an analytic part, the cluster port up to a constant, and a branch part led by the scale integral of the letters linearized at the wall, a stacked Gamma times a Breta of one bunch.

38.5 Corners of a wall of width one

Along a wall the stride is infinite except where the bottom letters vanish, and there its limit is indeterminate. At a bunch of width one of a plain table the stride along the centre ray at the strength one has an exact three-term form in the scale of the bunch, and its limits at the wall are read from it: they sit where both factors of one bottom letter vanish, the two corners of the wall, or where one factor is singular, and their values are products of native values of the four minors of the bunch, each read on the zero set of another. At every flag the points where native gauges of nearby directions can leave the torus lie over the singular locus of the step letters.

Definition 38.24 (Native gauges on a hypersurface; corner values)**.** For a plain table (X,θ) on a set Z of marks, $|Z|\geq 2$, put $f_X(u) = \big(K_X(u)K_X(u^{-1})\big)^{-1}$ on the torus $T_Z = (\mathbb{C}^\times)^Z/\mathbb{C}^\times$: the stride of the centre ray of X at the strength one when X is connected (Definition 38.13), with $f_X(u^{-1}) = f_X(u)$. For a second plain table Y on Z, a *native gauge of X on Y* is a smooth point u of the hypersurface $Z_Y = \{K_Y = 0\}$ of T_Z at which f_X is finite and nonzero and the restriction of $\log f_X$ to Z_Y has zero differential; it is *nondegenerate* when the Hessian of that restriction is nonsingular there. $N(X\,|\,Y)$ is the set of the values of f_X at the native gauges of X on Y; it does not change when Z_Y is replaced by its image $\{K_Y(u^{-1}) = 0\}$ under the Cremona. For a bunch B of width one of a plain table $(\mathcal{B},\theta)$, its weights factoring across B and its room R (Definition 19.2), the *corner values* of B are the products

$$N(\mathcal{B}|B\,|\,\mathcal{B}/R)\cdot N(\mathcal{B}/B\,|\,\mathcal{B}|R) \qquad \text{and} \qquad N(\mathcal{B}/R\,|\,\mathcal{B}|B)\cdot N(\mathcal{B}|R\,|\,\mathcal{B}/B),$$

taken element by element, the first set at the *corner of K* and the second at the *corner of Ψ*, the four minors carrying the weights they inherit.

Proposition 38.25 (The stride at a wall of width one)**.** *Let B be a bunch of width one of a plain table $(\mathcal{B},\theta)$, its weights factoring across B and its room $R\ni e_0$, and read the centre ray of the table at the strength one, $f^{-1} = K(\alpha)K(\alpha^{-1})$. With $\alpha_B = \rho u$ put*

$$P = K_{\mathcal{B}/R}(u)\,K_{\mathcal{B}|R}(\alpha_R), \qquad Q = K_{\mathcal{B}|B}(u)\,K_{\mathcal{B}/B}(\alpha_R),$$

and let $\bar P$, $\bar Q$ be the same at (u^{-1},α_R^{-1}). Then, exactly,

$$f^{-1} = \rho^{-1}\,P\bar Q + \Big(f^{-1}_{\mathcal{B}/R}(u)\,f^{-1}_{\mathcal{B}|R}(\alpha_R) + f^{-1}_{\mathcal{B}|B}(u)\,f^{-1}_{\mathcal{B}/B}(\alpha_R)\Big) + \rho\,Q\bar P,$$

with the strides f_X of Definition 38.24. P is the bottom letter $K^{[0]}$ of K at the wall of B (Lemma 38.19), and $\bar{Q} = u^{-B}\alpha_R^{-R}\,\Psi^{[0]}$ with the bottom letter $\Psi^{[0]} = \Psi_{\mathcal{B}|B}(u)\Psi_{\mathcal{B}/B}(\alpha_R)$ of Ψ.

Along the wall $\rho = 0$ the reciprocal stride is infinite, except on the zero set of $P\bar{Q}$, where it has the form $0 \cdot \infty$. So the native gauges of directions near the centre direction that leave for the wall of B arrive at points of that zero set, and the next statement says which.

Proposition 38.26 (Corners of a wall of width one)**.** *In Proposition 38.25 write $f^{-1} = \rho^{-1}Q_0 + Q_1 + \rho Q_2$, with $Q_0 = P\bar{Q}$, Q_1 the middle term and $Q_2 = Q\bar{P}$, functions of (u, α_R). Let $\alpha_i \in X_F$ be points with the defects $c^{(1)}(\alpha_i) \to 0$ (Definition 38.1), bunch scales $\rho_i \to 0$, positions $(u_i, \alpha_{R,i}) \to (u^*, \alpha_R^*)$ in $T_B \times T_R$, T_R read on the chart $\alpha_{e_0} = 1$, and $f(\alpha_i) \to \lambda \in \mathbb{C}^\times$. Each α_i is a native gauge of the direction whose masses are those of the centre direction moved by $-c^{(1)}(\alpha_i)$. Then $\lambda^{-1} = Q_1(u^*, \alpha_R^*)$, some factor of $P\bar{Q}$ vanishes at (u^*, α_R^*), and:*

(i) a factor of P and a factor of $\bar{Q}$ do not vanish there together; if exactly one factor vanishes there, its zero set is singular there;

(ii) if both factors of P vanish there and both are smooth there (the corner of K), then u^* is a native gauge of $\mathcal{B}|B$ on $\mathcal{B}/R$, α_R^* is a native gauge of $\mathcal{B}/B$ on $\mathcal{B}|R$, and $\lambda = f_{\mathcal{B}|B}(u^*)\, f_{\mathcal{B}/B}(\alpha_R^*)$; if both factors of $\bar{Q}$ vanish there and both are smooth there (the corner of Ψ), then u^* is a native gauge of $\mathcal{B}/R$ on $\mathcal{B}|B$ and α_R^* one of $\mathcal{B}|R$ on $\mathcal{B}/B$, both on the zero sets at the inverse point, and $\lambda = f_{\mathcal{B}/R}(u^*)\, f_{\mathcal{B}|R}(\alpha_R^*)$;

(iii) if exactly one factor vanishes there and it is a factor of P, then α_R^* is a critical point of $f_{\mathcal{B}/B}$ on T_R when the factor is $K_{\mathcal{B}/R}(u)$, and u^* one of $f_{\mathcal{B}|B}$ on T_B when it is $K_{\mathcal{B}|R}(\alpha_R)$, and $\lambda = f_{\mathcal{B}|B}(u^*)\, f_{\mathcal{B}/B}(\alpha_R^*)$; if it is a factor of $\bar{Q}$, then α_R^* is a critical point of $f_{\mathcal{B}|R}$ on T_R when the factor is $K_{\mathcal{B}|B}(u^{-1})$, and u^* one of $f_{\mathcal{B}/R}$ on T_B when it is $K_{\mathcal{B}/B}(\alpha_R^{-1})$, and $\lambda = f_{\mathcal{B}/R}(u^*)\, f_{\mathcal{B}|R}(\alpha_R^*)$.

Conversely, let u^* and α_R^* be nondegenerate native gauges of $\mathcal{B}|B$ on $\mathcal{B}/R$ and of $\mathcal{B}/B$ on $\mathcal{B}|R$, put $G = \bar{Q}(u^*, \alpha_R^*)$, and let μ_a, μ_c be the multipliers of the two constrained problems, $d_u\big(f_{\mathcal{B}|B}^{-1}\big)\, f_{\mathcal{B}/B}^{-1} = \mu_a\, dK_{\mathcal{B}/R}$ and $f_{\mathcal{B}|B}^{-1}\, d_{\alpha_R}\big(f_{\mathcal{B}/B}^{-1}\big) = \mu_c\, dK_{\mathcal{B}|R}$ at (u^*, α_R^*). Let $\mathbf{u} \in \mathbb{R}^{\mathcal{E}}$ with $u_{\mathcal{E}} = 0$ and $u_B = \sum_{e \in B} u_e \neq 0$, and suppose $Q_2 \neq \mu_a\mu_c/G$ at the point. Then for every small real $\varepsilon \neq 0$ the direction whose masses are those of the centre direction plus $\varepsilon\mathbf{u}$ has a native gauge with the bunch scale $\rho = \varepsilon r + O(\varepsilon^2)$, $r = u_B Q_1/(Q_2 - \mu_a\mu_c/G)$ at the point, whose position tends to (u^*, α_R^*) and whose native value tends to $f_{\mathcal{B}|B}(u^*) f_{\mathcal{B}/B}(\alpha_R^*)$ as $\varepsilon \to 0$. The same holds at the corner of Ψ, with the roles of the two pairs of minors exchanged.

Remark 38.27 (A corner is a wall after one blow-up). At the corner of K, with $a = K_{\mathcal{B}/R}(u)$ and $c = K_{\mathcal{B}|R}(\alpha_R)$, the chart $a = \rho\hat{a}$, $c = \rho\hat{c}$ of the blow-up of $\{\rho = a = c = 0\}$ gives $f^{-1} = Q\bar{Q} + O(\rho)$ by Proposition 38.25, since $P = \rho^2\hat{a}\hat{c}$. So on the exceptional divisor the stride is $f_{\mathcal{B}|B}(u)\, f_{\mathcal{B}/B}(\alpha_R)$, the product of the strides of two faces restricted to the zero sets of the other minors' letters, as along a wall in Theorem 38.20, and the corner values are the native values of this stratum. In the coordinates (ρ, u, α_R) the zero set of K off the wall is $\{P + \rho Q = 0\}$, whose closure has the trace $\{P = 0\}$ on the wall $\{\rho = 0\}$; the corner is the singular set $\{a = c = 0\}$ of that trace.

Corollary 38.28 (The corners of a class)**.** *Let $\mathcal{H}$ be a plain table on $R \sqcup \{h\}$, h neither a loop nor a coloop, and let $\mathcal{B} = \mathcal{H}\langle\mathcal{A} \text{ at } h\rangle$ be its gluing along h with a parallel class $\mathcal{A} = \binom{C \sqcup \{g\}}{1}$ or a series class $\mathcal{A} = \binom{C \sqcup \{g\}}{|C|}$ of $s = |C| \geq 2$ marks (Definition 21.1), with unit weights on the class. Then C is a bunch of width one of $\mathcal{B}$, and its corner values are*

$$N(\mathcal{H} \setminus h \,|\, \mathcal{H}/h) \quad \textit{(parallel class)}, \qquad N(\mathcal{H}/h \,|\, \mathcal{H} \setminus h) \quad \textit{(series class)},$$

the parallel class at the corner of Ψ and the series class at the corner of K; the other corner of each is empty. A single mark has no corner.

At the corner of Ψ a parallel class reads its core with the class silent: $f_{\mathcal{B}/R} \equiv 1$ on the zero set of $\sum_{e\in C} u_e^{-1}$, and the room is read through its deletion $\mathcal{H} \setminus h$ on the zero set of the letter of its contraction. The corners of a class are degenerate, since the factor of the class is constant along the zero set of its own letter, so the converse in Proposition 38.26 does not apply to them.

Definition 38.29 (Asymptotic native gauges)**.** An *asymptotic native gauge* of a ray is a sequence $x_m \in X_F$ that leaves every compact subset of the torus $(\mathbb{C}^\times)^{\mathcal{E}}/\mathbb{C}^\times$, with $c^{(1)}(x_m) \to 0$ and $f(x_m) \to \lambda \in \mathbb{C}^\times$; λ is an *asymptotic native value.* Each x_m is a native gauge of the direction whose masses are moved by $-c^{(1)}(x_m)$, a complex perturbation that tends to 0.

Proposition 38.30 (The far points lie over the singular locus of the step letters)**.** *Let a ray of a family of lists have an integral origin, $\kappa_{1,S} > 0$ for every nonempty proper S, and every letter of every list with a positive exponent in its direction. For a flag $\mathfrak{f}$ with the steps $Z_1, \dots, Z_{\ell+1}$, $\ell \geq 1$ (Definition 34.2), let $O_\mathfrak{f}$ be the set of the points of $D_{S_1} \cap \cdots \cap D_{S_\ell}$ in $X_\mathcal{E}$ on no other D_S (Definition 34.1), isomorphic to $\prod_i T_{Z_i}$, and put*

$$\Pi_\mathfrak{f} = \prod_{g\in \mathrm{Let}(F)} \prod_{i=1}^{\ell+1} g_{Z_i},$$

with g_{Z_i} the step letter of g at Z_i (Proposition 12.20) read on T_{Z_i}, one factor for each letter and each step. In the chart of an order adapted to the flag write $f^{-1} = \prod_{i<n} \varepsilon_i^{-\kappa_{1,S_i}} \Phi$, $\Phi = \prod_j \widetilde{K}_j^{s_{1j}} \widetilde{\Psi}_j^{t_{1j}}$ (Lemma 34.3). Let x_m be an asymptotic native gauge of value λ. After passing to a subsequence, x_m converges in $X_\mathcal{E}$ to a point $x^* \in O_\mathfrak{f}$ for a flag $\mathfrak{f}$ of length $\ell \geq 1$, and:

- *(i) $\Pi_\mathfrak{f}(x^*) = 0$: two of its factors vanish at x^*, or exactly one does and its zero set in $O_\mathfrak{f}$ is singular at x^*;*
- *(ii) in a chart through x^*, $\varepsilon_i \partial_{\varepsilon_i} \log \Phi(x_m) \to \kappa_{1,S_i}$ for every $i < n$, so that Φ vanishes along x_m at the rates that the walls of the flag set.*

Two factors that vanish together may be the step letters of one letter at two steps, as at the corners of a wall of width one, or factors of two letters. For a flag $\{S\}$ of length one this is Lemma 38.19(ii) read for complex perturbations, at every width: the bases T with $T \cap R$ a basis of $\mathcal{B}|R$ are the $T_R \sqcup T_B$ with T_B a basis of $\mathcal{B}/R$, so the bottom letter of K at the wall of B is $K_{\mathcal{B}/R}(u)\, K_{\mathcal{B}|R}(\alpha_R)$ whatever the width, and width one adds the exact three terms of Proposition 38.25, which decide the value at a corner.

38.6 What a value can contain

Theorem 38.31 (The values along a ray)**.** *Let a ray of a family have weights and origin in a subfield $\Bbbk$ of $\mathbb{C}$, with $\kappa_{1,S} > 0$ for every nonempty proper S.*

- *(i) The dimension of the ray is finite: it is the dimension over $\mathbb{C}(k)$ of the top cohomology of the twisted algebraic de Rham complex of the letter complement X_F, which is finite. It is at least the number of nondegenerate native gauges of the ray (Theorem 38.6). The native gauges are the critical points of the stride f, a product of powers of the letters with the exponents of the direction; for a direction off a proper algebraic subset they are $(-1)^{n-1}\,\mathrm{eu}(X_F)$ in number,* eu *the Euler characteristic, and all nondegenerate (Proposition 47.16(iii)), so that the dimension is then at least $(-1)^{n-1}\,\mathrm{eu}(X_F)$. An integral direction can lie in that exceptional set.*

(ii) For every insertion g with coefficients in $\Bbbk$ there are $p_0, \dots, p_h \in \Bbbk[k]$, $p_h \neq 0$, h at most the dimension, with $\sum_j p_j(k)\,\langle g\rangle_{k+j} = 0$ for all large k.

(iii) So there is k_1 such that every value $\langle g\rangle_k$, $k \geq k_1$, is a $\Bbbk$-linear combination of the h values $\langle g\rangle_{k_1}, \dots, \langle g\rangle_{k_1+h-1}$: the values along a ray span a $\Bbbk$-space of dimension at most that of the ray, and whatever Trailmoments those h values contain, no later value contains others.

Lemma 38.32 (Index by pole count)**.** *Let $\Bbbk$ be a subfield of $\mathbb{C}$, and let $r \in \Bbbk(k)$ have all its poles at negative integers, with largest order p, and $r(k) = O(k^{-2})$. Then $\sum_{k\geq 0} r(k) \in \Bbbk + \sum_{j=2}^{p} \Bbbk\,(\mathsf{T}_{j;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$. If moreover $r(-M-k) = -r(k)$ for an integer M, only odd j occur. If the poles lie in one coset $-b+\mathbb{Z}$, $b \in \mathbb{Q}$, the same holds with the Trailmoments of the lattice input $\mathbb{I}_{b+\mathbb{Z}}$ at its cuts; poles in several cosets leave, besides, differences of the index-one values of the cosets.*

A closing whose terms are rational functions of the lattice index brings Trailmoments of the counting input of index at most the largest order of its poles, and a reflection of the terms keeps only the odd indices. With Theorem 38.31 this is what bounds the complexity of a family along a ray: the space of values is finite-dimensional, spanned by finitely many of them, and where a closing writes the values as sums of rational terms the index is read off the orders of the poles, which along the ray can be bounded once for all its points.

Chapter 39

The two ends of a ray

The values of the insertions along a ray form one module over the rational functions of the strength k, and masters write the step from one strength to the next as one rational matrix, the one-step matrix. Finitely many relations of the period write the step on the Laurent part of the module, which is all of it when the direction uses every letter: on a box of insertions bounded by the powers of the letters in their denominators and by their growth against the reciprocal stride, one elimination over the rational functions of the strength gives a spanning set of that part, the matrix of the step on it and a certificate, and a search through the boxes stops. A family of functionals that respects the two relations of the ray is a solution of the module, and the one-step matrix is fixed by its solutions: by a full set of them outright, and by fewer exactly when they annihilate no submodule. The solutions come from the two ends of strength. At the high end the sources of the stride, components of its critical locus, carry formal solutions: one for a nondegenerate native gauge, one for each class of paths at a native gauge of corank one, one for every cycle on a clean family of native gauges. At the low end the values continue to the nonpositive integers, where their top principal parts are the constant terms of the powers of the reciprocal stride: the closings, one exact solution read on the compact torus. The symmetries of the ray, built from the automorphisms and the exchanges of the family and from the Cremona, act on the module; the values live on its invariant part, every orbit of nondegenerate native gauges contributes to it, and a degenerate native gauge only through the classes on which its stabilizer acts trivially. At a lean of a family with an exchange the exchange survives only composed with the Cremona: the integral keeps a symmetry that carries the basis half of a class of the centre onto its cobasis half, while the reading, which is oriented, separates the halves. Over the formal series at the high end the module splits by native values into pieces, each mapped to itself by the symmetries, and the closings glue the pieces back into the rational matrix. The closings, the values and the expansion at the native gauge of the direction vanish on the same elements, the positive orthant and the torus through that gauge meeting there and nowhere else: the closings determine the one-step matrix exactly where the values do, which is where that gauge sees every submodule, and a submodule that it does not see is invisible to the integral itself. Such a submodule can come from a table one mark larger: when the list is the contraction of an identically self-dual table, the integral over the contracted scale makes the automorphisms of the larger table act on the module, and the closings see only what they fix; each orbit of nondegenerate native gauges of the larger table that the symmetries of the ray split into s orbits adds $s-1$ to the dimension of what the closings miss, and at the centre of every $\binom{[2r+1]}{r}$, $r \geq 2$, the signs of $\binom{[2r+2]}{r+1}$ with two scales -1 split in two, with every symmetry of the ray of the four kinds in the group. On a wheel the letters are traces of one holonomy in SL_2, and the sources of its centre ray are read off the critical locus of the pair of traces and the

stratum where both holonomies are $-I$. The relations of a ray are exact forms on its model, so the ray is read in one cohomology, and at a tame high end its insertion lattice is free over the local ring at infinite strength, every eigenvalue of the step there being a reciprocal native value. The pencil of the ray, the direct image of the functions along the reciprocal stride, is its moment side: the nonzero roots of the symbol of the law are the reciprocals of its singular values, with the vanishing ranks as multiplicities, each a native value or an asymptotic native value, the far end has the maximal depth, and along a hinge tree the pencil is the iterated direct image of the marks under the node maps, one for each vertex.

39.1 The module of a ray

Definition 39.1 (The module of a ray; masters; the one-step matrix)**.** Let a ray of a family F have the stride f, the origin form ω_0 and the relation space $\mathcal{L}$ (Definitions 38.1 and 38.4). The *module* of the ray is the $\mathbb{C}(k)$-vector space

$$\mathfrak{M} = \big(\mathbb{C}[X_F] \otimes \mathbb{C}(k)\big)/\mathcal{L},$$

whose dimension is the dimension of the ray, finite when $\kappa_{1,S} > 0$ for every nonempty proper S (Theorem 38.31(i)); $[g]$ is the class of $g \otimes 1$. The *shift* is $\mathrm{Sh}[g \otimes r(k)] = [fg \otimes r(k+1)]$; it is well defined and bijective, and $\mathrm{Sh}(r(k)\,m) = r(k+1)\,\mathrm{Sh}(m)$. A *submodule* is a $\mathbb{C}(k)$-subspace $\mathfrak{N}$ with $\mathrm{Sh}(\mathfrak{N}) = \mathfrak{N}$, and $\mathfrak{N} \neq 0$ is *irreducible* when its only submodules are 0 and $\mathfrak{N}$. *Masters* of a finite-dimensional submodule $\mathfrak{N}$ are insertions $b_1, \dots, b_{\mathfrak{m}}$ whose classes form a basis of $\mathfrak{N}$, $\mathfrak{m} = \dim_{\mathbb{C}(k)} \mathfrak{N}$, and their *one-step matrix* $\mathbf{B_b} \in GL_{\mathfrak{m}}(\mathbb{C}(k))$ is the matrix of Sh^{-1} on them,

$$[f^{-1} b_i] = \sum_{l=1}^{\mathfrak{m}} \mathbf{B}_{\mathbf{b},il}(k)\,[b_l], \qquad 1 \le i \le \mathfrak{m}.$$

The *cyclic submodule* of $[1]$ is the span of the $\mathrm{Sh}^i[1]$, $i \in \mathbb{Z}$. When it is finite-dimensional, of dimension h, $[1], \mathrm{Sh}[1], \dots, \mathrm{Sh}^{h-1}[1]$ is a basis of it, and the *law* of $[1]$ is the relation

$$\sum_{i=0}^{h} p_i(k)\,\mathrm{Sh}^i[1] = 0, \qquad p_i \in \mathbb{C}[k] \text{ without a common factor,}$$

unique up to a constant factor; $p_0 p_h \neq 0$.

The law of $[1]$ is the shortest relation among the strides of 1 that the relations of the ray produce, so by Corollary 38.7 the values obey it, $\sum_i p_i(k)\langle 1\rangle_{k+i} = 0$ for all large k; its order h is at most the dimension of the ray.

Definition 39.2 (Solutions)**.** The *spaces of germs* are: the sequences on the integers $k \ge k_0$, for some k_0, two of them identified when they agree for all large k, the *germs at* $+\infty$; the same on the integers $k \le k_0$, the *germs at* $-\infty$; and, for $\lambda \in \mathbb{C}^\times$ and $\rho \in \mathbb{C}$, the *formal series* $\lambda^k k^\rho\,\mathbb{C}((1/k))$. Each carries the multiplication by $\mathbb{C}(k)$ and the shift ς: $(\varsigma x)(k) = x(k+1)$ on germs, and $\varsigma\big(\lambda^k k^\rho \varphi(k)\big) = \lambda^k k^\rho \cdot \lambda\big(1+\frac{1}{k}\big)^\rho \varphi(k+1)$ on formal series, re-expanded in powers of $1/k$; in each case $\varsigma(rx) = r(k+1)\,\varsigma(x)$ for $r \in \mathbb{C}(k)$. A *solution* of the ray with values in a space of germs $\mathcal{G}$, or in a finite direct sum of spaces of formal series, is a $\mathbb{C}(k)$-linear map $V : \mathfrak{M} \to \mathcal{G}$ with

$$V \circ \mathrm{Sh} = \varsigma \circ V.$$

A solution with values in $\lambda^k k^\rho\,\mathbb{C}((1/k))$ has the *type* $(\lambda, \rho + \mathbb{Z})$ and the *normalization* $\hat{V} = \lambda^{-k} k^{-\rho} V : \mathfrak{M} \to \mathbb{C}((1/k))$. For masters $\mathbf{b}$ the *solution vector* of V is $v_V = (V[b_1], \dots, V[b_{\mathfrak{m}}])$. The *annihilator* of a set $\mathcal{S}$ of solutions is $\mathrm{Ann}(\mathcal{S}) = \{m \in \mathfrak{M} :\ V(m) = 0 \text{ for every } V \in \mathcal{S}\}$.

When $\kappa_{1,S} > 0$ for every nonempty proper S, the values along the ray are a solution with values in germs at $+\infty$, $V[g] = \langle g \rangle_k$ (Theorem 38.3). At a nondegenerate native gauge α_c the expansion $f(\alpha_c)^k k^{-(n-1)/2} \sum_i a_i(g) k^{-i}$ of Theorem 38.6 is a solution of type $\big(f(\alpha_c), -\frac{n-1}{2} + \mathbb{Z}\big)$, written A_c; its normalization is the map $A^{(c)}$ there.

Lemma 39.3 (Solutions of distinct types)**.** *Let $A_1, \dots, A_r$ be solutions with values in formal series such that, for every type, those of that type among them are linearly independent over $\mathbb{C}$. Then their normalizations are linearly independent over $\mathbb{C}((1/k))$, and $\dim_{\mathbb{C}(k)} \mathfrak{N} \geq r$ for every submodule $\mathfrak{N}$ on which their restrictions are, type by type, linearly independent over $\mathbb{C}$.*

Theorem 39.4 (What solutions determine)**.** *Let $\mathbf{b}$ be masters of a submodule $\mathfrak{N}$, $\mathbf{B} = \mathbf{B_b}$, and let $\mathcal{S}$ be a set of solutions.*

(i) Every solution V has $\varsigma^{-1} v_V = \mathbf{B}\, v_V$, that is $v_V(k-1) = \mathbf{B}(k)\, v_V(k)$. When the values along the ray are a solution, $\langle b_i \rangle_{k-1} = \sum_l \mathbf{B}_{il}(k) \langle b_l \rangle_k$ for all large k.

(ii) $\mathrm{Ann}(\mathcal{S})$ is a submodule.

(iii) A matrix $\mathbf{B}' \in \mathrm{Mat}_{\mathfrak{m}}(\mathbb{C}(k))$ has $\varsigma^{-1} v_V = \mathbf{B}' v_V$ for every $V \in \mathcal{S}$ if and only if every row of $\mathbf{B}' - \mathbf{B}$, read as the element $\sum_l (\mathbf{B}' - \mathbf{B})_{il} [b_l]$ of $\mathfrak{N}$, lies in $\mathrm{Ann}(\mathcal{S})$. So $\mathbf{B}$ is the only such matrix exactly when $\mathrm{Ann}(\mathcal{S}) \cap \mathfrak{N} = 0$.

(iv) Let $\mathrm{Ann}(\mathcal{S}) \cap \mathfrak{N} = 0$, write $\mathbf{B} = P_0/Q_0$ with Q_0 the monic least common denominator of its entries, and put $D_0 = \max(\deg P_0, \deg Q_0)$. For $D \geq 0$ the equations $Q(k)\, \varsigma^{-1} v_V = P(k)\, v_V$, $V \in \mathcal{S}$, in pairs (P, Q) of a matrix and a scalar of polynomials of degree at most D, read at every integer beyond a bound past which (i) holds for a germ and at every power of k for a formal series, are linear and homogeneous in the coefficients of (P, Q). Their solutions are the pairs (cP_0, cQ_0) with $c \in \mathbb{C}[k]$ of degree at most $D - D_0$: only 0 for $D < D_0$, one line at $D = D_0$. For each D finitely many of the equations have the same solutions as all of them.

Corollary 39.5 (One solution of an irreducible module)**.** *If $\mathfrak{N}$ is irreducible, every solution that does not vanish on $\mathfrak{N}$ determines $\mathbf{B_b}$ in the sense of Theorem 39.4(iii). If the cyclic submodule of $[1]$ is finite-dimensional and irreducible, then for every solution V with $V[1] \neq 0$, $V[1]$ satisfies the law of $[1]$, $\sum_i p_i(k)\, \varsigma^i V[1] = 0$, and satisfies no relation $\sum_{i<h} q_i(k)\, \varsigma^i V[1] = 0$ with $q_i \in \mathbb{C}(k)$ not all zero.*

Masters are a basis of a submodule, the module itself or its invariant part (Theorem 39.12), while a box of insertions reduces to a spanning set of a submodule that contains [1], which is a set of masters exactly when it is independent (Section 39.4); the one-step matrix is the matrix of the inverse shift, so that the values of the masters step down in strength by $\mathbf{B_b}$. A solution is anything that respects the two relations: the values over the orthant, the expansion at a native gauge, the closings on the torus (Theorem 39.33). Each solution gives $\mathfrak{m}$ linear equations on the numerator and the denominator of $\mathbf{B_b}$ for every integer or every power of k, and the equations of a set of solutions determine $\mathbf{B_b}$ exactly when the solutions annihilate no submodule: a submodule annihilated by all of them is a direction in which a row of the matrix can move without any of them noticing. An irreducible module is determined by any one of its nonzero solutions, and the law of [1] by any solution that does not vanish at [1] when the cyclic submodule of [1] is irreducible.

Proposition 39.6 (The law of [1] read from a one-step matrix)**.** *Let insertions $b_1 = 1, b_2, \dots, b_{\mathfrak{m}}$ have classes that span a submodule $\mathfrak{N}$, and let $\mathbf{B} \in \mathrm{Mat}_{\mathfrak{m}}(\mathbb{C}(k))$ have $[f^{-1} b_i] = \sum_l \mathbf{B}_{il}(k) [b_l]$ for every i; for masters, $\mathbf{B} = \mathbf{B_b}$. Put $w_0 = (1, 0, \dots, 0)$ and $w_i(k) = w_{i-1}(k-1)\, \mathbf{B}(k)$, so that $w_i(k) = w_0\, \mathbf{B}(k-i+1) \cdots \mathbf{B}(k)$.*

(i) $\mathrm{Sh}^{-i}[1] = \sum_l w_{i,l}(k)[b_l]$. *So every solution* V *has* $\varsigma^{-i}V[1] = w_i\, v_V$, *with* $v_V = (V[b_1], \dots, V[b_{\mathfrak{m}}])$ *as in Definition 39.2, and when* $\kappa_{1,S} > 0$ *for every nonempty proper* S, $\langle 1\rangle_{k-i} = \sum_l w_{i,l}(k)\langle b_l\rangle_k$ *as meromorphic functions of* k.

(ii) *Let* h *be the least index at which* $w_0, \dots, w_h$ *are linearly dependent over* $\mathbb{C}(k)$, *so that* $h \le \mathfrak{m}$, *let* $\sum_{i=0}^{h} q_i(k)\, w_i(k) = 0$ *with* $q_i \in \mathbb{C}[k]$ *without a common factor, and put* $p_j(k) = q_{h-j}(k+h)$. *Then* $\sum_{j=0}^{h} p_j(k)\, \mathrm{Sh}^j[1] = 0$, *that is* $\sum_j p_j(k) f^j \in \mathcal{L}$; $p_0 \neq 0$, *and* $p_h \neq 0$ *when* $\mathbf{B}$ *is invertible. The order* h *is at least the dimension of the cyclic submodule of* $[1]$, *with equality when* $\mathbf{b}$ *are masters, and then the relation is the law of* $[1]$.

(iii) *Let* $\mathbf{W} = [w_0; \dots; w_{h-1}]$ *be the matrix of the first* h *rows and* J *a set of* h *columns with* $\det \mathbf{W}_J \neq 0$. *Then* $(q_i)_i$ *is proportional over* $\mathbb{C}(k)$ *to the signed maximal minors* $\big((-1)^i \det[w_0; \dots; \widehat{w_i}; \dots; w_h]_J\big)_i$. *With* Q *the monic least common denominator of the entries of* $\mathbf{B}$, q_h *divides the polynomial* $\det \mathbf{W}(k)_J \prod_{j=0}^{h-1} Q(k-j)^{h-j}$. *So at a zero* k_0 *of* q_h *with* $Q(k_0 - j) \neq 0$ *for* $0 \le j < h$ *the rows* $w_0(k_0), \dots, w_{h-1}(k_0)$ *are linearly dependent: there* $\langle 1\rangle_{k_0}, \dots, \langle 1\rangle_{k_0-h+1}$, *written by (i) as linear forms in the values of* $\mathbf{b}$ *at* k_0, *are dependent forms.*

(iv) *If* $h = \mathfrak{m}$, *then* $q_0(k) \det \mathbf{W}(k) = (-1)^h q_h(k) \det \mathbf{W}(k-1) \det \mathbf{B}(k)$.

(v) *The same holds for every element* $m = \sum_l c_l(k)[b_l]$ *of* $\mathfrak{N}$, *with the row* c *in place of* w_0, m *in place of* $[1]$, *and the cyclic submodule of* m, *the span of the* $\mathrm{Sh}^i m$, *in place of that of* $[1]$.

The first dependence among the rows w_i, which carry $\langle 1\rangle$ to the lower strengths in the coordinates of a spanning set, is a recurrence of the values of 1, and on masters it is the law of [1]. Its end coefficient $p_0(k) = q_h(k+h)$ vanishes only at shifted zeros of the denominator of $\mathbf{B}$ and at strengths where the rows line up, and when the rows reach the whole span, $h = \mathfrak{m}$, the end coefficients are tied to the determinant of $\mathbf{B}$. A spanning set that is not independent gives a relation whose order may exceed that of the law of [1].

39.2 The motive of a ray

Along a ray of a family of lists only the exponents move and the letters stay, so the whole ray lives in one motive: its relations are exact forms there, the left factors of the coaction do not depend on the strength, and the strength moves only a vector of de Rham coordinates, by the law of [1].

Definition 39.7 (The model of a ray)**.** Let a ray of a family F of lists on $\mathcal{E}$ have an integral origin, with $\kappa_{1,S} > 0$ for every nonempty proper S. Its *model* is

$$V = X_{\mathcal{E}} \setminus \bigcup_g \widetilde{Y}_g, \qquad D_V = D \cap V, \qquad H = H^{n-1}(V, D_V),$$

the union over the letters K_j and Ψ_j of every list of F, whatever the exponents of the ray, and the linear letters α_J, $|J| \ge 2$ (Definition 34.1). For an insertion $g = \alpha^u \prod_j K_j^{-a_j} \Psi_j^{-b_j}$ of the kind of Proposition 38.5 and an integer k with $\kappa_{0,S} + \kappa_S(g) + k\,\kappa_{1,S} \ge 1$ for every nonempty proper S, which holds for all large k, put $\omega_{g,k} = g\, f^k \omega_0$, extended linearly in g, and $\langle g\rangle_k^{\mathrm{mot}} = [H, \widetilde{\sigma}_{\mathcal{E}}, \omega_{g,k}]^{\mathrm{mot}}$ (Definition 34.5).

Proposition 39.8 (The relations of a ray are exact on its model)**.** *In Definition 39.7,* $\omega_{g,k}$ *is a regular form on* V, *and for every mark* e

$$\big((c_e^{(0)} + k\, c_e^{(1)} + \partial_{y_e})g\big)\, f^k \omega_0 = d\big(\iota_{\partial_{y_e}} \omega_{g,k}\big),$$

where $\iota_{\partial_{y_e}}\omega_{g,k}$ is a regular form on V whose restriction to every component of D_V vanishes. So both relations of the ray (Theorem 38.3) hold in H_{dR}: the class of the left side is 0*, and* $[f\,\omega_{g,k}] = [\omega_{g,k+1}]$.

Theorem 39.9 (A ray is one motive)**.** *Let a ray be as in Definition 39.7.*

(i) $\langle g\rangle_k$ *is the period of* $\langle g\rangle_k^{\mathrm{mot}}$*, and the motivic values satisfy both relations of the ray as identities of motivic periods; the law of* [1] *holds for* $\langle 1\rangle_k^{\mathrm{mot}}$ *at all large* k*.*

(ii) The Galois conjugates of every $\langle g\rangle_k^{\mathrm{mot}}$ *lie in* $L(H,\widetilde{\sigma}_{\mathcal{E}})$*, one space for the whole ray, of dimension at most* $\dim H_{\mathrm{dR}}$*.*

(iii) For a basis (e_i) *of* H_{dR}*,*

$$\Delta\langle g\rangle_k^{\mathrm{mot}} = \sum_i [H,\widetilde{\sigma}_{\mathcal{E}},e_i]^{\mathrm{mot}} \otimes [H,e_i^\vee,\omega_{g,k}]^{\mathrm{dR}};$$

the left factors depend neither on g *nor on* k*, and for every* i *the right factors* $k \mapsto [H,e_i^\vee,\omega_{1,k}]^{\mathrm{dR}}$ *satisfy the law of* [1] *at all large* k*.*

(iv) The coordinates $c_i(g,k) = e_i^\vee(\omega_{g,k})$ *in a basis of* H_{dR} *over* $\mathbb{Q}$ *are rational for an insertion* g *with rational coefficients, the sequences* $k \mapsto c_i(1,k)$ *are rational solutions of the law of* [1] *at all large* k*, and*

$$\langle 1\rangle_k = \sum_i c_i(1,k)\ \mathrm{per}[H,\widetilde{\sigma}_{\mathcal{E}},e_i].$$

Corollary 39.10 (The rows of the values at every order)**.** *For a ray as in Definition 39.7 let* $W \subseteq H_{\mathrm{dR}}$ *be the* $\mathbb{Q}$*-span of the classes* $\omega_{1,k}$*,* $k \geq k_1$*, with* k_1 *such that for every* $k \geq k_1$ *the classes satisfy the law (Theorem 39.9(i)) and* $p_h(k) \neq 0$*. Its dimension* m *is at most the order* h *of the law of* [1]*. In a basis* $w_1,\dots,w_m$ *of* W*,* $\omega_{1,k} = \sum_l c_l(k)\,w_l$ *with* c_l *rational solutions of the law, and*

$$\langle 1\rangle_k = \sum_{l=1}^{m} c_l(k)\ \mathrm{per}[H,\widetilde{\sigma}_{\mathcal{E}},w_l] \qquad (k \geq k_1).$$

So every value has a row in the m *coordinates* $\mathrm{per}[H,\widetilde{\sigma}_{\mathcal{E}},w_l]$*, whose coefficients are rational solutions of the law; a coordinate with a rational period joins the rational part.*

So along a ray the motive is fixed and the strength moves only a vector of de Rham coordinates, by a rational recurrence. The left factors are the periods of H against a basis, and by Theorem 34.13 and Corollary 34.15 those of weight at most w are sums of products of open periods of steps of at most $w+1$ marks, along any tree of bunches: the coaction is read once for the whole ray. Theorem 38.31(iii) bounds the space of the values; Corollary 39.10 writes each value in fixed coordinates with coefficients that solve the law.

39.3 Symmetries of a ray

Proposition 39.11 (The symmetries of a ray)**.** *Let a ray of* F *have the origin* $(\mathbf{m}_0;\mathbf{s}_0,\mathbf{t}_0)$ *and the direction* $(\mathbf{m}_1;\mathbf{s}_1,\mathbf{t}_1)$*, and put* $\sigma_i = \frac{1}{2}\sum_j(s_{ij}+t_{ij})$*,* $i = 0,1$*. On the torus* $(\mathbb{C}^\times)^{\mathcal{E}}/\mathbb{C}^\times$ *put, for a bijection* β *of the marks,* $\phi_\beta(\alpha) = \alpha\circ\beta$ *with* $(\alpha\circ\beta)_e = \alpha_{\beta(e)}$*; the* Cremona $\mathrm{cr}(\alpha) = \alpha^{-1}$*; and the* reversed *map* $\bar{\phi}_\beta = \mathrm{cr}\circ\phi_\beta$*,* $\bar{\phi}_\beta(\alpha) = (\alpha\circ\beta)^{-1}$*. A* symmetry *of the ray is a map* ϕ *among the* ϕ_β *and the* $\bar{\phi}_\beta$ *that keeps the stride and the density of the origin form,* $f\circ\phi = f$ *and* $(\omega_0/dy)\circ\phi = \omega_0/dy$*, the latter on the positive orthant with the principal powers when the origin is not integral; the*

symmetries form a group. Let h be a bijection of the tables, write $u \circ \beta^{-1}$ for $e \mapsto u_{\beta^{-1}(e)}$ and $\mathbf{a} \circ h^{-1}$ for $j \mapsto a_{h^{-1}(j)}$, and say that β carries, *respectively* exchanges, *the tables with h when it satisfies the conditions of Definition 11.13 on the bases and the weights, without its condition on the pairs.*

(i) If β carries the tables, $K_j \circ \phi_\beta = K_{h(j)}$ and $\Psi_j \circ \phi_\beta = \Psi_{h(j)}$. If β exchanges them, $K_j \circ \phi_\beta = \Psi_{h(j)}$, $\Psi_j \circ \phi_\beta = K_{h(j)}$, $K_j \circ \bar{\phi}_\beta = \alpha^{-\mathcal{E}} K_{h(j)}$ and $\Psi_j \circ \bar{\phi}_\beta = \alpha^{-\mathcal{E}} \Psi_{h(j)}$. Always $K_j \circ \mathrm{cr} = \alpha^{-\mathcal{E}} \Psi_j$ and $\Psi_j \circ \mathrm{cr} = \alpha^{-\mathcal{E}} K_j$.

(ii) The following maps are symmetries when, for $i = 0, 1$, every mark e and every table j:

map	*masses*	*exponents*
ϕ_β, *β carrying*	$m_{i,\beta(e)} = m_{i,e}$	$(s_{i,h(j)}, t_{i,h(j)}) = (s_{ij}, t_{ij})$
ϕ_β, *β exchanging*	$m_{i,\beta(e)} = m_{i,e}$	$(s_{i,h(j)}, t_{i,h(j)}) = (t_{ij}, s_{ij})$
cr	$\mathbf{m}_i = \sigma_i \mathbf{1}$	$s_{ij} = t_{ij}$
$\bar{\phi}_\beta$, *β exchanging*	$m_{i,\beta(e)} + m_{i,e} = 2\sigma_i$	$(s_{i,h(j)}, t_{i,h(j)}) = (s_{ij}, t_{ij})$

A symmetry maps X_F and the positive orthant onto themselves, has $\phi^* \omega_0 = \pm \omega_0$ when the origin is integral, and keeps the values, $\langle g' \circ \phi \rangle_k = \langle g' \rangle_k$ for every insertion g'.

(iii) On the insertions $\alpha^u \prod_j K_j^{-a_j} \Psi_j^{-b_j}$, written $(u; \mathbf{a}, \mathbf{b})$, the four kinds act by $(u; \mathbf{a}, \mathbf{b}) \mapsto$

$$(u \circ \beta^{-1}; \mathbf{a} \circ h^{-1}, \mathbf{b} \circ h^{-1}) \quad (\phi_\beta,\ \beta \text{ carrying}), \qquad (-u + |\mathbf{a} + \mathbf{b}|\mathbf{1}; \mathbf{b}, \mathbf{a}) \quad (\mathrm{cr}),$$
$$(u \circ \beta^{-1}; \mathbf{b} \circ h^{-1}, \mathbf{a} \circ h^{-1}) \quad (\phi_\beta,\ \beta \text{ exchanging}),$$
$$(-u \circ \beta^{-1} + |\mathbf{a} + \mathbf{b}|\mathbf{1}; \mathbf{a} \circ h^{-1}, \mathbf{b} \circ h^{-1}) \quad (\bar{\phi}_\beta,\ \beta \text{ exchanging}),$$

with $|\mathbf{a} + \mathbf{b}| = \sum_j (a_j + b_j)$.

The four kinds are the monomial maps of the torus that a list can certify: a permutation of the marks that carries the bases, one that carries them onto the cobases, the inversion of every scale, and the composite of the last two. The first keeps each letter, the second and the third swap the two letters of every table, and the fourth keeps each letter up to the monomial $\alpha^{-\mathcal{E}}$, which the masses absorb when the masses of a mark and of its image add up to $2\sigma_i$, twice the total strength. Composites of symmetries are symmetries, so a group generated by maps of the four kinds can be used whole.

Theorem 39.12 (The invariant module)**.** *Let G be a finite group of symmetries of a ray.*

(i) The maps $\phi^*[g'] = [g' \circ \phi]$, $\phi \in G$, are well defined on $\mathfrak{M}$ and commute with the shift. With $e_G = |G|^{-1} \sum_{\phi \in G} \phi^*$, $\mathfrak{M} = \mathfrak{M}^G \oplus (1 - e_G)\mathfrak{M}$ as submodules, and $\mathfrak{M}^G = e_G \mathfrak{M}$ consists of the classes of the invariant insertions.

(ii) A solution V with $V \circ \phi^* = V$ for every $\phi \in G$, the values along the ray among them, vanishes on $(1 - e_G)\mathfrak{M}$: $\langle g' \rangle_k = \langle e_G g' \rangle_k$. The cyclic submodule of $[1]$ lies in $\mathfrak{M}^G$, so the law of $[1]$ is read in $\mathfrak{M}^G$, on masters among the invariant insertions.

(iii) If $\phi \in G$ fixes a nondegenerate native gauge α_c, then $A_c \circ \phi^* = A_c$. For the G-orbit O of α_c, with stabilizer G_c, the sum $A_O = \sum_{\phi G_c \in G/G_c} A_c \circ \phi^*$ is invariant and does not vanish on $\mathfrak{M}^G$, and $\dim_{\mathbb{C}(k)} \mathfrak{M}^G$ is at least the number of G-orbits of nondegenerate native gauges.

Theorem 39.13 (A reversed exchange at a lean)**.** *Let β exchange a family with itself (Definition 11.13), with the bijection h of its tables, and let $\Upsilon = \Upsilon_{\boldsymbol{\sigma}, \boldsymbol{\delta}; \mathbf{1}}$ be a realization at the table's gauge with masses $\boldsymbol{\tau}$ (Definition 9.1).*

(i) $R_{h(j),\beta(e)}(\mathbf{1}) = 1 - R_{j,e}(\mathbf{1})$ *for every table and mark, and* $\tau_{\beta(e)} + \tau_e = 2\sigma$. *So* $\bar{\phi}_\beta$ *keeps the integrand* $\alpha^{\boldsymbol{\tau}} \prod_j K_j^{-s_j} \Psi_j^{-t_j}$ *of the period at the data of* Υ, *and it is a symmetry of the ray with origin* 0 *and direction* $(c\boldsymbol{\tau}; c\mathbf{s}, c\mathbf{t})$ *whenever that direction is integral. The exchange* ϕ_β *and the Cremona each take that integrand to the integrand at the data of* $\Upsilon_{\boldsymbol{\sigma},-\boldsymbol{\delta};\mathbf{1}}$.

(ii) For every mark e *and partners* $\mathbf{g} = (g_1, \dots, g_q)$, *with* $\beta(\mathbf{g}) = (\beta(g_1), \dots, \beta(g_q))$, *the views (Definition 10.1) satisfy*

$$\Phi^{\mathbf{E}}_{\beta(e),\beta(\mathbf{g})} = \Phi^{\mathbf{E}}_{e,\mathbf{g}}, \qquad \Phi^{\mathbf{O}}_{\beta(e),\beta(\mathbf{g})} = -\Phi^{\mathbf{O}}_{e,\mathbf{g}} :$$

the reading of $\beta(e)$ *at* $\boldsymbol{\delta}$ *is the reading of* e *at* $-\boldsymbol{\delta}$. *At the centre* β *maps every class onto itself; at a lean it permutes the classes of* Υ.

(iii) In a one-table molecule, β *maps every class* C *of the centre onto itself, and when* C *splits at the lean into* C_K *and* C_Ψ *(Theorem 11.17),* $\beta(C_K) = C_\Psi$ *and* $\beta(C_\Psi) = C_K$.

An exchange carries the bases of a family onto the cobases, and the integrand at a lean weighs the two unequally: the exchange alone takes the lean to its opposite, and so does the Cremona, which inverts every scale. Their composite keeps the integrand at every lean at the table's gauge, because there the masses of a mark and of its image add up to 2σ. So the integral at a lean keeps a symmetry carrying each mark to its image under the exchange, and insertions related by it have equal values; but the symmetry reverses every scale, $y \mapsto -\beta^* y$, and the reading, whose odd part changes sign under a reversal, sees $\beta(e)$ as e read at the opposite lean. A bijection that keeps the potential fixes every class (Lemma 14.18); the reversed exchange permutes the classes, and on a class of the centre that the lean splits it swaps the basis half and the cobasis half. At the centre the odd part is absent and the exchange, the Cremona and their composite all keep the integrand: the reversal is invisible to the reading there, and the classes it joins at the centre are those the lean separates.

Remark 39.14. The condition $m_{\beta(e)} + m_e = 2\sigma$ of Proposition 39.11 is met off the table's gauge as well, for instance by the uniform masses $\sigma\mathbf{1}$ at every lean of a family with $\sum_j \delta_j(2r_j - n) = 0$, as for one table with $2r = n$. The native gauge of such a realization on the positive orthant is fixed by $\bar{\phi}_\beta$ up to scale, and the views of $\beta(e)$ are those of e at the reflected arguments $v \mapsto -v$ up to affine terms in v, by the identities $\Phi_{\mathbf{O}}(-\beta^* y) = \Phi_{\mathbf{O}}(y)$ and $\Phi_{\mathbf{E}}(-\beta^* y) = \Phi_{\mathbf{E}}(y) - 2\sigma\langle \mathbf{1}, y\rangle$ of Section 50.38. When that gauge is not proportional to $\mathbf{1}$ the realization is not an atom (Theorem 11.4), though the integral keeps the reversed exchange.

39.4 The box of the walls

The module of a ray is the quotient by the relations of the period, and finitely many of them give a spanning set of its Laurent part and the step on it. An insertion is measured by its level, the powers of the letters in its denominator, and by its wall degree, the power of the reciprocal stride that dominates it, read on the walls of the direction. A box is the finite set of symbols of insertions within given levels and wall degree; its relations, the letter identities among them and the mark relations of its stems, are relations of the module, so they hold as identities of meromorphic functions of the strength. One elimination of a box leaves a spanning set of a submodule that contains [1] and the matrix of the inverse shift on it, with a certificate supported on the stems, and a search through the boxes stops by the finite dimension of the ray. When the origin carries no letter exponents, the relations $(c_e^{(0)} + k\, c_e^{(1)} + \partial_{y_e})(\alpha^w f^{-1})$ involve Laurent insertions alone, and they do not suffice: the evaluation at a singular point of the zero set of f^{-1} on the torus, when

there is one, vanishes on all of them and not on the law of [1]. Insertions are the regular functions on the letter complement X_F of Definition 38.1, on which every letter is inverted whatever its exponent along the ray; a box need carry no unit of a letter whose exponent along the ray vanishes identically, and its relations are relations of the module all the same.

Definition 39.15 (Levels, wall degree, boxes)**.** Let a ray of a family F of N tables on $n \geq 2$ marks have $\kappa_{1,S} > 0$ for every nonempty proper S, and let $\Bbbk \subseteq \mathbb{C}$ be a field that contains the weights and the origin.

(i) The *symbols* are the data $(u; \mathbf{a}, \mathbf{b})$ with $u \in \mathbb{Z}^{\mathcal{E}}$, $\mathbf{a}, \mathbf{b} \in \mathbb{N}^N$ and $u_{\mathcal{E}} = \sum_j (a_j r_j + b_j r_j^*)$. The *evaluation* of $(u; \mathbf{a}, \mathbf{b})$ is the insertion $\alpha^u \prod_j K_j^{-a_j} \Psi_j^{-b_j}$ (Proposition 39.11(iii)); its *level* is $(\mathbf{a}, \mathbf{b})$, and the symbols at the level $(\mathbf{0}, \mathbf{0})$ are the *Laurent* symbols α^u, $u_{\mathcal{E}} = 0$. A *formal combination* is a finite combination of symbols with coefficients in $\Bbbk(k)$, and its evaluation is the same combination of the insertions, an element of $\mathbb{C}[X_F] \otimes \mathbb{C}(k)$. The evaluations of the symbols span $\mathbb{C}[X_F]$.

(ii) The *walls* of a symbol $g = (u; \mathbf{a}, \mathbf{b})$ are those of its data, $\kappa_U(g) = u_U - \sum_j \big(a_j d_j(U) + b_j d_j^*(U)\big)$, and its *wall degree* is

$$\deg_\kappa g = \max_{\varnothing \neq U \subsetneq \mathcal{E}} \frac{-\kappa_U(g)}{\kappa_{1,U}},$$

the least real x with $\kappa_U(g) + x\,\kappa_{1,U} \geq 0$ for every nonempty proper U.

(iii) The *mark relation* of a symbol $g = (u; \mathbf{a}, \mathbf{b})$ at a mark e is the formal combination

$$\begin{aligned} \mathrm{MR}_e(g) = \big(m_{0,e} + k\,m_{1,e} + u_e\big)\,g &- \sum_j \big(s_{0j} + k\,s_{1j} + a_j\big) \sum_{T \ni e} \theta_{j,T}\,(u + \mathbf{1}_T; \mathbf{a} + \mathbf{e}_j, \mathbf{b}) \\ &- \sum_j \big(t_{0j} + k\,t_{1j} + b_j\big) \sum_{T \not\ni e} \theta_{j,T}\,(u + \mathbf{1}_{\mathcal{E}\setminus T}; \mathbf{a}, \mathbf{b} + \mathbf{e}_j), \end{aligned}$$

the sums over the bases T of table j, the terms whose coefficient vanishes identically in k omitted. Its evaluation is $(c_e^{(0)} + k\,c_e^{(1)} + \partial_{y_e})$ applied to that of g. The *letter identities* of g are $g - \sum_{T \in \mathcal{B}_j} \theta_{j,T}(u + \mathbf{1}_T; \mathbf{a} + \mathbf{e}_j, \mathbf{b})$, for K_j, and $g - \sum_{T \in \mathcal{B}_j} \theta_{j,T}(u + \mathbf{1}_{\mathcal{E}\setminus T}; \mathbf{a}, \mathbf{b} + \mathbf{e}_j)$, for Ψ_j; they evaluate to 0.

(iv) A letter K_j, or Ψ_j, is *active along the ray* when its exponent $s_{0j} + k\,s_{1j}$, or $t_{0j} + k\,t_{1j}$, does not vanish identically. *Level bounds* are $\bar{\mathbf{a}}, \bar{\mathbf{b}} \in \mathbb{N}^N$ with $\bar{a}_j \geq 1$ when K_j is active and $\bar{b}_j \geq 1$ when Ψ_j is active; put $\bar{a}_j^- = \max(\bar{a}_j - 1, 0)$ and $\bar{b}_j^- = \max(\bar{b}_j - 1, 0)$. For $\mathfrak{t} \in \mathbb{N}$ the *box* $\mathfrak{B} = \mathfrak{B}_{\mathfrak{t}}(\bar{\mathbf{a}}, \bar{\mathbf{b}})$ is the set of the symbols of wall degree at most $\mathfrak{t}$ at the levels $(\mathbf{a}, \mathbf{b})$ with $\mathbf{a} \leq \bar{\mathbf{a}}$ and $\mathbf{b} \leq \bar{\mathbf{b}}$, and its *stems* are its symbols at the level $(\bar{\mathbf{a}}^-, \bar{\mathbf{b}}^-)$. Its formal combinations form the space $\mathcal{F}_{\mathfrak{B}}$, and its *relations* $\mathcal{R}_{\mathfrak{B}} \subseteq \mathcal{F}_{\mathfrak{B}}$ are the $\Bbbk(k)$-span of the letter identities of its symbols $(u; \mathbf{a}, \mathbf{b})$, for K_j when $a_j < \bar{a}_j$ and for Ψ_j when $b_j < \bar{b}_j$, and of the mark relations of its stems at every mark. The box with *one unit of each active letter* has $\bar{a}_j = 1$ exactly when K_j is active and $\bar{b}_j = 1$ exactly when Ψ_j is; its stems are the Laurent symbols of wall degree at most $\mathfrak{t}$.

(v) The *Laurent part* $\mathfrak{M}_{\mathrm{L}}$ of the module $\mathfrak{M}$ (Definition 39.1) is the span of the classes of the Laurent insertions.

(vi) A group of symmetries generated by maps of the four kinds of Proposition 39.11(ii) carries every letter to a letter times a monomial (Proposition 39.11(i)): each of its elements ϕ permutes the letters, and the symbols, $g \mapsto \phi^* g$ (Proposition 39.11(iii)), the evaluation

of $\phi^* g$ being that of g composed with ϕ. Such a finite group G *keeps* the box when its permutations of the letters keep the level bounds, $\bar{a}_j$ being the bound of K_j and $\bar{b}_j$ that of Ψ_j.

Proposition 39.16 (The wall degree)**.** *For a ray as in Definition 39.15 and its symbols g:*

(i) For real x, $|g|\, f^x$ is bounded on the positive orthant exactly when $x \geq \deg_\kappa g$: the symbols of wall degree at most x are those whose evaluation is dominated by f^{-x}. For the origin 0 the value $\langle g \rangle_k$ converges absolutely exactly when $\operatorname{Re} k > \deg_\kappa g$, and for any origin it converges absolutely at every k with $\operatorname{Re} \kappa_{0,U} + (\operatorname{Re} k - \deg_\kappa g)\, \kappa_{1,U} > 0$ for every nonempty proper U.

(ii) A Laurent symbol α^u has the wall degree $\max_U(-u_U)/\kappa_{1,U} \geq 0$, zero exactly for $u = 0$. Every monomial of the Laurent polynomial f^{-1} has wall degree at most 1, and every monomial of $f^{-1}\alpha^u$ wall degree at most $\deg_\kappa \alpha^u + 1$.

(iii) The terms of the mark relations and of the letter identities of g have wall degree at most $\deg_\kappa g$.

(iv) At every level and for every real x there are finitely many symbols of wall degree at most x.

(v) For every element ϕ of a group as in Definition 39.15(vi), $\deg_\kappa \phi^* g = \deg_\kappa g$, and ϕ^* maps Laurent symbols to Laurent symbols.

Lemma 39.17 (The Laurent part)**.** *For a ray as in Definition 39.15, the Laurent part $\mathfrak{M}_{\mathrm{L}}$ is a submodule. It contains* [1]*, and the class of every insertion g with $f^{-l} g$ a Laurent polynomial for some $l \in \mathbb{N}$; when every letter exponent of the direction is positive, $s_{1j}, t_{1j} \geq 1$, it is $\mathfrak{M}$. For a finite group G of symmetries, $e_G \mathfrak{M}_{\mathrm{L}} = \mathfrak{M}_{\mathrm{L}} \cap \mathfrak{M}^G$ is a submodule, spanned by the classes of the invariant Laurent insertions.*

Proposition 39.18 (The relations of a box)**.** *Let $\mathfrak{B} = \mathfrak{B}_{\mathfrak{t}}(\bar{\mathbf{a}}, \bar{\mathbf{b}})$ be a box of a ray as in Definition 39.15.*

(i) Every term of every relation of the box lies in the box. The letter identities evaluate to 0 and the mark relation $\mathrm{MR}_e(g)$ of a stem to the element $(c_e^{(0)} + k\, c_e^{(1)} + \partial_{y_e}) g$ of $\mathcal{L}$: every relation evaluates into $\mathcal{L}$, and its value vanishes identically in k (Proposition 38.5(ii)).

(ii) A formal combination of symbols of the box whose evaluation is 0 is a combination of the letter identities of the box.

(iii) The mark relation at every mark of every symbol of wall degree at most $\mathfrak{t}$ at a level at most $(\bar{\mathbf{a}}^-, \bar{\mathbf{b}}^-)$ lies in $\mathcal{R}_{\mathfrak{B}}$.

(iv) If a finite group G of symmetries keeps the box, every $\phi \in G$ maps the box onto itself, its stems onto its stems and $\mathcal{R}_{\mathfrak{B}}$ onto itself; so, with $e_G = |G|^{-1} \sum_{\phi \in G} \phi^*$ and $\mathcal{F}_{\mathfrak{B}}^G = e_G \mathcal{F}_{\mathfrak{B}}$, $e_G \mathcal{R}_{\mathfrak{B}} = \mathcal{R}_{\mathfrak{B}} \cap \mathcal{F}_{\mathfrak{B}}^G$.

Proposition 39.19 (The closing relations have more solutions than the ray)**.** *Let a ray as in Definition 39.15 have an origin with $\mathbf{s}_0 = \mathbf{t}_0 = \mathbf{0}$, and write $f^{-1} = \sum_v \lambda_v \alpha^v$. For a Laurent insertion α^w and a mark e the* closing relation

$$\big(c_e^{(0)} + k\, c_e^{(1)} + \partial_{y_e}\big)\big(\alpha^w f^{-1}\big) = \sum_v \lambda_v \big(m_{0,e} + w_e + (1-k)\, v_e\big)\, \alpha^{w+v}$$

is an element of $\mathcal{L}$ whose terms are Laurent insertions. Let $z \in (\mathbb{C}^\times)^{\mathcal{E}}$ be a point at which f^{-1} and every $\partial_{y_e} f^{-1}$ vanish, a singular point of the zero set of f^{-1} on the torus.

(i) The evaluation at z, $\alpha^w \mapsto z^w$ on the Laurent insertions, extended $\mathbb{C}(k)$-linearly, vanishes on every closing relation.

(ii) It takes the value $q_0(k)$ on every element $\sum_{i=0}^{h} q_i(k) f^{-i}$, $q_i \in \mathbb{C}(k)$. So no element of $\mathcal{L}$ of this form with $q_0 \neq 0$ is a combination of closing relations, while $\mathcal{L}$ contains such elements: the law $\sum_j p_j(k)\,\mathrm{Sh}^j[1] = 0$ of $[1]$, with $p_0 p_h \neq 0$ (Definition 39.1), gives $\sum_{i=0}^{h} p_{h-i}(k-h) f^{-i} \in \mathcal{L}$. No $\mathbb{C}(k)$-linear form that vanishes on $\mathcal{L}$ agrees with the evaluation at z on the Laurent insertions.

The point z lies off X_F, a letter that the direction uses vanishing there. The relations of $\mathcal{L}$ that the closing relations lack involve the insertions with inverse letters, through the letter identities and the mark relations of the occupations, and a box supplies them through its units of the letters.

Definition 39.20 (The reduction of a box)**.** Let a finite group G of symmetries keep a box $\mathfrak{B} = \mathfrak{B}_{\mathfrak{t}}(\bar{\mathbf{a}}, \bar{\mathbf{b}})$ (Definition 39.15); G may be trivial.

(i) The *orbit average* of a symbol g of the box is $e_G g$, with e_G as in Proposition 39.18(iv); the orbit averages of the orbits of symbols form a basis of $\mathcal{F}^G_{\mathfrak{B}}$, and $\mathcal{R}^G_{\mathfrak{B}} = e_G \mathcal{R}_{\mathfrak{B}}$.

(ii) A *ranking* is a total order of these orbits in which every orbit at a positive level ranks above every Laurent orbit and, of two Laurent orbits, the one of larger wall degree ranks higher; the level of the symbols of an orbit is $(\mathbf{0}, \mathbf{0})$ for all of them or for none, and they all have the same wall degree (Proposition 39.16(v)). The *leading* orbit of a nonzero element of $\mathcal{F}^G_{\mathfrak{B}}$ is the highest-ranked orbit in it; an orbit is a *pivot* when it leads an element of $\mathcal{R}^G_{\mathfrak{B}}$, and *free* otherwise. The *reduction* of $x \in \mathcal{F}^G_{\mathfrak{B}}$ is the unique combination of the averages of the free orbits that is congruent to x modulo $\mathcal{R}^G_{\mathfrak{B}}$; if x involves no orbit ranked above a given orbit, neither does its reduction.

(iii) For $\mathfrak{s} \in \mathbb{N}$ with $\mathfrak{s} < \mathfrak{t}$, the *spanning set* of the box at $\mathfrak{s}$ is $\mathbf{b} = (b_1, \ldots, b_{\mathfrak{m}})$, the averages of the free Laurent orbits of wall degree at most $\mathfrak{s}$, listed with $b_1 = 1$, the orbit of 1 being free. Its *targets* are the invariant Laurent polynomials $f^{-1} b_i$, elements of $\mathcal{F}^G_{\mathfrak{B}}$. The box is *accepted* at $\mathfrak{s}$ when the reduction of every target is a combination of the spanning set, $f^{-1} b_i \equiv \sum_l \mathbf{B}_{il}\, b_l$ modulo $\mathcal{R}^G_{\mathfrak{B}}$ with $\mathbf{B}_{il} \in \Bbbk(k)$; $\mathbf{B}$ is then the *matrix* of the box.

Theorem 39.21 (The box gives a spanning set, the one-step matrix and a certificate)**.** *Let a finite group G of symmetries keep a box $\mathfrak{B} = \mathfrak{B}_{\mathfrak{t}}(\bar{\mathbf{a}}, \bar{\mathbf{b}})$ of a ray as in Definition 39.15, and let the box be accepted at $\mathfrak{s}$ (Definition 39.20), with the spanning set $\mathbf{b}$ and the matrix $\mathbf{B}$.*

(i) In the module, $[f^{-1} b_i] = \sum_l \mathbf{B}_{il}(k)[b_l]$ for every i. The classes of $\mathbf{b}$ span a submodule $\mathfrak{N}$ of $\mathfrak{M}^G$ that contains $[1]$: the span of the classes of the invariant combinations of Laurent symbols of wall degree at most $\mathfrak{s}$, which lies in $e_G \mathfrak{M}_{\mathrm{L}}$ (Lemma 39.17). The spanning set is a set of masters of $\mathfrak{N}$ exactly when its classes are linearly independent over $\mathbb{C}(k)$, and then $\mathbf{B} = \mathbf{B}_{\mathbf{b}}$ (Definition 39.1).

(ii) The certificate. *There are formal combinations $G_{i,e}$ of the stems, with coefficients in $\Bbbk(k)$, such that*

$$f^{-1} b_i - \sum_l \mathbf{B}_{il}(k)\, b_l = \sum_{e \in \mathcal{E}} \big(c_e^{(0)} + k\, c_e^{(1)} + \partial_{y_e} \big) G_{i,e}$$

as functions on X_F, the $G_{i,e}$ evaluated: a certificate of the one-step relation (Proposition 38.5(i)).

(iii) Every solution V has $\varsigma^{-1} v_V = \mathbf{B}\, v_V$, with $v_V = (V[b_1], \ldots, V[b_{\mathfrak{m}}])$, and $\langle b_i \rangle_{k-1} = \sum_l \mathbf{B}_{il}(k) \langle b_l \rangle_k$ as an identity of meromorphic functions of k. At every real k off the poles of

the coefficients with $\operatorname{Re}\kappa_{0,U} + (k-\mathfrak{t})\,\kappa_{1,U} > 0$ *for every nonempty proper* U*, all the values in (ii) converge absolutely and every term* $(c_e^{(0)} + k\,c_e^{(1)} + \partial_{y_e})s$*,* s *a stem, has the value* 0*, so the certificate integrates over the chart term by term.*

(iv) Proposition 39.6 applies to $\mathbf{b}$ *and* $\mathbf{B}$*: the first dependence of the rows gives a relation* $\sum_j p_j(k) f^j \in \mathcal{L}$*, with a certificate assembled from those of (ii), whose order is at least that of the law of* [1]*, with equality when the spanning set is a set of masters, and which then is the law of* [1]*.*

Theorem 39.22 (The search stops)**.** *Let* G *be a finite group of symmetries of a ray as in Definition 39.15, generated by maps of the four kinds of Proposition 39.11(ii) and possibly trivial, and fix a ranking for every box that* G *keeps. There are* $\mathfrak{t} \geq 1$*, level bounds kept by* G *and* $\mathfrak{s} < \mathfrak{t}$ *at which the box* $\mathfrak{B}_{\mathfrak{t}}(\bar{\mathbf{a}}, \bar{\mathbf{b}})$ *modulo* G *is accepted, with a spanning set whose classes span* $e_G\mathfrak{M}_{\mathrm{L}}$*, which is* $\mathfrak{M}^G$ *when every letter exponent of the direction is positive. So a search that runs through all the* $(\mathfrak{t}, \bar{\mathbf{a}}, \bar{\mathbf{b}}, \mathfrak{s})$ *with level bounds kept by* G*, in any order that reaches each, and tests the acceptance by one elimination over* $\Bbbk(k)$ *at each, stops.*

So the construction is finite and every step is an identity: a box is finite (Proposition 39.16(iv)), its relations are relations of the period read at the data of the ray (Proposition 39.18), so that whatever the box, the one-step relation and the recurrence it produces hold at every strength, and a search through the boxes stops (Theorem 39.22). The spanning set spans a submodule that contains [1], which is all a recurrence of the values of 1 needs; it is a set of masters exactly when it is independent, and then the recurrence that its rows give is the law of [1] and its matrix is $\mathbf{B}_{\mathbf{b}}$.

39.5 Sources at the high end

Definition 39.23 (Sources; regular points; the normal density)**.** The *critical locus* of a ray is the set of its native gauges, $\{\alpha \in X_F : \ c^{(1)}(\alpha) = 0\}$, the critical points of $\log f$. A *source* is an irreducible component Z of it; f is constant on Z, with value f_Z, its *native value*. A point $z \in Z$ is *regular* when it lies on no other source, Z is smooth at z of dimension $d = \dim Z$, and the Hessian of $\log f$ in y at z has rank $n-1-d$ on the tangent space of the torus; its kernel is then the tangent space of Z, and it induces a nondegenerate quadratic form on the normal space. Z is *clean* when it has a regular point; the regular points then form a dense open subset Z°. In local holomorphic coordinates (u, w) at a regular point, with $Z = \{w = 0\}$ and $-\log f = -\log f_Z + \frac{1}{2} w^{\mathsf{T}} A(u) w + O(|w|^3)$, the *normal density* is the d-form

$$\nu = \det A(u)^{-1/2} \, \frac{\omega_0}{du \wedge dw}\Big|_{w=0} du,$$

which does not depend on the coordinates up to its sign. For an integral origin ω_0 is single-valued on X_F, and the *normal cover* $\tilde{Z}^\circ \to Z^\circ$ is the double cover on which ν is single-valued, its deck involution changing the sign of ν. A source of dimension 0 is an isolated native gauge, clean exactly when it is nondegenerate.

Theorem 39.24 (A closed cycle on a source carries a solution)**.** *Let a ray have an integral origin, let* Z *be a clean source of dimension* d*,* $m = n-1-d$*, and let* γ *be a compact oriented cycle of real dimension* d *in* $\tilde{Z}^\circ$*.*

(i) Over γ *there is a chain* $N(\gamma)$ *of real dimension* $n-1$ *in* X_F*, a union of discs, one through each point* z *of* γ*, transverse to* Z*, on which* $|f| \leq |f_Z| e^{-c|v|^2}$ *at the displacement* v *from* z *for some* $c > 0$*, oriented by the sheet of* ν*; its boundary lies where* $|f| \leq |f_Z| e^{-\varepsilon}$ *for some*

$\varepsilon > 0$. *Two such chains over homologous cycles differ by a boundary and by pieces on which* $|f| \le |f_Z| e^{-\varepsilon}$.

(ii) As $k \to \infty$,

$$\int_{N(\gamma)} g\, f^k \omega_0 \sim f_Z^k\, k^{-m/2} \sum_{i \ge 0} c_i(\gamma; g)\, k^{-i}, \qquad c_0(\gamma; g) = (2\pi)^{m/2} \int_\gamma g\, \nu.$$

Where one family of holomorphic normal slices $\{u = \text{const}\}$, *coordinates* (u, w) *as in Definition 39.23, covers* Z°, $c_i(\gamma; g) = \int_\gamma a_i(\cdot\,; g)$, *with* $f_Z^k k^{-m/2} \sum_i k^{-i} a_i(u; g)$ *the Laplace expansion of the integral over the disc in the slice at* u: $a_0(\cdot\,; g) = (2\pi)^{m/2} g\, \nu$, *and each* $a_i(\cdot\,; g)$ *is a holomorphic* d*-form given by finitely many* w*-derivatives of* g, *of* $\omega_0/(du \wedge dw)$ *and of* $\log f$ *at* $w = 0$.

(iii) The map $A_\gamma : g \mapsto f_Z^k k^{-m/2} \sum_i c_i(\gamma; g)\, k^{-i}$ *is a solution of type* $\big(f_Z, -\frac{m}{2} + \mathbb{Z}\big)$. *It depends only on the homology class of* γ *in* $\tilde{Z}^\circ$, *and the image of* γ *under the deck involution gives* $-A_\gamma$.

(iv) If $\gamma_1, \dots, \gamma_r$ *are such cycles and* $g_1, \dots, g_r$ *insertions with* $\det \big[\int_{\gamma_a} g_b\, \nu \big]_{a,b} \neq 0$, *the* A_{γ_a} *are linearly independent over* $\mathbb{C}$, *and their normalizations over* $\mathbb{C}((1/k))$.

For $d = 0$, γ *is the point with a sheet and this is Theorem 38.6. For an origin that is not integral,* ν *is multivalued along* Z°, *and the same holds for cycles with coefficients in the local system of its branches.*

Corollary 39.25 (A curve of native gauges: residues and periods)**.** *Let a ray have an integral origin, let* Z *be a clean source of dimension one, and let* $\bar{Z}$ *be the smooth compact curve that contains* $\tilde{Z}^\circ$ *as the complement of finitely many* punctures*: the points over the points of* Z *that are not regular, among them its crossings with other sources and the points where the normal form degenerates, and the points where* Z *leaves* X_F. *The solutions of* Z *are spanned by those of a small loop around each puncture and those of a basis of the cycles of* $\bar{Z}$. *When* Z *is the closure of* $\{\alpha_0 b^{\mathbf{v}} : b \in \mathbb{C}^\times\}$, $\mathbf{v} \in \mathbb{Z}^{\mathcal{E}}$, *with* $b \mapsto \alpha_0 b^{\mathbf{v}}$ *injective, and the normal coordinates are those of one fixed complement* N *of* $\mathbb{C}\mathbf{v}$ *in* $\mathbb{C}^{\mathcal{E}}/\mathbb{C}\mathbf{1}$, $\alpha = \alpha_0 b^{\mathbf{v}} e^w$ *with* $w \in N$, *the determinant* $\det A(b)$ *is rational in* b, *every* $a_i(\cdot\,; g)$ *is* $r_i(b; g) \det A(b)^{-1/2}\, db/b$ *with* r_i *rational in* b, $\tilde{Z}^\circ$ *is an open part of the curve* $Y^2 = \det A(b)$, *and the loop around a puncture* q *gives* $2\pi i$ *times the residue at* q *of* $f_Z^k k^{-m/2} \sum_i k^{-i} a_i(\cdot\,; g)$.

Theorem 39.26 (A native gauge of corank at most one)**.** *Let* α_c *be an isolated native gauge of a ray at which the Hessian of* $\log f$ *in* y *has corank at most one. There are holomorphic coordinates* $(X, w) \in \mathbb{C} \times \mathbb{C}^{n-2}$ *at* α_c *with*

$$\log f = \log f(\alpha_c) - \tfrac{1}{2} \sum_i w_i^2 + c\, X^{\mu+1}, \qquad c \neq 0,$$

for an integer $\mu \ge 1$, *the* multiplicity*;* $\mu = 1$ *exactly when* α_c *is nondegenerate, and otherwise* ∂_X *spans the kernel of the Hessian at* α_c. *Then* α_c *is an* A_μ point, *and:*

(i) There are μ *solutions* $A_{c,i}$, $0 \le i < \mu$, $A_{c,i}$ *of type* $\big(f(\alpha_c), -\frac{n-2}{2} - \frac{i+1}{\mu+1} + \mathbb{Z}\big)$*: the expansions of the integrals of* $g\, f^k \omega_0$ *over the chains (real normal disc)*$\times \Gamma_i$, *where* Γ_i *is the combination of paths between the* $\mu + 1$ *sectors on which* $\operatorname{Re}(cX^{\mu+1}) < 0$ *with* $\int_{\Gamma_i} X^j e^{cX^{\mu+1}} dX = \delta_{ij}$ *for* $0 \le j < \mu$. *The leading coefficient of* $A_{c,i}(g)$ *is* $(2\pi)^{(n-2)/2}$ *times the coefficient of* X^i *in the Taylor expansion of* $g\, \omega_0/(dX \wedge dw)$ *at* α_c. *They are linearly independent, their exponents lying in distinct classes modulo* $\mathbb{Z}$, *and* $A_{c,0} = (2\pi)^{-1/2} A_c$ *for* $\mu = 1$.

(ii) If a symmetry ϕ of the ray fixes α_c and $\mu \geq 2$, its differential multiplies the kernel by a root of unity ζ_ϕ with $\zeta_\phi^{\mu+1} = 1$, and $A_{c,i} \circ \phi^* = \zeta_\phi^i A_{c,i}$.

Corollary 39.27 (Signs at a centre)**.** *On the centre ray of a family (Definition 38.13) let a sign η lie in X_F (Theorem 38.17). The Cremona is a symmetry of the ray that fixes η and acts on the tangent space there by -1.*

(i) If η is nondegenerate, $A_\eta \circ \mathrm{cr}^* = A_\eta$.

(ii) If η is isolated and the Hessian at η has corank one, η is an A_μ point with $\mu \geq 3$ odd, and $A_{\eta,i} \circ \mathrm{cr}^* = (-1)^i A_{\eta,i}$: the $\frac{\mu+1}{2}$ solutions of even i do not vanish on the Cremona-invariant insertions, and the $\frac{\mu-1}{2}$ of odd i vanish on them. For $\mu = 3$ the three exponents are $-\frac{n-2}{2} - \frac{1}{4}$, $-\frac{n-1}{2}$ and $-\frac{n-2}{2} - \frac{3}{4}$, the middle one odd.

Proposition 39.28 (Symmetries on the cycles of a source)**.** *Let a ray have an integral origin, and let a symmetry ϕ, with $\phi^*\omega_0 = \varepsilon_\phi \omega_0$, map a clean source Z onto a source. It maps Z° onto $\phi(Z)^\circ$ and lifts to $\tilde{\phi} : \tilde{Z}^\circ \to \widetilde{\phi(Z)}^\circ$, carrying each oriented normal disc to its image, and*

$$A_\gamma \circ \phi^* = \varepsilon_\phi \, A_{\tilde{\phi}_* \gamma}.$$

For a finite group G of symmetries, on $\mathfrak{M}^G$ the solution of γ is that of the averaged cycle $|G|^{-1} \sum_{\phi \in G} \varepsilon_\phi \, \tilde{\phi}_* \gamma$; a cycle class with $\sum_{\phi \in G_Z} \varepsilon_\phi \, \tilde{\phi}_*[\gamma] = 0$, G_Z the stabilizer of Z, gives a solution that vanishes on $\mathfrak{M}^G$.

Theorem 39.29 (What the invariant module sees at the high end)**.** *Let G be a finite group of symmetries of a ray, and let α_c be an A_μ point with stabilizer G_c. The solutions $A_{c,i}$ for which $\phi \mapsto \zeta_\phi^i$ is trivial on G_c (all of them when $\mu = 1$, with $\zeta_\phi^0 = 1$) average over G to invariant solutions that do not vanish on $\mathfrak{M}^G$; the others vanish on $\mathfrak{M}^G$. So*

$$\dim_{\mathbb{C}(k)} \mathfrak{M}^G \;\geq\; \sum_O \#\big\{0 \leq i < \mu_O : \; \zeta_\phi^i = 1 \text{ for every } \phi \in G_{c_O}\big\},$$

the sum over the G-orbits O of the isolated native gauges of corank at most one, α_{c_O} a point of O and μ_O its multiplicity.

Where the critical locus of the stride is not a set of nondegenerate points, its components still carry solutions. Over a clean family of native gauges the integral over a normal disc is a Gaussian, whose expansion on holomorphic normal slices is a holomorphic form of top degree on the family, so a closed one, with values in the orientation of the normal discs; every closed cycle carries a solution, because integration by parts is exact under the normal Gaussian and integrates to zero over a cycle along the family. On a curve the cycles are the loops around its punctures, among them its crossings with other sources and its degenerate points, and the cycles of its compactification: residues and periods, on the double cover where the determinant of the normal form has a square root. A native gauge of corank one carries one solution for each class of paths between the sectors where its reduced function decays, with exponents spaced by $\frac{1}{\mu+1}$. A symmetry that fixes a native gauge acts on its solutions: trivially at a nondegenerate one, and through the powers of its eigenvalue on the kernel at a degenerate one, so that at a sign of a centre, fixed by the Cremona, a point of multiplicity three carries an odd solution that every Cremona-invariant insertion misses. The invariant module counts each orbit of sources by the solutions its stabilizer leaves alone.

39.6 Closings at the low end

Definition 39.30 (Closings)**.** Let a ray have an integral origin, $\mathbf{m}_0 \in \mathbb{Z}^{\mathcal{E}}$ and $s_{0j}, t_{0j} \in \mathbb{Z}$, and a direction in which every letter has a positive exponent, $s_{1j}, t_{1j} \geq 1$. For an insertion g let $j(g)$ be the least integer such that $g\, f^{-j}\omega_0/dy$ is a Laurent polynomial for every $j \geq j(g)$. The *closings* of g are the constant terms

$$\mathsf{C}_j(g) = \mathrm{CT}\left(g\, f^{-j}\, \omega_0/dy\right) = \frac{1}{(2\pi i)^{n-1}} \oint_{|\alpha_e|=1,\ e\neq e_0} g\, f^{-j}\, \omega_0, \qquad j \geq j(g),$$

taken on the chart $\alpha_{e_0} = 1$, where they do not depend on e_0.

Proposition 39.31 (One form on the orthant and on the torus)**.** *Let a ray have origin* 0 *and* $\kappa_{1,S} > 0$ *for every nonempty proper* S*, let* $\alpha^\star$ *be the native gauge of its direction on the positive orthant,* $\alpha^\star_{e_0} = 1$*, and put* $A = f(\alpha^\star)^{-1}$*. On the chart* $\alpha_{e_0} = 1$*, with* $dy = \prod_{e\neq e_0} d\alpha_e/\alpha_e$*, the rational form* $\varpi_q = dy/(f^{-1} - q)$ *has*

$$\int_{y_{e_0}=0} \varpi_q = \sum_{k\geq 1} \langle 1\rangle_k\, q^{k-1} \qquad (|q| < A),$$

$$\frac{1}{(2\pi i)^{n-1}} \oint_{|\alpha_e|=\alpha^\star_e,\ e\neq e_0} \varpi_q = -\sum_{j\geq 0} \mathrm{CT}\left(f^{-j}\right) q^{-j-1} \qquad (|q| > A),$$

where $\mathrm{CT}(f^{-j})$ *is the constant term of the Laurent polynomial* f^{-j}*, the closing* $\mathsf{C}_j(1)$ *when every letter exponent of the direction is positive (Definition 39.30). So the generating function of the values near* $q = 0$ *and that of the constant terms near* $q = \infty$ *are the integrals of one form, whose denominator is the pencil* $\alpha^{-\mathbf{m}_1}\big(\prod_j K_j^{s_{1j}} \Psi_j^{t_{1j}} - q\,\alpha^{\mathbf{m}_1}\big)$ *of Theorem 38.14(ii), over the orthant and over the torus through* $\alpha^\star$*.*

Proposition 39.32 (The constant terms of a centre ray and its signs)**.** *On the centre ray of a family at the strengths* $\boldsymbol{\sigma}$ *(Definition 38.13), with the tables indexed by* l*, for every* $j \in \mathbb{N}$

$$\frac{1}{2^{n-1}} \sum_{\eta} \prod_{l} K_l(\eta)^{2j\sigma_l} = \sum_{v\in 2\mathbb{Z}^{\mathcal{E}}} [\alpha^v]\, f^{-j} \ \geq\ \mathrm{CT}\left(f^{-j}\right),$$

the sum over the 2^{n-1} *signs* η *of Theorem 38.17: the mean of the* j*-th powers of the values* $f^{-1}(\eta) = \prod_l K_l(\eta)^{2\sigma_l}$ *at the signs is the sum of the coefficients of* f^{-j} *at the monomials with even exponents.*

Theorem 39.33 (The closings are a solution)**.** *For a ray as in Definition 39.30,* $\mathsf{C}_j\big((c_e^{(0)} - j\, c_e^{(1)} + \partial_{y_e})g\big) = 0$ *and* $\mathsf{C}_j(fg) = \mathsf{C}_{j-1}(g)$ *for* $j > j(g)$*, and*

$$V_{\mathsf{C}}\Big(\sum_i g_i \otimes r_i\Big)(k) = \sum_i r_i(k)\, \mathsf{C}_{-k}(g_i),$$

at the integers $k \leq -\max_i j(g_i)$ *off the poles of the* r_i*, is a well defined solution with values in germs at* $-\infty$*. So for masters* $\mathbf{b}$*,* $\mathsf{C}_{j+1}(\mathbf{b}) = \mathbf{B}_{\mathbf{b}}(-j)\, \mathsf{C}_j(\mathbf{b})$ *for all large* j*, with* $\mathsf{C}_j(\mathbf{b}) = (\mathsf{C}_j(b_1), \ldots, \mathsf{C}_j(b_{\mathfrak{m}}))$*, and the law of* [1] *gives* $\sum_i p_i(-j)\, \mathsf{C}_{j-i}(1) = 0$ *for all large* j*.*

Proposition 39.34 (The closings are the top principal parts)**.** *Let a ray as in Definition 39.30 have origin* 0*, so that* $\omega_0 = dy$ *and* $\langle g\rangle_k = \int_{y_{e_0}=0} g\, f^k\, dy$*, and* $\kappa_{1,S} > 0$ *for every nonempty proper* S*, and put*

$$V_1 = \sum_{\pi} \prod_{l=2}^{n} \kappa_{1,U_l}^{-1} > 0,$$

the sum over the orders π *of the marks with tails* U_l *(Theorem 17.5(i)). For every insertion* g *the value* $\langle g\rangle_k$ *continues to a meromorphic function of* k *whose poles have order at most* $n-1$*, and for every integer* $j \geq j(g)$

$$\lim_{k\to -j} (k+j)^{n-1} \langle g\rangle_k = V_1\, \mathsf{C}_j(g).$$

Proposition 39.35 (The low end, for every direction)**.** *Let a ray have* $\kappa_{1,S} > 0$ *for every nonempty proper* S*; its letter exponents* $s_{1j}, t_{1j} \in \mathbb{N}$ *may vanish.*

(i) For an integral origin, every pole of the value of an insertion $g = \alpha^u \prod_j K_j^{-a_j} \Psi_j^{-b_j}$ *is a* k *with* $\kappa_{0,U} + \kappa_U(g) + k\,\kappa_{1,U} \in \{0, -1, -2, \dots\}$ *for some nonempty proper* U *(Proposition 38.5(ii)), and so lies on one of the lines* $\kappa_{1,U}\, k \in \mathbb{Z}$ *set by the walls of the direction; its order is at most* $n-1$*.*

(ii) For the origin 0*, for every insertion* g *and every* $j \in \mathbb{N}$ *with* $f^{-j}g$ *a Laurent polynomial, with* CT *its constant term as in Definition 39.30,*

$$\lim_{k\to -j} (k+j)^{n-1} \langle g\rangle_k = V_1\ \mathrm{CT}\left(f^{-j} g\right), \qquad V_1 = \sum_{\pi} \prod_{l=2}^{n} \kappa_{1,U_l}^{-1}$$

as in Proposition 39.34; in particular $\lim_{k\to -j} (k+j)^{n-1} \langle 1\rangle_k = V_1\, \mathrm{CT}(f^{-j})$ *for every* $j \in \mathbb{N}$*.*

Corollary 39.36 (The law read at the low end)**.** *For a ray as in Proposition 39.34, with the law* $\sum_{i=0}^{h} p_i(k)\, \mathrm{Sh}^i[1] = 0$ *of* $[1]$*, the closings of* 1*,* $\mathsf{C}_j(1) = \mathrm{CT}(f^{-j})$*, satisfy*

$$\sum_{i=0}^{\min(h,j)} p_i(-j)\, \mathsf{C}_{j-i}(1) = 0 \qquad \text{for every } j \geq 0.$$

On the centre ray of a family with every $\sigma_j \geq 1$*,* $f^{-1} = \prod_j \left(K_j(\alpha) K_j(\alpha^{-1})\right)^{\sigma_j}$*, and* $\mathsf{C}_j(1)$ *is the constant term of its* j*-th power.*

Definition 39.37 (The low-end coefficients)**.** For a ray with origin 0 and $\kappa_{1,S} > 0$ for every nonempty proper S, the *low-end coefficients* L_i, $i \in \mathbb{N}$, are the Laurent coefficients of the values of 1 at $k = 0$,

$$\langle 1\rangle_k = \sum_{i \geq 0} \mathsf{L}_i\, k^{i-n+1} \qquad \text{near } k = 0;$$

$\mathsf{L}_0 = V_1 > 0$.

Corollary 39.38 (The low-end relation)**.** *Let a ray have origin* 0 *and* $\kappa_{1,S} > 0$ *for every nonempty proper* S*, whatever its letter exponents, and let* $p_0, \dots, p_h \in \mathbb{C}[k]$ *have* $\sum_i p_i(k) f^i \in \mathcal{L}$*: the law of* $[1]$*, or a relation given by Proposition 39.6, by a box among them (Theorem 39.21(iv)).*

(i) $\sum_i p_i(k) \langle 1\rangle_{k+i} = 0$ *as meromorphic functions of* k*, and at every* k *with* $\mathrm{Re}\, k > 0$*; and* $\sum_{i=0}^{\min(h,j)} p_i(-j)\ \mathrm{CT}\left(f^{i-j}\right) = 0$ *for every* $j \in \mathbb{N}$*.*

(ii) p_0 *vanishes to order at least* $n-1$ *at* $k=0$*, and the* low-end relation

$$[k^{n-1}]p_0\cdot \mathsf{L}_0+\sum_{i=1}^{h} p_i(0)\,\langle 1\rangle_i=0$$

holds.

(iii) If $\sum_i p_i(k)f^i=\sum_e \big(k\,c_e^{(1)}+\partial_{y_e}\big)G_e$ *is a certificate whose* G_e *have no pole at* $k=0$*, then* $\sum_{i\geq 1} p_i(0)f^i=\sum_e \partial_{y_e}G_e(0)$*, and on the chart the flux of the field* $\big(G_e(0)-G_{e_0}(0)\big)_{e\neq e_0}$ *out of the cube* $\{|y_e|\leq R,\ e\neq e_0\}$ *tends to* $-[k^{n-1}]p_0\cdot\mathsf{L}_0$ *as* $R\to\infty$*: the low-end relation is the flux at infinity of the bottom piece of the certificate (Proposition 38.8).*

Proposition 39.39 (The low-end coefficients are integrals over the faces of the sectors)**.** *Let a ray have origin* 0 *and* $\kappa_{1,S}>0$ *for every nonempty proper* S*. For an order* π *of* $\mathcal{E}$ *with tails* U_l *write* $\kappa_l=\kappa_{1,U_l}$ *and, in the sector coordinates* $q\in[0,1]^{n-1}$ *(Theorem 8.5(ii)),* $f=\prod_{l=2}^{n} q_l^{\kappa_l}\,\varphi_\pi(q)$ *with* $\varphi_\pi=\prod_j k_{j,\pi}^{-s_{1j}}\psi_{j,\pi}^{-t_{1j}}$*, positive and smooth on a neighbourhood of the cube. For* $A\subseteq\{2,\dots,n\}$ *and a function* h *on the cube put*

$$h_{[A]}=\sum_{B\subseteq A}(-1)^{|A\setminus B|}\,h\big|_{q_l=0,\ l\notin B},$$

a function of q_A *that vanishes where some* q_l*,* $l\in A$*, vanishes. Then*

$$\mathsf{L}_i=\sum_\pi\sum_A\prod_{l\notin A}\kappa_l^{-1}\sum_{m+|\boldsymbol{\gamma}|=i-|A|}\frac{1}{m!}\int_{[0,1]^A}\prod_{l\in A}\frac{(\kappa_l\log q_l)^{\gamma_l}}{\gamma_l!\,q_l}\,\big(\log^m\varphi_\pi\big)_{[A]}\,dq_A,$$

the second sum over $A\subseteq\{2,\dots,n\}$ *and the third over* $m\in\mathbb{N}$ *and* $\boldsymbol{\gamma}\in\mathbb{N}^A$*, every integral converging. So* $\mathsf{L}_0=V_1$ *and*

$$\mathsf{L}_1=\sum_\pi\prod_l\kappa_l^{-1}\log\varphi_\pi(0)=-\sum_\pi\prod_l\kappa_l^{-1}\sum_j\big(s_{1j}\log\theta_{j,T^+_{j,\pi}}+t_{1j}\log\theta_{j,T^-_{j,\pi}}\big),$$

with the greedy bases of Lemma 8.3; up to $i=n-1$ *only the faces* $A\neq\{2,\dots,n\}$ *of the cube enter,* $1_{[A]}$ *being* 0 *for* $A\neq\varnothing$*, and the whole cube enters from* $i=n$ *on.*

At the low end of strength the values of a ray from the origin have poles at the nonpositive integers, and the leading coefficient of each pole is one constant, the volume read by the walls of the direction, times the constant term of a Laurent polynomial: the closings. Integration by parts lowers the pole of every monomial but the constant one, so only the constant term survives at the top order. The closings are the values over the compact torus, a cycle on which every negative power of the stride is single-valued, and they obey every relation of the ray; read at $k=-j$, the law of [1] is a recurrence for the constant terms of the powers of f^{-1}, from $j=0$ on.

Remark 39.40. The constant term of a Laurent polynomial is its mean over every torus $|\alpha_e|=\rho_e$. When the walls of the direction are positive, on the torus through the native gauge $\alpha^\star$ of the direction $|f^{-1}|$ is largest at $\alpha^\star$ alone, and as $j\to\infty$ the closings localize there, with the expansion of $A_\star$ read at $k=-j$ (Theorem 39.57). Where another torus can be deformed into descent cycles of $|f^{-1}|$, the closings decompose over the sources met on the way, with integer multiplicities, a family of native gauges among them. The decomposition does not enlarge what they see: they annihilate exactly what $A_\star$ annihilates (Section 39.10), and what they supply is a cheap stream of equations with the strength of that one solution.

39.7 Separating the sources and gluing them

Proposition 39.41 (The high end reads the formal type)**.** *Let* $\mathbf{B} = \mathbf{B}_\mathbf{b}$ *be regular at* $k = \infty$, $\mathbf{B}(k) = \mathbf{B}_0 + \mathbf{B}_1 k^{-1} + O(k^{-2})$, *and let* V *be a solution of type* $(\lambda, \rho + \mathbb{Z})$ *whose solution vector is* $v_V = \lambda^k k^\rho (a_0 + a_1 k^{-1} + \cdots)$ *with* $a_0 \neq 0$. *Then* $\mathbf{B}_0 a_0 = \lambda^{-1} a_0$, *and for every row vector* w *with* $w\mathbf{B}_0 = \lambda^{-1} w$ *and* $wa_0 \neq 0$, $\rho = -\lambda\, w\mathbf{B}_1 a_0/(wa_0)$. *So the native value of every source with a solution that does not vanish on* $\mathfrak{N}$ *is the reciprocal of an eigenvalue of* $\mathbf{B}(\infty)$*; its exponent, congruent modulo* $\mathbb{Z}$ *to* $-\frac{n-1-d}{2}$ *for a clean source of dimension* d *and to* $-\frac{n-2}{2} - \frac{i+1}{\mu+1}$ *for the solution* $A_{c,i}$ *of an* A_μ *point, is read from* $\mathbf{B}_1$ *when a left eigenvector of* $\mathbf{B}_0$ *for* λ^{-1} *does not annihilate* a_0, *as when* λ^{-1} *is a simple eigenvalue.*

Proposition 39.42 (The spectrum at infinite strength; changes of masters)**.** *Let insertions* $b_1 = 1, b_2, \dots, b_\mathfrak{m}$ *have classes that span a submodule* $\mathfrak{N}$, *and let* $\mathbf{B} \in \mathrm{Mat}_\mathfrak{m}(\mathbb{C}(k))$ *have* $[f^{-1} b_i] = \sum_l \mathbf{B}_{il}[b_l]$*: masters with* $\mathbf{B}_\mathbf{b}$, *or the spanning set and the matrix of an accepted box (Theorem 39.21). For a nondegenerate native gauge* α_c *put* $\beta_c = \big(b_l(\alpha_c)\big)_l$, *nonzero as* $b_1 = 1$, *and let* $\hat{A}_c$ *be the normalization of the expansion* A_c *(Definition 39.2).*

(i) If the vectors β_c *of a set* C *of nondegenerate native gauges span* $\mathbb{C}^\mathfrak{m}$, *the classes of the* b_l *are linearly independent: they are masters of* $\mathfrak{N}$, $\dim_{\mathbb{C}(k)} \mathfrak{N} = \mathfrak{m}$, *and* $\mathbf{B} = \mathbf{B}_\mathbf{b}$.

(ii) If $\mathbf{B}$ *is regular at* $k = \infty$, *then* $\mathbf{B}(\infty)\,\beta_c = f(\alpha_c)^{-1}\beta_c$ *for every nondegenerate native gauge* α_c*: the reciprocal of every nondegenerate native value is an eigenvalue of* $\mathbf{B}(\infty)$, *with the values of the* b_l *at the gauge as an eigenvector. So gauges of distinct native values have independent vectors* β_c, *there are at most* $\mathfrak{m}$ *distinct nondegenerate native values, and under (i)* $\mathbf{B}(\infty)$ *is diagonalizable with the eigenvalues* $f(\alpha_c)^{-1}$, $\alpha_c \in C$. *In particular, when two nondegenerate native gauges of distinct native values have proportional vectors* β_c, $\mathbf{B}$ *is not regular at* $k = \infty$.

(iii) Let $T \in GL_\mathfrak{m}(\mathbb{C}(k))$ *make* $\tilde{\mathbf{B}}(k) = T(k-1)\,\mathbf{B}(k)\,T(k)^{-1}$, *the matrix of* Sh^{-1} *on the elements* $\tilde{b}_i = \sum_l T_{il}(k)[b_l]$, *regular at* $k = \infty$. *Then* $f(\alpha_c)^{-1}$ *is an eigenvalue of* $\tilde{\mathbf{B}}(\infty)$ *for every nondegenerate native gauge* α_c, *with the leading coefficient of the series vector* $T(k)\big(\hat{A}_c(b_l)\big)_l$ *as an eigenvector; and if* $T(k-1)T(k)^{-1} \to I$ *as* $k \to \infty$, *the eigenvalues of* $\mathbf{B}(k)$ *tend to those of* $\tilde{\mathbf{B}}(\infty)$, *with their multiplicities.*

(iv) The condition $T(k-1)T(k)^{-1} \to I$ *cannot be dropped. For a constant* $\mathbf{B}_\circ = \begin{bmatrix} x_{11} & x_{12} \\ x_{21} & x_{22} \end{bmatrix} \in GL_2(\mathbb{C})$ *with* $x_{12} \neq 0$ *and* $S(k) = \begin{bmatrix} 1 & 0 \\ k & 1 \end{bmatrix}$, *the matrix* $\mathbf{B}(k) = S(k-1)\,\mathbf{B}_\circ\, S(k)^{-1}$ *is not regular at* $k = \infty$, *the change* $T = S^{-1}$ *makes it* $\mathbf{B}_\circ$, *with* $T(k-1)T(k)^{-1} = \begin{bmatrix} 1 & 0 \\ 1 & 1 \end{bmatrix}$, *and at every* k *the eigenvalues of* $\mathbf{B}(k)$ *are the roots of* $\lambda^2 - (x_{11} + x_{22} - x_{12})\lambda + x_{11}x_{22} - x_{12}x_{21}$, *which are not those of* $\mathbf{B}_\circ$.

Definition 39.43 (Insertion lattice; native algebra; tame high end)**.** Let $A \subset \mathbb{C}(k)$ be the ring of the rational functions regular at $k = \infty$, a discrete valuation ring with the uniformizer k^{-1}. For a ray with $\kappa_{1,S} > 0$ for every nonempty proper S, its *insertion lattice* is the A-span $\Lambda_F = \sum_{g \in \mathbb{C}[X_F]} A\,[g]$ in its module $\mathfrak{M}$ (Definition 39.1); its *native algebra* is $N_F = \mathbb{C}[X_F]/J_F$, with J_F the ideal generated by the defects $c_e^{(1)}$, $e \in \mathcal{E}$, of the direction: the ring of the functions on the critical locus (Definition 39.23) with its scheme structure. The ray is *tame at the high end* when Λ_F is finitely generated over A.

Theorem 39.44 (A tame high end)**.** *Let a ray have $\kappa_{1,S} > 0$ for every nonempty proper S and be tame at the high end.*

(i) *Λ_F is free over A of rank $\dim \mathfrak{M}$, and $\operatorname{Sh} \Lambda_F = \Lambda_F$. There are masters $\mathbf{b}$ among the insertions with $\Lambda_F = \bigoplus_l A\,[b_l]$, and their one-step matrix lies in $GL_{\mathfrak{m}}(A)$.*

(ii) *$g \mapsto [g] + k^{-1}\Lambda_F$ induces a surjection $N_F \to \Lambda_F/k^{-1}\Lambda_F$, whose kernel is stable under the multiplication by f, and $\mathbf{B}_{\mathbf{b}}(\infty)$ is the matrix of the multiplication by f^{-1} on $\Lambda_F/k^{-1}\Lambda_F$.*

(iii) *Every eigenvalue of $\mathbf{B}_{\mathbf{b}}(\infty)$ is the reciprocal native value f_Z^{-1} of a source Z. Every nonzero root of the symbol of the law of [1] (Corollary 38.7) is a native value.*

(iv) *If every native gauge is nondegenerate, they are $\dim \mathfrak{M}$ in number, $N_F \to \Lambda_F/k^{-1}\Lambda_F$ is an isomorphism, and $\mathbf{B}_{\mathbf{b}}(\infty)$ is diagonalizable with the eigenvalues $f(\alpha_c)^{-1}$, one for each native gauge α_c.*

Theorem 39.44 is the converse of Proposition 39.42(ii): there the reciprocal of every nondegenerate native value is an eigenvalue of $\mathbf{B}(\infty)$ in every basis regular at $k = \infty$; here, when the insertion classes span a lattice over A, nothing else is. Tameness asks more than masters with $\mathbf{B}$ regular at $k = \infty$: step (ii) needs the classes $[c_e^{(0)} g + \partial_{y_e} g]$ of all insertions to lie in the lattice. Section 39.8 reads the whole spectrum without that hypothesis.

Theorem 39.45 (Separating the sources)**.** *Let $\mathbf{B} = \mathbf{B}_{\mathbf{b}}$ be regular at $k = \infty$, and let the spectrum of $\mathbf{B}(\infty)$ be the disjoint union of nonempty sets $\Lambda_1, \dots, \Lambda_s$. Over $\mathbb{C}((1/k))$, with the shift ς,*

$$\mathfrak{N} \otimes \mathbb{C}((1/k)) = \bigoplus_{a=1}^{s} \hat{\mathfrak{N}}_a,$$

uniquely, with every $\hat{\mathfrak{N}}_a$ stable under the shift and the matrix of Sh^{-1} on it regular at ∞ in a suitable basis, with value at ∞ of spectrum Λ_a; equivalently there is $T \in GL_{\mathfrak{m}}(\mathbb{C}[[1/k]])$ with $T(k-1)\,\mathbf{B}(k)\,T(k)^{-1}$ block diagonal. A solution of type $(\lambda, \rho + \mathbb{Z})$ with $\lambda^{-1} \in \Lambda_a$ vanishes on every $\hat{\mathfrak{N}}_b$ with $b \neq a$, and every group of symmetries that maps $\mathfrak{N}$ onto itself maps each $\hat{\mathfrak{N}}_a$ onto itself.

Corollary 39.46 (Gluing at the two ends)**.** *Let $\mathcal{S}$ consist of formal solutions and the closings V_{C}, and let $\mathfrak{N}_{\mathsf{C}} = \operatorname{Ann}(V_{\mathsf{C}}) \cap \mathfrak{N}$ be the submodule the closings miss. Then $\mathcal{S}$ determines $\mathbf{B}_{\mathbf{b}}$ exactly when no nonzero submodule of $\mathfrak{N}_{\mathsf{C}}$ is annihilated by all the formal solutions in $\mathcal{S}$. The closings alone determine it exactly when $\mathfrak{N}_{\mathsf{C}} = 0$, as they do when $\mathfrak{N}$ is irreducible and V_{C} does not vanish on it; formal solutions alone determine it when $\mathfrak{m}$ of them are linearly independent over $\mathbb{C}$ on $\mathfrak{N}$, type by type.*

At the high end the module comes apart: over the formal series in $1/k$ it is the direct sum of one piece for each cluster of native values, the pieces are canonical, and every symmetry of the ray maps each piece to itself. This is where distinguishable sources are separated before the symmetric procedure runs: a piece is read with its own solutions, each class at a degenerate point and each cycle on a family counted by its character under the stabilizer, and the formal type of the one-step matrix at infinity, its eigenvalues and its exponents, contains the native values and the exponents of the sources that the module sees. The pieces need not be rational. The rational one-step matrix glues them, and the closings, an exact solution at the other end of strength, supply the glue: they determine the matrix on every submodule that meets their annihilator only in 0, every irreducible submodule on which they do not vanish among them, and formal solutions are needed only on the submodule that the closings miss.

39.8 The pencil of a ray

A ray is one function carried by a pencil (Theorem 38.14), and its values and closings are the integrals of one form over the orthant and over the torus (Proposition 39.31). Made exact, this turns the high end into a question in one variable: the module of the ray is the moment side of the module of the fibre integrals of the pencil f^{-1}, the symbol of the law is the principal symbol of that module's equation, and the roots are the reciprocals of its singular values, which are native values or limits of the values of f at points that leave the torus with vanishing defect. Throughout, a ray has an integral origin and $\kappa_{1,S} > 0$ for every nonempty proper S; write $\varphi = f^{-1}$, a unit of $\mathbb{C}[X_F]$, so that the *pencil* is the map $\varphi : X_F \to \mathbb{C}^\times$, and let $\mathcal{D} = \mathbb{C}[t^{\pm 1}]\langle \partial_t \rangle$.

Definition 39.47 (The pencil module; singular values; vanishing ranks)**.** On X_F let $\Omega^\bullet[\partial] = \Omega^\bullet_{X_F} \otimes \mathbb{C}[\partial]$ carry the differential $d - \partial\, d\varphi\wedge$. The *pencil module* $\mathcal{G}_F$ is its cohomology in the top degree $n-1$: every top form is $h\,\omega_0$ with $h \in \mathbb{C}[X_F]$, and $\mathcal{G}_F$ is spanned by the classes $h\partial^j$ of $h\,\omega_0\,\partial^j$, linear in h, subject to the relations

$$R(e,h,j) = \big(c_e^{(0)} h + \partial_{y_e} h\big)\partial^j - \big(h\,\partial_{y_e}\varphi\big)\partial^{j+1} \qquad (e \in \mathcal{E},\ j \in \mathbb{N}).$$

It is a $\mathcal{D}$-module with $\partial_t \cdot h\partial^j = h\partial^{j+1}$ and $t \cdot h\partial^j = (\varphi h)\partial^j - j\,h\partial^{j-1}$, and its periods are the *fibre integrals* $h\partial^j \mapsto \partial_t^j \int_\gamma h\,\omega_0/d\varphi$ over families of cycles γ in the fibres $\{\varphi = t\}$. The *orthant fibre integral* of h is $P_h(t) = \int_{\{\varphi = t\}\cap \mathbb{R}^{\mathcal{E}}_{>0}} h\,\omega_0/d\varphi$ for real t above the least value $A = f(\alpha^\star)^{-1}$ of φ on the orthant (Theorem 38.14), and the *torus fibre integral* is $T(t) = \sum_{j\ge 0} \mathsf{C}_j(1)\, t^{-j-1}$ (Proposition 39.31). $\mathcal{D}_F[1] \subseteq \mathcal{G}_F$ is the submodule generated by $1 = 1\partial^0$. A point $t_0 \in \mathbb{C}^\times$ is a *singular value* of a holonomic $\mathcal{D}$-module N when N is not a connection on any neighbourhood of t_0, and the *vanishing rank* $r_{t_0}(N)$ is the multiplicity of the conormal line of t_0 in the characteristic cycle of N; for $N = \mathcal{D}/\mathcal{D}Q$ it is the order of vanishing at t_0 of the principal coefficient of Q.

Proposition 39.48 (The ray is the moment side of its pencil)**.** *The assignment* $\Theta(h\partial^j) = (k)_j\,\mathrm{Sh}^j[h]$, $(k)_j = k(k+1)\cdots(k+j-1)$, *induces an isomorphism of* $\mathbb{C}(k)\langle \mathrm{Sh}^{\pm 1}\rangle$*-modules*

$$\mathbb{C}(k) \otimes_{\mathbb{C}[t\partial_t]} \mathcal{G}_F \ \cong\ \mathfrak{M}, \qquad t \mapsto \mathrm{Sh}^{-1}, \quad \partial_t \mapsto k\,\mathrm{Sh}, \quad t\partial_t \mapsto k-1.$$

For a real origin the values are the moments of the orthant fibre integrals: $\langle h\rangle_k = \int_A^\infty t^{-k} P_h(t)\,dt$ *for all large* k*, with* ∂_t *read in the sense of distributions on* $[A,\infty)$*,* P_h *extended by* 0 *below* A*.*

So the high end of the ray, $k \to \infty$, is the far end of the moment variable of a module in the one variable t, and the shift is the multiplication by t^{-1}.

Theorem 39.49 (The symbol is the principal symbol of the pencil)**.** *Let* $L = \sum_{i=0}^{h} p_i(k)\,\mathrm{Sh}^i$ *be the law of* $[1]$*, with* d *the largest degree of the* p_i *and the symbol* $\chi(\lambda) = \sum_i c_i\lambda^i$*,* c_i *the coefficient of* k^d *in* p_i *(Corollary 38.7), and put* $A_L = \sum_i p_i(t\partial_t + 1)\,t^{-i} \in \mathcal{D}$*, of order* d *in* ∂_t *with the principal coefficient* $t^d\chi(1/t)$*.*

(i) Some $c(t\partial_t)A_L$*,* $c \neq 0$ *a polynomial, annihilates* 1 *in* $\mathcal{G}_F$*, and every element of* $\mathcal{D}$ *that annihilates* 1 *has a principal coefficient divisible by* $t^d\chi(1/t)$ *up to a power of* t*.*

(ii) The nonzero roots of χ *are exactly the* $1/t_0$ *with* $t_0 \in \mathbb{C}^\times$ *a singular value of* $\mathcal{D}_F[1]$*.*

(iii) The multiplicity of the root $1/t_0$ *is the vanishing rank* $r_{t_0}(\mathcal{D}_F[1])$*.*

(iv) Every singular value of $\mathcal{D}_F[1]$ *is a singular value of* $\mathcal{G}_F$*.*

So the roots of the symbol are the singular values of one holonomic module in one variable, the module of the fibre integral of the origin form along the pencil, and their multiplicities are its vanishing ranks. Theorem 39.44 is the case in which those singular values are native values.

Lemma 39.50 (An orbit counts at most once)**.** *Let a finite group G act on X_F preserving φ, with $\phi^*\omega_0 = \chi_0(\phi)\,\omega_0$ for $\phi \in G$. Let $t_0 \in \mathbb{C}^\times$ be a value at which there is no asymptotic native gauge (Definition 38.29) of the value $1/t_0$, and all of whose native gauges are isolated and nondegenerate. Then $r_{t_0}(\mathcal{D}_F[1])$ is at most the number of G-orbits of these native gauges.*

Theorem 39.51 (The symbol is read off the sources)**.** *Let a ray have an integral origin, $\kappa_{1,S} > 0$ for every nonempty proper S, and every letter with a positive exponent in its direction. Every nonzero root of the symbol of the law of* [1] *is a native value or an asymptotic native value (Definition 38.29). For the centre ray of a plain table at the strength one, an asymptotic native value whose points converge in $X_{\mathcal{E}}$ to a point of the orbit of the flag $\varnothing \subsetneq B \subsetneq \mathcal{E}$, with B a bunch of width one whose room contains e_0, is one of the values of Proposition 38.26(ii) and (iii).*

Corollary 39.52 (Where the spectrum is native)**.** *(i) If a ray as in Theorem 39.51 has no asymptotic native value, every nonzero root of the symbol of the law of* [1] *is a native value.*

(ii) For a ray of a family of lists as in Proposition 38.30, suppose that for every flag $\mathfrak{f}$ of length at least one the factors of $\Pi_{\mathfrak{f}}$ have nonsingular zero sets in $O_{\mathfrak{f}}$, no two of which meet. Then the ray has no asymptotic native value, and every nonzero root of the symbol is a native value.

(iii) On the centre ray of a plain table at the strength one, an asymptotic native gauge whose points converge to the orbit of the flag $\varnothing \subsetneq B \subsetneq \mathcal{E}$ of a bunch B of width one has at the limit both factors of one bottom letter vanishing, or exactly one factor vanishing with a singular zero set; at its limit no factor of $K^{[0]}$ vanishes together with a factor of $\Psi^{[0]}$.

Factors on two different steps are functions of separate variables, so their zero sets meet as soon as both are nonempty: the hypothesis of (ii) asks that on every flag at most one step carry factors that are not monomials. For $\binom{\mathcal{E}}{1}$, $|\mathcal{E}| \geq 4$, a set S with $|S|, |\mathcal{E} \setminus S| \geq 2$ gives the factor $\alpha_{\mathcal{E}\setminus S}$ of K and the factor $\sum_{e\in S} \alpha_e^{-1}$ of Ψ on two steps, and (ii) does not apply; (iii) excludes these points at the walls, a factor of K with a factor of Ψ giving $\varphi \to 0$, as the roots of its symbol, the sign values (Theorem 42.12), require.

Theorem 39.53 (Uncarried letters)**.** *Let a ray have an integral origin and $\kappa_{1,S} > 0$ for every nonempty proper S. Split its letters as $L_c \sqcup L_u$, those with a positive exponent in its direction and those with the exponent* 0 *there, and in the torus $T = (\mathbb{C}^\times)^{\mathcal{E}}/\mathbb{C}^\times$ put*

$$X' = T \setminus \bigcup_{g\in L_c} \{g = 0\} = \varphi^{-1}(\mathbb{C}^\times), \qquad Y = X' \cap \bigcup_{g\in L_u} \{g = 0\},$$

so that $X_F = X' \setminus Y$, and stratify Y by the intersections of the zero sets of the uncarried letters, refined to a Whitney stratification. Then every nonzero root of the symbol of the law of [1] *is the value of f at one of:*

(a) a native gauge in X_F;

(b) a critical point of the restriction of f to a stratum of Y;

(c) an asymptotic native gauge of X_F, or a sequence on a stratum of Y that leaves every compact subset of T with the differential of $\log f$ *along the stratum tending to* 0 *and f tending to a nonzero value.*

Rays of this kind are the values of an insertion with a letter that the direction does not carry, and the rays on a face of the cone of the exponents; the strata of Y carry the native gauges of X on Y of Definition 38.24 in this setting.

Proposition 39.54 (The far end of the pencil)**.** *Let a ray have origin* 0*,* $\kappa_{1,S} > 0$ *for every nonempty proper* S*, and every letter with a positive exponent in its direction, and let* T_∞ *be the monodromy of the solutions of* $\mathcal{D}_F[1]$ *once around* $t = \infty$*. On the part of the orthant fibre integral* $P = P_1$ *on which* T_∞ *has the eigenvalue* 1*,*

$$(T_\infty - 1)^{n-2} P = (\pm 2\pi i)^{n-2}\, V_1\, T,$$

with V_1 *the volume of the direction (Proposition 39.34) and* T *the torus fibre integral. So* T_∞ *has a Jordan block of size* $n-1$ *for the eigenvalue* 1*, the largest that the fibres of dimension* $n-2$ *allow, and the torus fibre integral, whose coefficients are the closings, spans the invariant line of that block.*

The low end of the ray is thus the point $t = \infty$ of its pencil, where the degeneration is maximal: the torus is the invariant cycle there, the closings are its period, and the volume of the direction is the coefficient that joins the orthant to the torus under the monodromy. The exercises read these statements on lists of a few marks (Section 55.4).

39.9 The pencil along a hinge tree

The core of a substitution reads each cell through two letters of the cell, its contraction letter and its deletion letter, the first off a basis of the core and the second on it. Read that way every node of a hinge tree is a polynomial map, the letters of a family are the composite of the node maps applied to its marks, and the pencil module of every ray is the iterated direct image of the modules of the marks along the tree: each vertex applies one direct image to the external product of the modules of its children. Throughout, as in Section 39.8, a ray has an integral origin and $\kappa_{1,S} > 0$ for every nonempty proper S, and $\mathcal{D} = \mathbb{C}[t^{\pm 1}]\langle \partial_t \rangle$.

Definition 39.55 (The homogeneous reading; the data of a vertex)**.** Let $\mathcal{H}$ be a table on a finite set G, with the weights of a core (Definition 21.1). For pairs $(u_c, w_c)_{c \in G}$ its *homogeneous reading* is

$$\mathcal{H}^{\hom}(\mathbf{u}, \mathbf{w}) = \sum_T \theta_T \prod_{c \in T} w_c \prod_{c \notin T} u_c,$$

read with the weights of K, or with those of Ψ and then written $\mathcal{H}^{\hom}_\Psi$. Let the tables of a family $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$ on $\mathcal{E}$ have a common hinge tree $\mathfrak{T}$ rooted at o, with the nodes $\mathcal{H}_{v,j}$ (Definition 23.15), and fix a ray of F with the direction $(\mathbf{m}_1; \mathbf{s}_1, \mathbf{t}_1)$ (Definition 38.1); put $|\mathbf{t}_1| = \sum_j t_{1j}$ and $p_e = |\mathbf{t}_1| - m_{1,e}$. The *children* of a vertex v are the marks of $\mathcal{E}_v$ and the vertices directly below v, a child read in $\mathcal{H}_{v,j}$ at itself if it is a mark and at the marker of its edge if it is a vertex. A point of $V = (\mathbb{C}^4)^N \times \mathbb{C}^\times$ is written $\zeta = \big((c_j, d_j, c'_j, d'_j)_j, \mu\big)$.

(i) The *data* of a mark e is $\lambda_e(\alpha_e) = \big((1, \alpha_e, 1, \alpha_e^{-1})_j,\ \alpha_e^{p_e}\big)$, a closed embedding of $\mathbb{C}^\times$ into V.

(ii) For $v \neq o$, with the hinge g_v, the marker of its parent edge, the *node map* $N_v : V^{\text{children}} \to V$ has, for every j, the coordinates

$$\big((\mathcal{H}_{v,j}/g_v)^{\hom}(\mathbf{c}, \mathbf{d}),\ (\mathcal{H}_{v,j} \setminus g_v)^{\hom}(\mathbf{c}, \mathbf{d}),\ (\mathcal{H}_{v,j}/g_v)^{\hom}_\Psi(\mathbf{c}', \mathbf{d}'),\ (\mathcal{H}_{v,j} \setminus g_v)^{\hom}_\Psi(\mathbf{c}', \mathbf{d}')\big),$$

the children's coordinates of table j in the place of the pairs and the hinge minors with the inherited weights (Definition 7.3), and the last coordinate $\prod_c \mu_c$. The *data* of v is $\lambda_v = N_v \circ \prod_c \lambda_c$, a morphism from the torus $T_v = (\mathbb{C}^\times)^{B_v}$ of the marks B_v below v.

(iii) The *root map* of the ray is

$$R_o\big((\zeta_c)_c\big) = \prod_c \mu_c \prod_j \mathcal{H}^{\hom}_{o,j}(\mathbf{c},\mathbf{d})^{s_{1j}}\, \mathcal{H}^{\hom}_{o,j,\Psi}(\mathbf{c}',\mathbf{d}')^{t_{1j}},$$

over the children of o, and U_o is the open set of V^{children} on which every $\mathcal{H}^{\hom}_{o,j}(\mathbf{c},\mathbf{d})$ and every $\mathcal{H}^{\hom}_{o,j,\Psi}(\mathbf{c}',\mathbf{d}')$ is nonzero.

The reading is multilinear in the pairs, and where every $u_c \neq 0$ it is $\prod_c u_c$ times the letter of $\mathcal{H}$ at the ratios w_c/u_c: the hinge values of the cells (Definition 21.1).

Theorem 39.56 (The pencil along a hinge tree)**.** *In Definition 39.55 write $K^\Psi_{\mathcal{X}}$ for the basis letter of a table $\mathcal{X}$ read with the weights of Ψ, so that $\Psi_{\mathcal{X}}(\alpha) = \alpha^{\mathcal{X}} K^\Psi_{\mathcal{X}}(\alpha^{-1})$, $\alpha^{\mathcal{X}}$ the product over the marks of $\mathcal{X}$.*

(i) For every vertex $v \neq o$ and every j, the coordinates of table j of $\lambda_v(\alpha)$ are

$$\big(K_{\mathcal{A}_{v,j}/g_v}(\alpha),\ K_{\mathcal{A}_{v,j}\backslash g_v}(\alpha),\ K^\Psi_{\mathcal{A}_{v,j}/g_v}(\alpha^{-1}),\ K^\Psi_{\mathcal{A}_{v,j}\backslash g_v}(\alpha^{-1})\big),$$

those of the subtree cell $\mathcal{A}_{v,j}$, and its last coordinate is $\alpha_{B_v}^{p|_{B_v}}$. At the root $K_j = \mathcal{H}^{\hom}_{o,j}(\mathbf{c},\mathbf{d})$ and $\alpha^{-\mathcal{E}}\Psi_j = \mathcal{H}^{\hom}_{o,j,\Psi}(\mathbf{c}',\mathbf{d}')$ at the data of the children of o. So the pencil $\varphi = f^{-1}$ is $R_o \circ \prod_c \lambda_c$ on the torus $(\mathbb{C}^\times)^{\mathcal{E}}$, and the letter complement is the preimage of U_o, divided by the scale.

(ii) Put $\mathbb{G}_e = H^0(\lambda_e)_+\mathcal{O}_{\mathbb{C}^\times}$ for a mark and $\mathbb{G}_v = H^0(N_v)_+\big(\boxtimes_c \mathbb{G}_c\big)$ for $v \neq o$. Then $\mathbb{G}_v = H^0(\lambda_v)_+\mathcal{O}_{T_v}$, and the pencil module is the iterated direct image

$$\mathcal{G}_F \cong H^0(R_o|_{U_o})_+\Big(\big(\boxtimes_c \mathbb{G}_c\big)\big|_{U_o}\Big),$$

the scale of the torus contributing one factor in the top degree.

(iii) With the origin $(\mathbf{m}_0;\mathbf{s}_0,\mathbf{t}_0)$ put $q_e = m_{0,e} - |\mathbf{t}_0|$ and $\varepsilon_e = [\alpha_e^{q_e} d\alpha_e/\alpha_e] \in \mathbb{G}_e$, and $\mathcal{M}_e = \mathbb{G}_e$. For $v \neq o$ let $\mathcal{M}_v$ be the submodule of $H^0(N_v)_+\big(\boxtimes_c \mathcal{M}_c\big)$ generated by the image ε_v of $\boxtimes_c \varepsilon_c$, and let $\mathcal{M}_o$ be the submodule of $H^0(R_o|_{U_o})_+\big((\boxtimes_c \mathcal{M}_c)|_{U_o}\big)$ generated by

$$\varepsilon_o = \prod_j \mathcal{H}^{\hom}_{o,j}(\mathbf{c},\mathbf{d})^{-s_{0j}}\, \mathcal{H}^{\hom}_{o,j,\Psi}(\mathbf{c}',\mathbf{d}')^{-t_{0j}}\ \ \boxtimes_c \varepsilon_c.$$

Then $\mathcal{D}_F[1]$ is a quotient of $\mathcal{M}_o$, by a map carrying ε_o to 1; and for $v \neq o$ the submodule of $\mathbb{G}_v$ generated by the class of $\alpha^{\mathbf{q}|_{B_v}} \prod_{e\in B_v} d\alpha_e/\alpha_e$ is a quotient of $\mathcal{M}_v$.

(iv) Every singular value of $\mathcal{D}_F[1]$ is a singular value of $\mathcal{M}_o$, with a vanishing rank there at most that of $\mathcal{M}_o$; so every nonzero root $1/t_0$ of the symbol of the law of $[1]$ has t_0 a singular value of $\mathcal{M}_o$ and a multiplicity at most $r_{t_0}(\mathcal{M}_o)$. Every composition factor of $\mathcal{G}_F$, and so of $\mathcal{D}_F[g]$ for every insertion g, is a composition factor of $H^0(R_o|_{U_o})_+\big((\boxtimes_c S_c)|_{U_o}\big)$ for composition factors S_c of the $\mathbb{G}_c$; every composition factor of $\mathbb{G}_v$ is one of $H^0(N_v)_+\big(\boxtimes_c S_c\big)$ for composition factors S_c of the modules of its children; and the $\mathbb{G}_e$ of the marks are simple. Through the moment dictionary (Proposition 39.48) the composition factors of the module that $[g]$ generates along the ray, whose annihilator is the law of $[g]$, are localizations of composition factors of $\mathcal{D}_F[g]$.

So the pencil of every ray is built from its marks, vertex by vertex: a mark brings the module of a curve, each vertex applies one direct image, under its node map, to the external product of the modules of its children, and the root closes the product with the exponents of the ray. A vertex enters the pencil only through its node map, whatever lies below it, and its children only through their modules; the composition factors of the pencil, and with them the factors of the law of every insertion, are generated from the marks by these operations. The native gauges are read down the same tree (Theorem 42.24), and the period along it by Theorem 23.17.

39.10 What the closings see

Theorem 39.57 (The closings, the values and the native gauge)**.** *Let a ray have an integral origin and an integral direction in which every letter has a positive exponent, $s_{1j}, t_{1j} \geq 1$, with $\kappa_{1,S} > 0$ for every nonempty proper S, and let $\alpha^\star$ be the native gauge of the direction on the positive orthant, where f is largest (Theorem 38.14(i)). Then $\alpha^\star$ is a nondegenerate native gauge of the ray; write $A_\star$ for the expansion over the orthant near it. For every $m \in \mathfrak{M}$ the following are equivalent:*

(i) the closings vanish on m: $V_{\mathsf{C}}(m) = 0$;

(ii) the values vanish on m: $\langle m \rangle_k = 0$ for all large integers k;

(iii) the expansion at $\alpha^\star$ vanishes on m: $A_\star(m) = 0$;

and when they hold, the continuation of $\langle m \rangle_k$ in k vanishes identically. So $\operatorname{Ann}(V_{\mathsf{C}}) = \operatorname{Ann}(\langle\cdot\rangle) = \operatorname{Ann}(A_\star)$, and the closings, the values and $A_\star$ each determine $\mathbf{B}_{\mathbf{b}}$ on exactly the same submodules (Theorem 39.4(iii)). Moreover, for every insertion g,

$$j^{(n-1)/2} f(\alpha^\star)^j \, \mathsf{C}_j(g) \;\sim\; (2\pi)^{-(n-1)} \, \hat{A}_\star(g)\big|_{k=-j} \qquad (j \to \infty).$$

The positive orthant and the torus through $\alpha^\star$ meet only at $\alpha^\star$. The values are read on the orthant, where f is largest at $\alpha^\star$. The closings are means of Laurent polynomials over any torus, and on the torus through $\alpha^\star$ the reciprocal stride has its largest modulus at $\alpha^\star$ alone, because the letters have positive coefficients and the walls of the direction are positive. So the two ends of strength expand at one point, and their expansions are one formal solution, $A_\star$, read as $k \to \infty$ and at $k = -j$. An element on which $A_\star$ vanishes has a density of values that vanishes near the top of its range, and analyticity carries the vanishing to the whole range; and the values reach the closings through their principal parts (Proposition 39.34). The closings see exactly what the values see, and both see exactly what the native gauge of the direction sees.

Definition 39.58 (The value module; what a solution sees)**.** For a ray with $\kappa_{1,S} > 0$ for every nonempty proper S, the *kernel of the values* is $\operatorname{Ann}(\langle\cdot\rangle)$, the submodule of the elements whose values vanish for all large k (Theorem 39.4(ii)), and the *value module* is $\mathfrak{M}/\operatorname{Ann}(\langle\cdot\rangle)$. A solution *sees* a submodule when it does not vanish on it, and a nondegenerate native gauge α_c sees it when A_c does.

Corollary 39.59 (When the closings miss nothing)**.** *Under the hypotheses of Theorem 39.57, let $\mathfrak{N}$ be a submodule. The closings annihilate no nonzero submodule of $\mathfrak{N}$ exactly when the values vanish on no nonzero element of $\mathfrak{N}$, and exactly when $\alpha^\star$ sees every nonzero submodule of $\mathfrak{N}$. Every symmetry of the ray fixes $\alpha^\star$, so for every finite group G of symmetries the closings, the values and $A_\star$ vanish on $(1 - e_G)\mathfrak{M}$: the condition is to be read on $\mathfrak{M}^G$. Let $\mathbf{B} = \mathbf{B}_{\mathbf{b}}$, for masters of $\mathfrak{N}$, be regular at $k = \infty$ with $1/f(\alpha^\star)$ a simple eigenvalue of $\mathbf{B}(\infty)$, let $\hat{\mathfrak{N}}_\star$ be the line of Theorem 39.45 for that eigenvalue, and let $\alpha^\star$ see $\mathfrak{N}$. Then $\alpha^\star$ sees a submodule $\mathfrak{N}'$ exactly when*

$\hat{\mathfrak{N}}_\star \subseteq \mathfrak{N}' \otimes \mathbb{C}((1/k))$*; when it sees every nonzero submodule,* $\mathfrak{N}$ *has exactly one minimal nonzero submodule; and when* $\mathfrak{N} = \mathfrak{N}_1 \oplus \mathfrak{N}_2$ *with* $\mathfrak{N}_1, \mathfrak{N}_2$ *nonzero submodules, the closings annihilate one of the two.*

Corollary 39.60 (What the closings determine)**.** *Under the hypotheses of Theorem 39.57, the closings determine the one-step matrix of the value module: for insertions whose classes modulo* $\mathrm{Ann}(\langle\cdot\rangle)$ *form a basis of the image of a submodule, Theorem 39.4(iii) and (iv) hold on the value module with the closings alone. For polynomials* $p_0, \dots, p_h$, $\sum_i p_i(k)\langle 1\rangle_{k+i} = 0$ *for all large* k *exactly when* $\sum_i p_i(-j)\,\mathsf{C}_{j-i}(1) = 0$ *for all large* j*: the values of* 1 *and the closings of* 1 *satisfy the same recurrences, read at* k *and at* $-j$*, and have the same tier (Proposition 38.11).*

Proposition 39.61 (The closings measure what they miss)**.** *Let* $\mathbf{b}$ *be masters of a submodule* $\mathfrak{N}$*,* $\mathfrak{m}$ *of them, under the hypotheses of Theorem 39.33; let* $d = \dim_{\mathbb{C}(k)}\big(\mathrm{Ann}(V_{\mathsf{C}}) \cap \mathfrak{N}\big)$*, the dimension of the largest submodule of* $\mathfrak{N}$ *that the closings annihilate, and for* $D \geq 0$ *let* $\mathcal{S}_D$ *be the space of pairs* (P, Q) *of a matrix and a scalar of polynomials of degree at most* D *with* $Q(-j)\,\mathsf{C}_{j+1}(\mathbf{b}) = P(-j)\,\mathsf{C}_j(\mathbf{b})$ *for all large* j*. Then* $\dim \mathcal{S}_D = (\mathfrak{m}d + 1)D + O(1)$ *as* $D \to \infty$*. When* $d = 0$*,* $\dim \mathcal{S}_D = \max(0, D - D_0 + 1)$ *with* D_0 *as in Theorem 39.4(iv); so a single step* $\dim \mathcal{S}_{D+1} - \dim \mathcal{S}_D > 1$ *proves* $d > 0$*.*

The closings therefore certify a one-step matrix by themselves exactly when the native gauge of the direction sees every nonzero submodule. When it does not, the closings show it, by a step of more than one in $\dim \mathcal{S}_D$, and the slope of $\dim \mathcal{S}_D$ is $\mathfrak{m}d + 1$; a slope of one over the degrees computed is evidence that nothing is missed, not a certificate, the degrees of the missed part not being bounded here. What the closings miss is missed by the values as well. It is no defect of the torus: a submodule that the native gauge of the direction does not see is invisible to the integral itself, and an element of it is a relation among values that the relations of the ray do not produce. The symmetries of the ray account for some of these, on $(1 - e_G)\mathfrak{M}$, and so can symmetries that are not maps of its torus at all: when the list is the contraction of an identically self-dual table, the integral over the contracted scale carries the module of the larger table onto that of the ray, and the automorphisms of the larger table act through it.

Proposition 39.62 (A table one mark larger)**.** *Let* $(\mathcal{B}', \theta')$ *be a connected identically self-dual table on* $\mathcal{E}' = \mathcal{E} \sqcup \{g\}$*,* $|\mathcal{E}| \geq 2$ *(Corollary 23.12(iii)), and* $(\mathcal{B}, \theta)$ *its contraction at* g *(Definition 7.3), with letters* K, Ψ*; then* $(\mathcal{B}, \theta)$ *is connected, and the letter of* $\mathcal{B}'$ *is* $K' = \Psi + \alpha_g K$*. Let* F' *and* F *be the two tables at the strength* 1*, read on their centre rays (Definition 38.13),* F' *on a chart* $y_{e_0} = 0$ *with* $e_0 \in \mathcal{E}$*; their strides are* $f' = \alpha^{\mathbf{1}}\alpha_g/K'^2$ *and* $f = \alpha^{\mathbf{1}}/(K\Psi)$*, their modules* $\mathfrak{M}'$ *and* $\mathfrak{M}$*. For a Laurent polynomial* h *on* $\mathcal{E}$*,* $a \in \mathbb{Z}$ *and* $j \in \mathbb{N}$ *with* $\alpha_g^a K'^{-j} h$ *of degree* 0*, put*

$$\pi_*\big(\alpha_g^a K'^{-j} h\big) = r_{a,j}(k)\Big(\frac{\Psi}{K}\Big)^a \Psi^{-j} h, \qquad r_{a,j}(k) = \frac{\Gamma(k+a)\,\Gamma(k+j-a)\,\Gamma(2k)}{\Gamma(k)^2\,\Gamma(2k+j)} \in \mathbb{Q}(k).$$

(i) For every insertion g' *of* F'*, at the points of the positive orthant and for all large* k*,* $\int_0^\infty g' f'^k \, d\alpha_g/\alpha_g = \Gamma_{\!1}^{\,2}\!\left[\begin{matrix} k,\ k \\ 2k \end{matrix}\right] f^k\, \pi_* g'$*. So* $\langle g' \rangle'_k = \Gamma_{\!1}^{\,2}\!\left[\begin{matrix} k,\ k \\ 2k \end{matrix}\right] \langle \pi_* g' \rangle_k$ *for all large* k*, and* $\mathsf{C}'_j(g') = \binom{2j}{j}\,\mathsf{C}_j\big(\pi_* g'|_{k=-j}\big)$ *for all large* j*. The native gauges of* F' *are the points* $\alpha_{c'} = \big(\alpha_c, \Psi(\alpha_c)/K(\alpha_c)\big)$ *over the native gauges* α_c *of* F*, with* $f'(\alpha_{c'}) = f(\alpha_c)/4$*, and* $\alpha_{c'}$ *is non-degenerate exactly when* α_c *is; then* $A'_{c'}(g') = \Gamma_{\!1}^{\,2}\!\left[\begin{matrix} k,\ k \\ 2k \end{matrix}\right] A_c(\pi_* g')$*, the stacked Gamma read as its expansion at* $k = \infty$ *and the disc at* $\alpha_{c'}$ *taken over the disc at* α_c*.*

(ii) *π_* induces a bijection $\mathfrak{M}' \to \mathfrak{M}$, with $\pi_* \operatorname{Sh}' = \frac{k}{2(2k+1)} \operatorname{Sh} \pi_*$.*

(iii) *Every automorphism β of $(\mathcal{B}', \theta')$ acts on $\mathfrak{M}$ by $T_\beta = \pi_* \phi_\beta^* \pi_*^{-1}$, which commutes with* Sh*; $T_\beta = \phi_\beta^*$ when $\beta(g) = g$, and when the transposition β of a mark $e \in \mathcal{E}$ and g is an automorphism,*

$$T_\beta[\alpha^u] = \frac{\Gamma(k+u_e)\,\Gamma(k-u_e)}{\Gamma(k)^2} \Big[\alpha^{u-u_e \mathbf{1}_e} \Big(\frac{\Psi}{K}\Big)^{u_e}\Big].$$

With the Cremona, which π_* carries to the Cremona, the T_β generate a finite group G'.

(iv) *The values, the closings and $A_\star$, at the native gauge $\alpha^\star = \mathbf{1}$, are invariant under G' and vanish on $(1 - e_{G'})\mathfrak{M}$. For a group $G \subseteq G'$ of symmetries of F, $\mathfrak{M}^G = \mathfrak{M}^{G'} \oplus (1 - e_{G'})\mathfrak{M}^G$ as submodules, and π_* maps the invariant module of F' under its automorphisms and the Cremona onto $\mathfrak{M}^{G'}$.*

Corollary 39.63 (The cousins of a fused table)**.** *Let $(\mathcal{B}, \theta)$ be a connected fusable table on n marks, of the fusion width $c \geq 1$, with $n + c \geq 3$, and $(\mathcal{B}^\sharp, \theta^\sharp)$ its Foreman fusion (Definition 30.4). Then $\mathcal{B}^\sharp$ is connected, and Proposition 39.62 applies to $\mathcal{B}^\sharp$ and each of its cousins (Proposition 30.20): the automorphisms of $\mathcal{B}^\sharp$ act on the module of the centre ray of every cousin.*

The scale of g enters the letter of the larger table linearly, so the integral over it is a Beta corner, and it carries the centre of F' onto the centre of F insertion by insertion: a power of α_g becomes the same power of Ψ/K, the ratio at which the scale of g is native, times a rational function of k. The relations at the scale of g are exactly what that integral forgets, so the two modules are one, with the shift twisted by the Beta corner. An automorphism of $\mathcal{B}'$ that moves g is no symmetry of F, nor a map of its torus: it moves insertions, not points, and on native gauges it is the lift $\alpha_c \mapsto \alpha_{c'}$ followed by the permutation and the projection. The values, the closings and the expansion at $\alpha^\star$ are read on the orthant, the torus and the point $\mathbf{1}$ of F', which every automorphism keeps; so they see only the part of $\mathfrak{M}$ that G' fixes, and when $\mathfrak{M}^G$ is larger than $\mathfrak{M}^{G'}$ the closings miss the difference, with every symmetry of F in G. A sign η of F lifts to the sign $(\eta, \eta^{\mathcal{E}})$ of F', since $\Psi(\eta) = \eta^{\mathcal{E}} K(\eta)$, with $f(\eta) = 4/K'(\eta, \eta^{\mathcal{E}})^2$; signs that the automorphisms of $\mathcal{B}'$ carry to one another have one native value. Proposition 39.64 measures what is missed in this way: an orbit of nondegenerate native gauges of F' that the symmetries of F split into several orbits gives, orbit against orbit, solutions that vanish on $\mathfrak{M}^{G'}$ and not on $\mathfrak{M}^G$.

Proposition 39.64 (What a table one mark larger hides from the closings)**.** *Let $(\mathcal{B}', \theta')$, g, F', F, π_* and G' be as in Proposition 39.62. Let Γ' be the group of symmetries of the centre ray of F' generated by the maps ϕ_β, β an automorphism of $(\mathcal{B}', \theta')$, and the Cremona, and G the group of symmetries of F generated by the maps ϕ_β, β an automorphism of $(\mathcal{B}', \theta')$ with $\beta(g) = g$ read on $\mathcal{E}$, and the Cremona, so that $G \subseteq G'$ (Proposition 39.62(iii)). A native gauge α_c of F lies* below *the native gauge $\alpha_{c'} = \big(\alpha_c, \Psi(\alpha_c)/K(\alpha_c)\big)$ of F' (Proposition 39.62(i)).*

(i) *Let $O'_1, \dots, O'_q$ be distinct orbits of Γ' of nondegenerate native gauges of F', and let the native gauges of F below O'_a form s_a orbits of G. Then*

$$\dim_{\mathbb{C}(k)} (1 - e_{G'})\mathfrak{M}^G \;\geq\; \sum_{a=1}^{q} (s_a - 1),$$

and the closings, the values and $A_\star$ vanish on the submodule $(1 - e_{G'})\mathfrak{M}^G$. For an orbit O' fix an expansion $A'_{c'_0}$ at one of its points, put $A'_{\gamma(c'_0)} = A'_{c'_0} \circ \gamma^*$ for $\gamma \in \Gamma'$, and for α_c below O' put $A_c = \Gamma^{\,2}_{\,1}\Big[\begin{smallmatrix} k, & k \\ & 2k \end{smallmatrix}\Big]^{-1} A'_{c'} \circ \pi_*^{-1}$, the stacked Gamma read as its expansion at $k = \infty$. If

O_1 and O_2 are two orbits of G below O', the solution $|O_1|^{-1}\sum_{c\in O_1}A_c - |O_2|^{-1}\sum_{c\in O_2}A_c$ is invariant under G, vanishes on $\mathfrak{M}^{G'}$ and does not vanish on $(1-e_{G'})\mathfrak{M}^G$.

(ii) For $r\geq 2$ let $\mathcal{B}'=\binom{[2r+2]}{r+1}$ with unit weights and $g=2r+2$, so that F is $\binom{[2r+1]}{r}$ read on its centre ray at the strength 1; G is then the group generated by the symmetries of the four kinds of that ray (Proposition 39.11): the maps ϕ_β, β a bijection of $[2r+1]$, and the Cremona. With $C_r=\frac{1}{r+1}\binom{2r}{r}$, the signs of F with one and with two scales -1, $2r+1$ and $\binom{2r+1}{2}$ of them, are nondegenerate native gauges of the native value C_r^{-2} and form two orbits of G, and the native gauges above them are the $\binom{2r+2}{2}$ signs of F' with two scales -1, one orbit of Γ'. At the sign of F' with the scales -1 on $D=\{a_1,a_2\}$, with $C=[2r+2]\setminus D$, the Hessian H' of $\log f'$ is such that $-H'$ has, modulo $\mathbf{1}$, the eigenvalue $r+1$ on $\mathbf{1}_{a_1}-\mathbf{1}_{a_2}$, the eigenvalue $\frac{r+1}{2r-1}$ on every $\mathbf{1}_c-\mathbf{1}_{c'}$ with $c,c'\in C$, and the eigenvalue $-(r+1)$ on $r\mathbf{1}_D-\mathbf{1}_C$; at the signs of F with one and with two scales -1, on a chart, $\det(-H)=-(r+1)^{2r}/(2r-1)^{2r-1}$. So $(1-e_{G'})\mathfrak{M}^G\neq 0$: at the centre of every $\binom{[2r+1]}{r}$, $r\geq 2$, the closings miss a nonzero submodule of $\mathfrak{M}^G$, with every symmetry of the four kinds in G.

The two kinds of signs of $\binom{[2r+1]}{r}$ share their native value because the signs above them are one orbit of the symmetric group of $\binom{[2r+2]}{r+1}$, while the symmetries of the ray keep the two kinds apart; the mean of the solutions over the one kind less the mean over the other is a solution that sees what the larger table hides. Exercise 54.20 reads the small centres with these statements; at $r=2$ the part of the span of a box that the larger table hides from the closings is a line.

39.11 Wheels: the letters as a holonomy

Proposition 39.65 (The holonomy of a wheel)**.** *For $p\geq 3$ let W_p be the list of the wheel graph: a hub and rim vertices $1,\dots,p$ in cyclic order, the marks the spokes s_i, joining the hub to i, and the rims r_i, joining i to $i+1$, indices modulo p; its bases are the spanning trees, of rank p on $n=2p$ marks. With*

$$\mathbf{U}(a)=\begin{bmatrix}1 & a\\ 0 & 1\end{bmatrix},\qquad \mathbf{L}(b)=\begin{bmatrix}1 & 0\\ b & 1\end{bmatrix},\qquad \mathbf{h}(\alpha)=\prod_{i=1}^{p}\mathbf{U}(\alpha_{s_i})\,\mathbf{L}(\alpha_{r_i}^{-1})\in SL_2,$$

the product taken in the order $i=1,\dots,p$,

$$K(\alpha)=\prod_i \alpha_{r_i}\big(\operatorname{tr}\mathbf{h}(\alpha)-2\big),\qquad \Psi(\alpha)=\prod_i \alpha_{s_i}\big(\operatorname{tr}\mathbf{h}(\alpha^{-1})-2\big).$$

The bijection x with $x(s_i)=r_{p+1-i}$ and $x(r_i)=s_{p+1-i}$ has $\operatorname{tr}\mathbf{h}(\alpha\circ x)=\operatorname{tr}\mathbf{h}(\alpha^{-1})$, so $K\circ\phi_x=\Psi$ and x exchanges W_p. At the table's gauge $\mathbf{h}(\mathbf{1})=\begin{bmatrix}2 & 1\\ 1 & 1\end{bmatrix}^p$, whose eigenvalues are $\lambda_\pm^p$ with $\lambda_\pm=\frac{3\pm\sqrt{5}}{2}$, the squares of the golden ratio and of its inverse; so $K(\mathbf{1})=\lambda_+^p+\lambda_-^p-2$, the Lucas number of index $2p$ less 2.

Proposition 39.66 (The centre ray of a wheel)**.** *Put $\mathfrak{d}(\alpha)=\operatorname{tr}\mathbf{h}(\alpha)-2$ and $\mathfrak{d}^*(\alpha)=\operatorname{tr}\mathbf{h}(\alpha^{-1})-2=\mathfrak{d}(\alpha\circ x)$. The centre ray of W_p at the strength σ has the stride $f=(\mathfrak{d}\,\mathfrak{d}^*)^{-\sigma}$, and $X_F=\{\mathfrak{d}\,\mathfrak{d}^*\neq 0\}$.*

(i) Its native gauges are the points of X_F with $\mathfrak{d}^*\,d\mathfrak{d}+\mathfrak{d}\,d\mathfrak{d}^*=0$. At every one $d\mathfrak{d}$ and $d\mathfrak{d}^*$ are linearly dependent: the native gauges lie on the critical locus of the pair of traces $(\mathfrak{d},\mathfrak{d}^*)$, where its differential has rank at most one. The native value is $(\mathfrak{d}\,\mathfrak{d}^*)^{-\sigma}$.

(ii) At a sign η, $\mathfrak{d}^*(\eta) = \mathfrak{d}(\eta)$ and the native value is $\mathfrak{d}(\eta)^{-2\sigma}$; at the table's gauge it is $(\lambda_+^p + \lambda_-^p - 2)^{-2\sigma}$.

(iii) Every point with $\mathbf{h}(\alpha) = -I$ has $d\mathfrak{d} = 0$. The torsion stratum *$\{\mathbf{h}(\alpha) = \mathbf{h}(\alpha^{-1}) = -I\}$ lies in X_F and consists of native gauges of native value $16^{-\sigma}$ at which $d\mathfrak{d} = d\mathfrak{d}^* = 0$; it is cut out of the torus of dimension $2p-1$ by six equations, so that each of its components has dimension at least $2p-7$.*

Proposition 39.67 (The classes of a wheel)**.** *At the table's gauge the occupation of a spoke is*

$$R_{\mathrm{s}} = \frac{\lambda_+^p - \lambda_-^p}{\sqrt{5}\left(\lambda_+^p + \lambda_-^p - 2\right)},$$

equal to $\frac{1}{2}$ exactly for $p = 3$; the occupation of a rim is $R_{\mathrm{r}} = 1 - R_{\mathrm{s}}$, and the masses of $\Upsilon_{\sigma,\delta;\mathbf{1}}$ are $\sigma + \delta(2R_{\mathrm{s}} - 1)$ on the spokes and $\sigma - \delta(2R_{\mathrm{s}} - 1)$ on the rims. W_p is an atom at the centre. For $p \geq 4$ its classes at every lean are the spokes and the rims, which the reversed exchange $\bar{\phi}_x$, a symmetry of the integrand at every lean (Theorem 39.13), interchanges; $W_3 = M(K_4)$ is an atom at every lean.

Remark 39.68. The uniform masses $\sigma\mathbf{1}$ lie on the balance wall of W_p at every lean, since $2r = n$, and they meet the condition of Proposition 39.11 for $\bar{\phi}_x$, which therefore keeps the integrand of every such realization; its native gauge is constant on the spokes and on the rims. For $p = 3$ the uniform masses are the masses of the table's gauge at every lean, R_{s} being $\frac{1}{2}$, and the native gauge stays at $\mathbf{1}$; for $p \geq 4$ they are not, and the native gauge leaves $\mathbf{1}$ as soon as the realization leans. For W_4, at the gauge c on the spokes and 1 on the rims, $K = c(c+2)^2(c+4)$ and $\Psi = (2c+1)^2(4c+1)$. At the full basis lean nativity asks every occupation to be $\frac{1}{2}$, which on a spoke reads $c^2+2c-4 = 0$: the native gauge on the orthant has spokes $\sqrt{5}-1$, twice the inverse of the golden ratio, against rims 1, and at the full cobasis lean, where the condition reads $4c^2 - 2c - 1 = 0$, spokes $\frac{\sqrt{5}+1}{4}$, half the golden ratio, its reciprocal. The other roots, $-\sqrt{5}-1$ and $\frac{1-\sqrt{5}}{4}$, are native gauges as well, with negative spokes and in X_F: sources off the orthant. At the basis lean the integrand is $c^{4\sigma}K^{-2\sigma} = \big(c/((c+2)^2(c+4))\big)^{2\sigma}$, whose base is $\frac{5\sqrt{5}-11}{8}$ at the positive root and $-\frac{5\sqrt{5}+11}{8}$ at the negative one, a quarter of the inverse fifth power of the golden ratio and minus a quarter of its fifth power; the cobasis lean gives the same two numbers. Off the centre the gauge on the orthant is not proportional to $\mathbf{1}$, so the realization is not an atom (Theorem 11.4); its classes are the spokes and the rims, and $\bar{\phi}_x$ interchanges them. The torsion stratum of W_4 is a union of curves.

The letters of a wheel are traces of one product of unipotent matrices, the holonomy of a transfer around the rim, and the planar self-duality of the wheel is the transpose of that product. On the centre ray the stride is the inverse product of the two traces, at α and at α^{-1}, so a native gauge lies on the critical locus of the pair of traces, and wherever both holonomies are $-I$ both traces are critical at once: a stratum of native gauges of native value $16^{-\sigma}$, of dimension at least $2p-7$ wherever it is not empty. At a sign η the two traces agree, in an integer $\mathfrak{d}(\eta)$, and the native value is $\mathfrak{d}(\eta)^{-2\sigma}$; at the table's gauge the holonomy is the p-th power of the step $\begin{bmatrix} 2 & 1 \\ 1 & 1 \end{bmatrix}$, whose eigenvalues are the squares of the golden ratio and of its inverse. The wheel is an atom at the centre and splits into spokes and rims at every lean once $p \geq 4$, the reversed exchange interchanging them; with uniform masses its native gauge then leaves the table's gauge as soon as the realization leans, and for W_4 at a full lean the ratio of the scales of spokes and rims is twice the inverse of the golden ratio or half the golden ratio.

39.12 The procedure

The statements of this chapter assemble into a procedure that reads the one-step matrix and the law of [1] of a ray from its two ends, with no box (Definition 39.15) reduced.

(1) *Symmetries.* From the list read the automorphisms and the exchanges, and keep the maps of Proposition 39.11 that are symmetries of the ray; at a lean of a self-dual family at the table's gauge these include the reversed exchanges (Theorem 39.13). Work in $\mathfrak{M}^G$ with invariant insertions (Theorem 39.12). When the list is the contraction of an identically self-dual table at a mark, the automorphisms of that table act as well, through the integral over the scale of the mark, and the values live on the part they fix, which the centre of the larger table reads directly (Proposition 39.62).

(2) *Sources.* Read the critical locus of the stride modulo G: orbits of nondegenerate native gauges, one solution each; A_μ points, with the classes of trivial character (Theorems 39.26 and 39.29); clean families, with their averaged cycles (Theorem 39.24, Corollary 39.25, Proposition 39.28). Their native values and exponents enter the formal type of the one-step matrix at infinity (Proposition 39.41).

(3) *Closings.* Compute the closings of the candidate masters, constant terms of Laurent polynomials (Definition 39.30).

(4) *Masters.* Choose invariant insertions whose solution vectors over the supplied sources and the closings are linearly independent; there are at most $\dim \mathfrak{M}^G$ of them, and the count of Theorem 39.29 bounds $\dim \mathfrak{M}^G$ below.

(5) *The one-step matrix.* Solve the homogeneous linear equations of Theorem 39.4(iv) at increasing degree D. When the supplied solutions annihilate no submodule, the first degree with a nonzero solution is D_0, the solution is unique up to a constant factor, and it is $\mathbf{B_b}$.

(6) *The law.* The law of [1] is the least relation among $[1], \mathrm{Sh}[1], \dots$, computed with $\mathbf{B_b}$; on a ray from the origin it is read again on the closings of 1 at $-j$ (Corollary 39.36).

A case is certified when the supplied solutions annihilate no submodule: by Corollary 39.46 this holds when $\mathfrak{m}$ supplied formal solutions are linearly independent over $\mathbb{C}$ on $\mathfrak{M}^G$ type by type, a full set from the high end; and when the walls of the direction are positive the closings alone certify exactly when the native gauge of the direction sees every nonzero submodule of $\mathfrak{M}^G$ (Corollary 39.59), as when $\mathfrak{M}^G$ is irreducible and they do not vanish on it. The closings show it when they miss something: the dimension of the solutions of their equations then has slope $\mathfrak{m}d + 1$, with d the dimension of the largest missed submodule $\mathrm{Ann}(V_{\mathsf{C}}) \cap \mathfrak{M}^G$, and a single step of more than one proves $d > 0$ (Proposition 39.61); a slope of one over the degrees computed is evidence that nothing is missed, not a certificate. When they miss something they still give the one-step matrix of the value module and the law of the values (Corollary 39.60), and the missing part is read from sources whose solutions see it: when it comes from a table one mark larger, the centre of that table reads $\mathfrak{M}^{G'}$ (Proposition 39.62), and the differences of the solutions over the orbits of native gauges that the symmetries of the ray split do not vanish on the rest (Proposition 39.64). With fewer formal solutions and no such knowledge of $\mathfrak{M}^G$, a unique solution at the least degree that also meets equations held out is evidence, not a certificate: a submodule annihilated by every supplied solution would leave a different matrix that meets all of them. Masters that span $\mathfrak{M}^G$ come from a box when every letter exponent of the direction is positive: the spanning set of a box accepted at $\mathfrak{s}$ spans the classes of the invariant Laurent combinations of wall degree at most $\mathfrak{s}$ (Theorem 39.21(i)), which increase with $\mathfrak{s}$, and some box is accepted with a spanning set whose

classes span $\mathfrak{M}^G$ (Theorem 39.22). That spanning set is a set of masters of $\mathfrak{M}^G$ when it is independent: when as many solutions as it has elements are linearly independent on its span, type by type (Lemma 39.3), or when its values at nondegenerate native gauges span $\mathbb{C}^{\mathfrak{m}}$ (Proposition 39.42(i)).

Chapter 40

The stride's law and the gauge end

The values of a ray with real origin and positive walls are the moments of one measure, the stride's law: the image of the origin form on the positive part of the chart under the stride. It is carried by $(0, f(\alpha^\star)]$, and the values are read from it three ways, as a Trailmoment on a line, through one Gramma on the Laplace side, and as the log-partition of the exponential family that the Breta shape laws form along the ray. Its two ends are the two ends of strength: near 0 its mass grows like a power of the logarithm, with the volume of the direction as coefficient, and at the native value $f(\alpha^\star)$ it ends in a power $(f(\alpha^\star) - t)^{\frac{n-3}{2}}$ times a function holomorphic there, whose value is read off the Hessian at the native gauge. Its density is real-analytic in between. Every recurrence of the values is a differential equation for the density, the recurrence read backwards, and holds at every strength once it holds at the large integers. At the native value of the direction, when it is a simple root of the symbol, the germs of solutions that the equation lets end there form a line; the density spans it, its exponent is forced to $\frac{n-3}{2}$, and its continuation along the open support is the density: so the recurrence, the native gauge of the direction and the Hessian there give the values and their derivatives in the strength exactly, with no datum from the low end and no inequality. At a centre the same native gauge lies on the unit torus, where the stride is real and at least $f(\alpha^\star)$; the torus value continues the closings in the strength, and the densities of the chart and of the torus at the native value are the two cut solutions of one function, on its two sides.

40.1 The stride's law

Definition 40.1 (The stride's law)**.** Let a ray of a family on $n \geq 2$ marks have a real origin and $\kappa_{1,S} > 0$ for every nonempty proper S (Definition 38.1). On the positive part of the chart, $\alpha_{e_0} = 1$ and $y = \log \alpha \in \mathbb{R}^{\mathcal{E}\setminus e_0}$, the origin form $\omega_0 = (\omega_0/dy)\, dy$ is a positive measure, its density $\alpha^{\mathbf{m}_0} \prod_j K_j^{-s_{0j}} \Psi_j^{-t_{0j}}$ taken with the principal powers. The *stride's law* of the ray is its image under the stride,

$$\mu_f(A) = \int_{\{y:\ f(e^y) \in A\}} \omega_0 \qquad (A \subseteq (0,\infty) \text{ a Borel set}),$$

a measure on $(0,\infty)$, and ϱ_f is its density where it has one. For the origin 0, $\omega_0 = dy$, and μ_f is the image under f of the Lebesgue input of the chart (Definition 5.4).

Proposition 40.2 (A ray is one Trailmoment on a line and one Gramma)**.** *Let a ray be as in Definition 40.1, let $\alpha^\star$ be the native gauge of its direction on the positive orthant, $\alpha^\star_{e_0} = 1$ (Theorem 38.14), and write in this statement $f^\star = f(\alpha^\star)$.*

(i) *μ_f is carried by $(0, f^\star]$, it is finite on $[t, f^\star]$ for every $t > 0$, and at every complex k at which $\langle 1\rangle_k$ converges*

$$\langle 1\rangle_k = \int_{(0,f^\star]} t^k \, \mu_f(dt) = \big(\mathsf{T}_{k;(1)}[t^{-1}]\,\mu_f\big)\big((0,\infty)\big) = (\mathsf{T}_{k;(1)}[x]\,\iota_*\mu_f)((0,\infty)), \qquad \iota(t) = t^{-1}:$$

the values are the Trailmoments on a line of index k, one unit exponent and the coefficient function x of one input, the image of μ_f under the reciprocal.

(ii) *Let the origin carry no letter exponents, $\mathbf{s}_0 = \mathbf{t}_0 = \mathbf{0}$, so that $\omega_0 = \alpha^{\mathbf{m}_0} dy$, and write $f^{-1} = \sum_i w_i\, \alpha^{\mathbf{v}_i}$ on the chart, a Laurent polynomial in the scales α_e, $e \neq e_0$, with positive coefficients w_i and exponents $\mathbf{v}_i \in \mathbb{Z}^{\mathcal{E}\setminus e_0}$; put $\mathbf{v} = (\mathbf{v}_i)_i$ and $\mathbf{w} = (w_i)_i$. The cone of $\mathbf{v}$ is $\mathbb{R}^{\mathcal{E}\setminus e_0}$, so the Gramma $\mathsf{G}_{\nu;\mathbf{v}}(u\mathbf{w})$ is entire in ν (Theorem 2.2), and at every k with $\operatorname{Re} k > 0$ at which $\langle 1\rangle_k$ converges*

$$\Gamma(k)\,\langle 1\rangle_k = \int_0^\infty u^{k-1}\, \mathsf{G}_{\mathbf{m}_0|_{\mathcal{E}\setminus e_0};\,\mathbf{v}}(u\,\mathbf{w})\, du,$$

the Laplace side (Theorem 5.11) of (i), whose Laplace transform beyond the cut 0 is the Gramma of the reciprocal stride.

(iii) *For real k at which $\langle 1\rangle_k$ converges, let $U \sim \mathrm{Breta}^\circ(F; \mathbf{m}_0 + k\mathbf{m}_1; \mathbf{s}_0 + k\mathbf{s}_1, \mathbf{t}_0 + k\mathbf{t}_1)$ (Definition 8.10). The law of $f(U)$ is $t^k \mu_f(dt)/\langle 1\rangle_k$: along the ray the shape laws are the exponential family with the sufficient statistic $\log f$, the base measure μ_f and the log-partition $\log\langle 1\rangle_k$, so that*

$$\frac{d}{dk}\log\langle 1\rangle_k = \mathbb{E}\big[\log f(U)\big], \qquad \frac{d^2}{dk^2}\log\langle 1\rangle_k = \mathrm{Var}\,\big[\log f(U)\big] > 0.$$

Proposition 40.3 (The two ends of the stride's law)**.** *Let a ray be as in Definition 40.1, with $\alpha^\star$ as in Proposition 40.2 and H the Hessian of $-\log f$ at $\log\alpha^\star$ on the chart (Theorem 38.15); write in this statement $f^\star = f(\alpha^\star)$ and $w^\star = (\omega_0/dy)(\alpha^\star)$.*

(i) The open support. *μ_f has a density ϱ_f, real-analytic and positive on $(0, f^\star)$.*

(ii) The native value. *Near $f^\star$, $\varrho_f(t) = (f^\star - t)^{\frac{n-3}{2}} g(f^\star - t)$ for $t < f^\star$, with g holomorphic at 0 and*

$$g(0) = \frac{w^\star}{\Gamma(\frac{n-1}{2})\sqrt{\det H}}\Big(\frac{2\pi}{f^\star}\Big)^{\frac{n-1}{2}}.$$

(iii) The low end. *Let the origin be 0, let κ be the wall at a tilt of the question of the direction (Definitions 17.1 and 17.3), read at y, and put $C_- = \prod_j K_j(\mathbf{1})^{-s_{1j}-t_{1j}}$, $C_+ = \prod_j \theta_{j,\min}^{-s_{1j}-t_{1j}}$, $\theta_{j,\min}$ the least weight of table j. Then $C_- e^{-\kappa(y)} \le f(e^y) \le C_+ e^{-\kappa(y)}$ on the chart, $\int e^{-\kappa(y)} dy = V_1$ with the volume $V_1 = \sum_\pi \prod_{l=2}^n \kappa_{1,U_l}^{-1}$ of the direction (Proposition 39.34, Theorem 17.5(i)), and for $0 < t \le C_-$*

$$\frac{V_1}{(n-1)!}\Big(\log\frac{C_-}{t}\Big)^{n-1} \le \mu_f\big([t, f^\star]\big) \le \frac{V_1}{(n-1)!}\Big(\log\frac{C_+}{t}\Big)^{n-1}.$$

So $\mu_f([t, f^\star]) \sim \frac{V_1}{(n-1)!}(\log\frac{1}{t})^{n-1}$ as $t \downarrow 0$, and $C_-^k V_1 \le k^{n-1}\langle 1\rangle_k \le C_+^k V_1$ for every real $k > 0$.

The two ends of the stride's law are the two ends of strength. At the low end the mass of μ_f near 0 is set by the walls of the direction alone, through the volume of the direction, and the values blow up at $k = 0$ with that volume as coefficient (Proposition 39.35). At the high end μ_f ends at the native value of the direction in a power fixed by the number of marks, with a coefficient read off the Hessian of the stride at its native gauge; the branch of the generating function in Theorem 38.15 is this end read through the pencil.

40.2 The gauge end

Definition 40.4 (The density operator of a recurrence)**.** Let $\mathbf{p} = (p_0, \dots, p_h)$ be polynomials in $\mathbb{C}[k]$, not all zero, of largest degree D, with the symbol $\chi(\lambda) = \sum_i c_i \lambda^i$, $c_i = [k^D]p_i$ (Corollary 38.7), and the *second symbol* $\chi_1(\lambda) = \sum_i [k^{D-1}]p_i\, \lambda^i$. Its *density operator* is

$$\mathfrak{D}_{\mathbf{p}} = \sum_{i=0}^{h} t^i\, p_i(-1-i-\theta), \qquad \theta = t\frac{d}{dt},$$

a differential operator with polynomial coefficients acting on functions and distributions on $(0,\infty)$; written $\sum_{j=0}^{D} a_j(t)\, \partial_t^j$, its leading coefficient is $a_D = (-1)^D t^D \chi(t)$. At a root $\lambda \neq 0$ of χ, in the variable $s = \lambda - t$, write $\mathfrak{D}_{\mathbf{p}} = \sum_j b_j(s)\, \partial_s^j$ and $b_{j,l} = [s^l]\, b_j$. A function u on an interval $(\lambda-\delta, \lambda)$, or $(\lambda, \lambda+\delta)$, *extends by zero* at λ when it is integrable there, $\mathfrak{D}_{\mathbf{p}} u = 0$ there, and the distribution $u\, \mathbf{1}_{(\lambda-\delta,\lambda)}$, or $u\, \mathbf{1}_{(\lambda,\lambda+\delta)}$, is annihilated by $\mathfrak{D}_{\mathbf{p}}$ on $(\lambda-\delta, \lambda+\delta)$; this is a property of the germ of u at λ.

The density operator is the recurrence read on the other side of the moments: $\mathfrak{D}_{\mathbf{p}}$ is the operator whose formal adjoint sends t^k to $\sum_i p_i(k)\, t^{k+i}$, so a measure on $(0,\infty)$ annihilated by it has moments that satisfy the recurrence, and its singular points in $\mathbb{C}^\times$ are the roots of the symbol.

Proposition 40.5 (A recurrence of the values is an equation for the density)**.** *Let a ray be as in Definition 40.1, let $f^\star$ be as in Proposition 40.2 and $\mathbf{p} = (p_0, \dots, p_h)$ as in Definition 40.4. The following are equivalent:*

(a) $\sum_i p_i(k)\langle 1\rangle_{k+i} = 0$ *for all large integers k;*

(b) $\sum_i p_i(k)\langle 1\rangle_{k+i} = 0$ *at every complex k at which every $\langle 1\rangle_{k+i}$ converges, and as an identity of meromorphic functions of k (Proposition 38.5(ii));*

(c) the distribution $\mathfrak{D}_{\mathbf{p}}\, \mu_f$ on $(0,\infty)$ vanishes.

When they hold, $\mathfrak{D}_{\mathbf{p}} \varrho_f = 0$ on $(0, f^\star)$ and the germ of ϱ_f at $f^\star$ extends by zero; and for the origin 0, the conclusions of Corollary 39.38(i) and (ii) hold for $p_0, \dots, p_h$: $\sum_{i \le \min(h,j)} p_i(-j)\, \mathrm{CT}(f^{i-j}) = 0$ for every $j \in \mathbb{N}$, and p_0 vanishes to order at least $n-1$ at 0 with $[k^{n-1}]p_0 \cdot \mathsf{L}_0 + \sum_{i\ge 1} p_i(0)\langle 1\rangle_i = 0$.

So a recurrence that the values satisfy at the large integers, whether or not it follows from the relations of the ray, holds at every strength: no bound on the pieces of a certificate is needed down to $k \to 0$, and the low-end relation follows for it as for the law of [1].

Theorem 40.6 (The gauge end)**.** *Let a ray be as in Definition 40.1, with $\alpha^\star$, $f^\star = f(\alpha^\star)$, the density ϱ_f and the function g of Proposition 40.3, and let $\mathbf{p} = (p_0, \dots, p_h)$ satisfy the equivalent conditions of Proposition 40.5; let $f^\star$ be a simple root of the symbol χ, and use the notation of Definition 40.4 at $\lambda = f^\star$. Put $[x]_j = x(x-1)\cdots(x-j+1)$ and $R_m(x) = \sum_j b_{j,m-D+1+j}\, [x]_j$, with $b_{j,l} = 0$ for $l < 0$.*

(i) $D \ge 1$, $b_{D,0} = 0$, $b_{D,1} = -(f^\star)^D \chi'(f^\star) \neq 0$, and $s^{D-1}\mathfrak{D}_{\mathbf{p}} = \sum_{m\ge 0} s^m R_m(s\partial_s)$ with

$$R_0(x) = b_{D,1}\, [x]_{D-1}\, (x-\gamma), \qquad \gamma = D - 1 - \frac{b_{D-1,0}}{b_{D,1}} = -1 + \frac{\chi_1(f^\star)}{f^\star \chi'(f^\star)}\,:$$

$s = 0$ is a regular singular point of $\mathfrak{D}_{\mathbf{p}}$ with the exponents $0, 1, \dots, D-2$ and γ.

(ii) The line. *The germs at $f^\star$ of functions on the chart's side, $t < f^\star$, that extend by zero form a space of dimension at most one.*

(iii) *The germ of ϱ_f extends by zero, so it spans that space, and $\gamma = \frac{n-3}{2}$.*

(iv) The germ. *If $\gamma \notin \{0, 1, \dots, D-2\}$, then $g(s) = g(0)\,\Phi(s)$, where $\Phi = \sum_N \Phi_N s^N$, $\Phi_0 = 1$, is fixed by $R_0(\gamma+N)\Phi_N = -\sum_{m=1}^{N} R_m(\gamma+N-m)\Phi_{N-m}$, $N \geq 1$. If $\gamma \in \{0, 1, \dots, D-2\}$, then $\varrho_f = \sum_r u_r s^r$ near $f^\star$ with $u_r = 0$ for $r < \gamma$, $u_\gamma = g(0)$, the u_r with $\gamma < r \leq D-2$ fixed one at a time by $\mathsf{p}_r(u) = 0$, where*

$$\mathsf{p}_r(u) = \sum_{i \leq r} \sum_{i < j \leq D} (-1)^l \binom{j-1-i}{l}\, i!\, l!\, b_{j,l}\, u_i, \qquad l = j + r + 1 - D - i \geq 0,$$

whose coefficient of u_r is $r!\, b_{D,1}(r-\gamma)$, and the u_N with $N \geq D-1$ by $R_0(N)u_N = -\sum_{m=1}^{N} R_m(N-m)u_{N-m}$.

(v) The values. *ϱ_f extends holomorphically to a neighbourhood of $(0, f^\star)$ in $\mathbb{C}$ on which $\mathfrak{D}_{\mathbf{p}}\varrho_f = 0$: it is the continuation of the germ of (iv) along $(0, f^\star)$, around the roots of χ on the segment by small arcs on either side. For every $j \in \mathbb{N}$ and every k at which $\langle 1 \rangle_k$ converges,*

$$\frac{\partial^j}{\partial k^j} \langle 1 \rangle_k = \int_0^{f^\star} t^k\, (\log t)^j\, \varrho_f(t)\, dt.$$

The theorem reads a ray from its gauge end. The recurrence fixes the operator, and the native gauge of the direction fixes the rest: $f^\star$, the exponent, which the recurrence must reproduce, and the scale $g(0)$, through the Hessian. For odd n the exponent is an integer and the line lies among the holomorphic solutions; when the exponent is at most $D-2$, the equations $\mathsf{p}_r(u) = 0$, the absence of point masses at $f^\star$, single it out. For even n it is the half-integer class. Nothing from the low end enters, nor any inequality, nor the native values on the segment $(0, f^\star)$, which the density passes analytically.

Proposition 40.7 (The law knows the dimension of its chart)**.** *Let a ray have $\kappa_{1,S} > 0$ for every nonempty proper S, let $\mathbf{p} = (p_0, \dots, p_h)$ have $\sum_i p_i(k) f^i \in \mathcal{L}$ (Definition 38.4), as the law of* [1] *has, and let λ be a simple root of its symbol that is the native value of a nondegenerate native gauge. Then the formal solutions of $\sum_i p_i(k) x(k+i) = 0$ of type $(\lambda, \rho + \mathbb{Z})$ (Definition 39.2) form a line, spanned by $\lambda^k k^{\rho_\lambda}(1 + \sum_{m \geq 1} e_m k^{-m})$ with $\rho_\lambda = -\chi_1(\lambda)/(\lambda\chi'(\lambda)) = -\frac{n-1}{2}$, and λ is a regular singular point of $\mathfrak{D}_{\mathbf{p}}$ with the exponents $0, 1, \dots, D-2$ and $-1-\rho_\lambda = \frac{n-3}{2}$.*

So a recurrence read off closings, integers indexed by one strength, has to carry the dimension $n-1$ of the chart at every simple root of its symbol that is a native value: a test that a candidate law must pass. A root of the symbol need not be a native value, and at such a root the exponent is whatever the recurrence makes it.

Proposition 40.8 (The germ at the gauge end is local data at the native gauge)**.** *Let a ray have the origin 0 and $\kappa_{1,S} > 0$ for every nonempty proper S, with $\alpha^\star$, $f^\star = f(\alpha^\star)$, H and g as in Proposition 40.3; in the coordinates y of the chart, centred at $\log \alpha^\star$, write $\log f = \log f^\star - \frac{1}{2}H_{ab}y^a y^b + \frac{1}{6}h_{abc}y^a y^b y^c + \frac{1}{24}h_{abcd}y^a y^b y^c y^d + \cdots$, with the summation over repeated indices in $\mathcal{E} \setminus e_0$ and $G = H^{-1}$.*

(i) *For $m \geq 2$ the Taylor tensor of order m of $\log f$ at $\log \alpha^\star$ is -2^{-m} times rung m of the still of the realization $\big((s_{1j}, t_{1j})_j; \alpha^\star\big)$ (Definition 9.4), that is $-\sum_j \big(s_{1j}\kappa_{j,\alpha^\star} + (-1)^m t_{1j}\kappa_{j,(\alpha^\star)^{-1}}\big)$ in the cumulants of the basis laws (Proposition 9.6).*

(ii) As $k \to \infty$,

$$\langle 1\rangle_k = (f^\star)^k \Big(\frac{2\pi}{k}\Big)^{\frac{n-1}{2}} \frac{1}{\sqrt{\det H}} \Big(1 + \frac{c_1}{k} + O(k^{-2})\Big),$$

with

$$c_1 = \tfrac{1}{8} h_{abcd} G^{ab} G^{cd} + \tfrac{1}{8} h_{abc} h_{def} G^{ab} G^{cd} G^{ef} + \tfrac{1}{12} h_{abc} h_{def} G^{ad} G^{be} G^{cf}.$$

(iii) With $g(s) = \sum_m g_m s^m$, the asymptotic expansion of $\langle 1\rangle_k$ is $\sum_m g_m (f^\star)^{k+\frac{n-1}{2}+m} \mathrm{B}\big(k + 1, \frac{n-1}{2} + m\big)$, read term by term, and the term of g_m begins at $(f^\star)^k k^{-\frac{n-1}{2}-m}$ with the coefficient $(f^\star)^{\frac{n-1}{2}+m}\Gamma(\frac{n-1}{2} + m) g_m$. So the coefficients of the expansion of $(f^\star)^{-k} k^{\frac{n-1}{2}} \langle 1\rangle_k$ in powers of k^{-1} and the Taylor coefficients of g determine each other, the m-th by the first $m + 1$.

Proposition 40.9 (Slopes from the gauge end)**.** *Let a ray and $\mathbf{p}$ be as in Theorem 40.6, with $\varrho_f(t) = (f^\star - t)^{\frac{n-3}{2}} \sum_m g_m (f^\star - t)^m$ near $f^\star$.*

(i) For every $j \in \mathbb{N}$, $\sum_{l=0}^{j} \binom{j}{l} \sum_i p_i^{(j-l)}(k)\, \partial_k^l \langle 1\rangle_{k+i} = 0$ identically in k: the j-th derivative of the values satisfies the recurrence, with an inhomogeneity made of the lower derivatives.

(ii) If the series $\sum_m g_m s^m$ converges on $[0, f^\star)$ and $\sum_m |g_m| (f^\star)^m \mathrm{B}\big(K' + 1, \frac{n-1}{2} + m\big) < \infty$ for a real K', then for every real $K > K'$ and every $j \in \mathbb{N}$

$$\partial_k^j \langle 1\rangle_k \big|_{k=K} = \sum_{m \geq 0} g_m \frac{\partial^j}{\partial a^j} \Big[(f^\star)^{a+\frac{n-1}{2}+m}\, \mathrm{B}\big(a + 1, \tfrac{n-1}{2} + m\big) \Big]_{a=K}.$$

The derivatives of the values in the strength, the slopes, need no datum from the low end either: they are the logarithmic moments of the same density, and the recurrence differentiated carries them down from large strengths once they are read there.

Definition 40.10 (The procedure that reads a ray from its gauge end)**.** Input: a ray as in Definition 40.1 with its data in a field $\Bbbk \subseteq \mathbb{R}$, and polynomials $\mathbf{p} = (p_0, \dots, p_h)$ over $\Bbbk$ with $\sum_i p_i(k) \langle 1\rangle_{k+i} = 0$ for all large integers k, $f^\star = f(\alpha^\star)$ a simple root of their symbol. Output: the germ of the density at $f^\star$, and the values and slopes at the positive integers.

(1) *The native gauge.* $\alpha^\star$, the unique critical point of $\log f$ on the positive part of the chart, where $-\log f$ is strictly convex (Theorem 17.5(ii)); $f^\star$, $\det H$ and $(\omega_0/dy)(\alpha^\star)$; the constant $g(0)$ (Proposition 40.3(ii)).

(2) *The operator.* $\mathfrak{D}_{\mathbf{p}}$ and its coefficients $b_{j,l}$ at $f^\star$ (Definition 40.4), and γ (Theorem 40.6(i)); a recurrence with $\gamma \neq \frac{n-3}{2}$ is not a recurrence of the values (Theorem 40.6(iii)).

(3) *The germ.* The Taylor coefficients of g, by Theorem 40.6(iv), over $\Bbbk(f^\star)$ up to the factor $g(0)$.

(4) *Large strengths.* For K large and $0 < \delta$ less than the radius of convergence of g, $\langle 1\rangle_{K+i} = \int_{f^\star - \delta}^{f^\star} t^{K+i} \varrho_f(t)\, dt + \epsilon_{K+i}$, $0 \leq i < h$, the integral read from the germ, and $0 \leq \epsilon_k \leq (f^\star - \delta)^{k-k'} \langle 1\rangle_{k'}$ for every $k' \leq k$ at which $\langle 1\rangle_{k'}$ converges; for the origin 0, $\langle 1\rangle_{k'} \leq C_+^{k'} V_1 k'^{1-n}$ (Proposition 40.3(iii)).

(5) *The run back.* The recurrence, which holds at every positive integer (Proposition 40.5), solved for $\langle 1\rangle_k$ at the $k < K$ with $p_0(k) \neq 0$, from $k = K - 1$ down; at a positive integer zero of p_0, and below it, the values are read as moments of ϱ_f continued along $(0, f^\star)$ (Theorem 40.6(v)).

(6) *Slopes.* The same with $(\log t)^j$ in the integrals and the differentiated recurrence (Proposition 40.9).

(7) *Checks.* For the origin 0, the low-end relation (Corollary 39.38(ii)) read on the output returns V_1; two depths K give the same values.

Every step but the truncations in step (4) is an identity: the germ is exact over $\Bbbk(f^\star)$ up to $g(0)$, the error ϵ_k of the cut at $f^\star-\delta$ is bounded by step (4), and the run back is exact arithmetic on exact coefficients. The truncation of the series of g on $[f^\star-\delta, f^\star]$ is estimated, by the size of the last terms kept and by the agreement of two depths. The run back multiplies an error at K by the growth of the other solutions of the recurrence from K down to 1, which is why the depth K grows with the precision asked. The exercises read the centres of three and five marks this way (Exercises 54.3 and 54.15), and a ray of a list on four marks whose symbol has a root on the segment $(0, f^\star)$ (Exercise 55.2).

40.3 The torus value

Definition 40.11 (The torus value)**.** Let the centre ray of a family at the strengths $\boldsymbol{\sigma}$ (Definition 38.13) be given, with its stride $f=\prod_j \big(K_j(\alpha)K_j(\alpha^{-1})\big)^{-\sigma_j}$ and $f^\star=f(\mathbf{1})$. On the torus $\mathbb{T}=\{\alpha:\ |\alpha_e|=1\ (e\in\mathcal{E}),\ \alpha_{e_0}=1\}$, $\alpha_e=e^{i\vartheta_e}$, with the normalized measure $d\vartheta/(2\pi)^{n-1}$, the stride is $f=\prod_j |K_j(\alpha)|^{-2\sigma_j}$, a function with values in $[f^\star,\infty]$, equal to ∞ exactly where an active letter vanishes. The *torus law* $\nu_f^{\mathbb{T}}$ is the image of $d\vartheta/(2\pi)^{n-1}$ under f, a probability measure on $[f^\star,\infty)$, $\varrho_f^{\mathbb{T}}$ its density where it has one, and the *torus value* is

$$\langle 1\rangle_k^{\mathbb{T}}=\int t^k\,\nu_f^{\mathbb{T}}(dt)=\frac{1}{(2\pi)^{n-1}}\int_{\mathbb{T}} f^k\,d\vartheta \qquad (\operatorname{Re}k\le 0).$$

When no letter K_j of the family vanishes on $\mathbb{T}$, so that $\mathbb{T}$ lies in X_F, it is $(2\pi i)^{1-n}\langle 1\rangle_{k;\mathbb{T}}$ in the notation of Definition 38.1, $\mathbb{T}$ oriented by $d\vartheta$.

Proposition 40.12 (The torus is the second chain)**.** *For the centre ray of a family at the strengths $\boldsymbol{\sigma}$, with the notation of Definition 40.11, ϱ_f and g as in Proposition 40.3:*

(i) On $\mathbb{T}$, $f>f^\star$ off $\mathbf{1}$; the zero set of every active letter on $\mathbb{T}$ has measure zero. $\langle 1\rangle_k^{\mathbb{T}}$ is continuous on $\operatorname{Re}k\le 0$ and holomorphic on $\operatorname{Re}k<0$, and $\langle 1\rangle_{-j}^{\mathbb{T}}=\mathrm{CT}(f^{-j})$ for $j\in\mathbb{N}$, the closing $\mathsf{C}_j(1)$ when every $\sigma_j\ge 1$ (Definition 39.30).

(ii) Let every $\sigma_j\ge 1$, and let $\mathbf{p}=(p_0,\dots,p_h)$ satisfy $\sum_i p_i(k)\langle 1\rangle_{k+i}=0$ for all large integers k, as the law of $[1]$ does. Then $\sum_i p_i(k)\langle 1\rangle_{k+i}^{\mathbb{T}}=0$ for every k with $\operatorname{Re}k\le -h$, and the distribution $\mathfrak{D}_{\mathbf{p}}\,\nu_f^{\mathbb{T}}$ on $(0,\infty)$ vanishes.

(iii) Near $f^\star$, $\nu_f^{\mathbb{T}}$ has a density, and with the one function g

$$\varrho_f(t)=(f^\star-t)^{\frac{n-3}{2}}g(f^\star-t)\quad(t<f^\star),\qquad \varrho_f^{\mathbb{T}}(t)=(2\pi)^{1-n}(t-f^\star)^{\frac{n-3}{2}}g(f^\star-t)\quad(t>f^\star).$$

(iv) For $\mathbf{p}$ as in (ii) with $f^\star$ a simple root of its symbol, the germ of ϱ_f on the chart's side spans the line of Theorem 40.6(ii), the germ of $\varrho_f^{\mathbb{T}}$ extends by zero on the torus's side, and the two are the cut solutions $|f^\star-t|^{\frac{n-3}{2}}g(f^\star-t)$ of one germ on its two sides, the second with the factor $(2\pi)^{1-n}$.

At a centre the native gauge of the direction lies on the positive orthant and on the unit torus, and the two meet only there (Theorem 39.57). The torus value continues the closings in the strength, as the values continue them at the poles of the low end (Proposition 39.34), and it satisfies every recurrence of the values. Its density is the density of the chart seen from the other side of the native value: the Morse function of the stride at $\mathbf{1}$ changes sign between the orthant and the torus, so the one function g enters both, and the asymptotic statement at the end of Theorem 39.57 is the shadow of this exact one. Exercise 54.4 works the three-mark centre, where the torus value, the values and the solution at the sign are tied by an explicit connection.

Chapter 41

Reading a ray

A ray is read from its list and its direction. A box of its relations gives a spanning set of a submodule that contains [1], the one-step matrix on it with a certificate, and a recurrence of the values that holds at every strength (Section 39.4); the gauge end then gives the values themselves (Chapter 40). This chapter assembles the reading and says what each step certifies. At the low end a recurrence of the values meets the values at the positive integers through the poles at the nonpositive integers: the low-end relation at 0 and, where the coefficients of the recurrence vanish to the order of the poles, second low-end relations at the other poles, with coefficients in the field of the recurrence, the weights and the volume of the direction. At the high end the generating function of the values is holomorphic off the reciprocals of $(0, f(\alpha^\star)]$, and its jump across them is the density of the stride's law. When every other root of the symbol lies outside the closed disc of radius $f(\alpha^\star)$, the values are, up to scale, the only solution of the recurrence whose exponential rate of growth is at most $f(\alpha^\star)$; the low-end relation fixes the scale, and solutions over the field of the recurrence approximate the values at the rate $f(\alpha^\star)/\lambda'$, λ' the least modulus of the other roots. Positivity is the moment problem of the stride's law on $[0, f(\alpha^\star)]$. Against a solution carried by a segment that ends at a real point λ off $[0, f(\alpha^\star)]$ its brackets shrink at the rate of the Green function of the plane cut along $[0, f(\alpha^\star)]$, read at λ; it cannot see a solution carried by $[0, f(\alpha^\star)]$ and dominated by the stride's law, which the analyticity of the density excludes; and for a recurrence of order two it gives the value at $k = 1$ as the volume of the direction times a continued fraction in the coefficients. The procedure that reads a ray from its list runs the box by evaluation at strengths drawn at random, modulo primes for a list, and bounds the chance of a wrong output by degrees that the box fixes, or removes it with enough strengths. Its cost is set by the stencils of the relations on a lattice, by the degrees of the one-step matrix, which the number of pivots bounds, and by the order and the degree of the recurrence. The nondegenerate native gauges bound the sizes of a reading from below; over all exponents at once they form the graph of one map, through which they are found by continuation and certified one at a time.

41.1 The low end and the slit

The low-end relation of a recurrence of the values is Corollary 39.38(ii), with the low-end coefficients of Definition 39.37; by Proposition 40.5 it holds for every recurrence that the values satisfy at the large integers, whether or not it follows from the relations of the ray. The poles at the negative integers (Proposition 39.35) give more relations.

Proposition 41.1 (The low-end relations at every pole)**.** *Let a ray have the origin* 0 *and* $\kappa_{1,S} > 0$ *for every nonempty proper* S*, with the volume* V_1 *of its direction (Proposition 39.34), and let*

$p_0, \dots, p_h \in \mathbb{C}[k]$ *satisfy* $\sum_i p_i(k)\langle 1\rangle_{k+i} = 0$ *for all large integers* k. *Let* $j \in \mathbb{N}$, *and let* $m_0 \in \{0, \dots, n-1\}$ *be such that every* p_i *with* $i \le \min(h, j)$ *vanishes to order at least* m_0 *at* $k = -j$.

(i) The function $\sum_{i \le \min(h,j)} p_i(k)\langle 1\rangle_{k+i}$ *is holomorphic at* $k = -j$, *with the value* $-\sum_{i=j+1}^{h} p_i(-j)\langle 1\rangle_{i-j}$ *there.*

(ii) If $m_0 < n-1$, *then* $\sum_{i \le \min(h,j)} [(k+j)^{m_0}] p_i \cdot \mathrm{CT}\left(f^{i-j}\right) = 0$.

(iii) If $m_0 = n-1$, *then*

$$V_1 \sum_{i \le \min(h,j)} [(k+j)^{n-1}] p_i \cdot \mathrm{CT}\left(f^{i-j}\right) + \sum_{i=j+1}^{h} p_i(-j)\,\langle 1\rangle_{i-j} = 0.$$

At $j = 0$ *this is the low-end relation; at* $j \ge 1$ *it is the* second low-end relation *at* $-j$, *a linear relation among the values at the positive integers whose coefficients lie in the field generated by those of the* p_i, *the weights and* V_1.

At $m_0 = 0$, (ii) is the recurrence of the constant terms, $\sum_i p_i(-j)\,\mathrm{CT}(f^{i-j}) = 0$ (Corollary 39.38(i)). At larger m_0 it ties the derivatives of order m_0 of $p_0, \dots, p_j$ at $-j$, and (i) ties the values at the positive integers to the Laurent coefficients of the values at the poles $-j, \dots, 0$, those at 0 being integrals over the faces of the sector cubes (Proposition 39.39).

The generating function of the values is read on the plane cut along the reciprocals of $(0, f(\alpha^\star)]$. The segment $(0, f(\alpha^\star))$ of the plane of native values is the *slit*.

Proposition 41.2 (The values live on the slit plane)**.** *Let a ray have a real origin and* $\kappa_{1,S} > 0$ *for every nonempty proper* S, *with* $\alpha^\star$, $f^\star = f(\alpha^\star)$, μ_f *and* ϱ_f *as in Proposition 40.3, and let* k_0 *be an integer at which* $\langle 1\rangle_{k_0}$ *converges.*

(i) For $|q| < 1/f^\star$, $G(q) = \sum_{k \ge k_0} \langle 1\rangle_k q^{k-k_0} = \int t^{k_0} \mu_f(dt)/(1-qt)$, *and the right side is holomorphic on* $\mathbb{C} \setminus [1/f^\star, \infty)$: G *continues to the plane cut along the reciprocals of* $(0, f^\star]$.

(ii) For $x > 1/f^\star$, G *continues holomorphically across a neighbourhood of* x *in* $(1/f^\star, \infty)$ *from either side, with the limits* $G(x \pm i0)$, *and* $G(x+i0) - G(x-i0) = 2\pi i\, x^{-1-k_0}\, \varrho_f(1/x)$: *the jump of* G *across the cut is the density of the stride's law.*

(iii) On the centre ray of a family, every native gauge on the torus $\mathbb{T}$ *of Definition 40.11 has its native value in* $[f^\star, \infty)$, *off the slit.*

(iv) Every conjugate of $f^\star$ *over the field of the weights is the native value of a nondegenerate native gauge (Proposition 38.10), and a root of the symbol of every recurrence that the values satisfy at the large integers with coefficients in that field; the real conjugates in* $(0, f^\star)$ *lie on the slit.*

A root λ of a symbol on the slit sits on the cut, at $1/\lambda \in (1/f^\star, \infty)$, where the generating function of the values continues from either side and jumps by the density of the stride's law; a root off $[0, f^\star]$ sits where it is holomorphic. Not every root of a symbol is a native value: whenever the values satisfy $\sum_i p_i(k)\langle 1\rangle_{k+i} = 0$, they satisfy the recurrence with the coefficients $p_{i-1}(k+1) - \lambda_0\, p_i(k)$, $0 \le i \le h+1$, $p_{-1} = p_{h+1} = 0$, which follows from the relations when the first does and has the symbol $(\lambda - \lambda_0)\chi(\lambda)$, for every λ_0. In the other direction, the native value of every nondegenerate native gauge is a root of the symbol of every recurrence that follows from the relations (Corollary 38.7), and that of every native gauge when the recurrence has a certificate as in Proposition 38.8. Exercises 55.1 and 55.2 work second low-end relations on a list of four marks.

41.2 Positive selection

Theorem 41.3 (Positive selection)**.** *Let a ray have a real origin and $\kappa_{1,S} > 0$ for every nonempty proper S, with $f^\star = f(\alpha^\star)$, and let $p_0, \dots, p_h \in \mathbb{C}[k]$, $h \geq 1$, satisfy $\sum_i p_i(k)\langle 1\rangle_{k+i} = 0$ for all large integers k, so that the recurrence holds at every integer at which the values converge (Proposition 40.5). Let p_0 and p_h have the largest degree D, so that the symbol χ has degree h and $\chi(0) \neq 0$; then $f^\star$ is a root of χ, and let the roots of χ be distinct, $\lambda_1 = f^\star, \lambda_2, \dots, \lambda_h$. Let k_1 be an integer at which the values converge, with $p_0(k)p_h(k) \neq 0$ for every integer $k \geq k_1$. A* solution *is a sequence $(x(k))_{k\geq k_1}$ with $\sum_i p_i(k)x(k+i) = 0$ for every $k \geq k_1$; the solutions form a space $\mathcal{V}$ of dimension h, and the values are one of them.*

(i) For every solution, $X(q) = \sum_{k\geq k_1} x(k)q^{k-k_1}$ satisfies $L_q X = R_x$ as a formal power series, with

$$L_q = \sum_{i=0}^{h} q^{h-i}\, p_i\Big(q\frac{d}{dq} + k_1 - i\Big)$$

and R_x a polynomial of degree less than h that depends linearly on $x(k_1), \dots, x(k_1+h-1)$. The coefficient of $(d/dq)^D$ in L_q is $q^{D+h}\chi(1/q)$, so the singular points of L_q in $\mathbb{C}^\times$ are the points $1/\lambda_c$. For the values, X continues holomorphically to $\mathbb{C}\setminus[1/f^\star, \infty)$ (Proposition 41.2).

(ii) The solutions with $x(k) = O(r^k)$ for every $r > f^\star$ form a subspace of $\mathcal{V}$ whose dimension is the number of roots in the closed disc $|\lambda| \leq f^\star$; the values lie in it, $\langle 1\rangle_k = C\,(f^\star)^k k^{-\frac{n-1}{2}}\big(1+o(1)\big)$ with $C > 0$, and the exponent $-\chi_1(f^\star)/(f^\star\chi'(f^\star))$ of the root $f^\star$ is $-\frac{n-1}{2}$.

(iii) Let every root other than $f^\star$ have modulus greater than $f^\star$, and put $\lambda' = \min_{c\geq 2}|\lambda_c|$. Then the solutions with $x(k) = O(r^k)$ for some $r < \lambda'$ are the multiples of the values, and so are those whose generating function converges on $|q| < 1/f^\star$: the values are, up to a constant factor, the solution of least growth*. Let moreover the origin be 0, $k_1 = 1$ and $a = [k^{n-1}]p_0 \neq 0$, and put $\ell(x) = -a^{-1}\sum_{i=1}^{h} p_i(0)\,x(i)$. Then $\ell(\langle 1\rangle) = V_1$, and $\langle 1\rangle_k = V_1\,x(k)/\ell(x)$ for every nonzero solution x of least growth: the values divided by the volume of the direction are a function of the recurrence alone.*

(iv) Under the hypotheses of (iii), let $x^{(0)} \in \mathcal{V}$ have $\ell(x^{(0)}) = V_1$ and let $x^{(1)}, \dots, x^{(h-1)}$ be a basis of $\{\ell = 0\}$, so that $\langle 1\rangle = x^{(0)} + \sum_{i\geq 1} M_i x^{(i)}$ for one $M \in \mathbb{C}^{h-1}$. For all large K the equations $x^{(0)}(K+l) + \sum_{i\geq 1} M_i^{(K)} x^{(i)}(K+l) = 0$, $0 \leq l \leq h-2$, have exactly one solution $M^{(K)}$, and $|M^{(K)} - M| = O\big((f^\star/\lambda')^K K^{C'}\big)$ for some C'. When the p_i have their coefficients in a field $\Bbbk$ that contains V_1, the $x^{(i)}$ can be taken with values in $\Bbbk$, and then every $M^{(K)}$ lies in $\Bbbk^{h-1}$.

The selection runs on growth alone: among the solutions, the values are the one that grows like the native value of the direction, and the other roots of the symbol, outside the closed disc of radius $f^\star$, give solutions that grow faster and are cut away. The hypothesis of (iii) is what makes the values the solution of least growth: a root in the closed disc, in particular one on the slit, gives a solution whose exponential rate of growth is at most that of the values, and growth cannot remove it (Section 41.3). The low-end relation then fixes the scale through the volume of the direction, so the values over that volume are a function of the recurrence alone.

41.3 Positivity as a moment problem

Proposition 41.4 (Positivity is the moment problem of the stride's law)**.** *Let a ray have a real origin and $\kappa_{1,S} > 0$ for every nonempty proper S, with $f^\star = f(\alpha^\star)$ and μ_f as in Proposition 40.3.*

For a real polynomial $p = \sum_m p_m t^m$, a real K and a sequence x defined at $K + \mathbb{N}$, put $L_{K,p}(x) = \sum_m p_m\, x(K+m)$.

(i) If $\langle 1\rangle_K$ converges, $p \ge 0$ on $[0, f^\star]$ and $p \ne 0$, then $L_{K,p}(\langle 1\rangle) = \int t^K p(t)\, \mu_f(dt) > 0$.

(ii) Every real polynomial of degree at most N that is nonnegative on $[0, f^\star]$ is a sum of polynomials q^2, $t\,q^2$, $(f^\star - t)\,q^2$ and $t(f^\star - t)\,q^2$ of degree at most N, with real q. So for a real sequence x, $L_{K,p}(x) \ge 0$ for every such p exactly when the Hankel matrices

$$\begin{matrix} \big[x(K+i+i')\big], & \big[x(K+1+i+i')\big], \\ \big[f^\star x(K+i+i') - x(K+1+i+i')\big], & \big[f^\star x(K+1+i+i') - x(K+2+i+i')\big], \end{matrix}$$

with $0 \le i, i' < \lfloor \frac{N}{2} \rfloor + 1$, $\lfloor \frac{N+1}{2} \rfloor$, $\lfloor \frac{N+1}{2} \rfloor$ and $\lfloor \frac{N}{2} \rfloor$ respectively, are positive semidefinite.

(iii) A real sequence $(x(K+m))_{m\in\mathbb{N}}$ has $L_{K,p}(x) \ge 0$ for every real $p \ge 0$ on $[0, f^\star]$ exactly when $x(K+m) = \int t^m \nu(dt)$ for every m, for a positive measure ν on $[0, f^\star]$, which is then unique; for the values, $\nu = t^K \mu_f$.

So the positivity of the values is the statement that they are the moments of a positive measure on $[0, f^\star]$, and Theorem 38.14(iii) is its first family, the Hankel determinants of the values. For a family $x^{(0)} + \sum_i M_i x^{(i)}$ of solutions of a recurrence, as in Theorem 41.3(iv), each condition $L_{K,p} \ge 0$ is one linear inequality in the coordinates M, and the conditions of degree at most N at the strength K cut out a closed convex set, the *bracket* of degree N, which contains the coordinates of the values.

Theorem 41.5 (The rate of positivity off the segment)**.** *Let a ray be as in Proposition 41.4, K an integer at which $\langle 1\rangle_K$ converges, $\lambda \in \mathbb{R} \setminus [0, f^\star]$ and I_λ the closed segment between 0 and λ. Let $u(k) = \int_{I_\lambda} t^k\, \nu(t)\, dt$ for the integers $k \ge K$, where ν is a real function on I_λ with $\int_{I_\lambda} |t|^K |\nu(t)|\, dt < \infty$ and $\nu(t) = c\,|\lambda - t|^a\big(1 + o(1)\big)$ as $t \to \lambda$ in I_λ, with $c \ne 0$ and $a > -1$. Let E_N be the set of the real ε with $L_{K,p}(\langle 1\rangle + \varepsilon u) \ge 0$ for every real $p \ge 0$ on $[0, f^\star]$ of degree at most N. Then E_N is a closed interval that contains 0, and there is a constant C with its length at most $C\, N^{a+1} e^{-N g(\lambda)}$ for all large N, where*

$$g(\lambda) = \log\big|w + \sqrt{w^2 - 1}\big| > 0, \qquad w = \frac{2\lambda}{f^\star} - 1,$$

the branch of the square root with $|w + \sqrt{w^2-1}| > 1$. For $\lambda > f^\star$, with $\rho = f^\star/\lambda$,

$$e^{-g(\lambda)} = \frac{1 - \sqrt{1-\rho}}{1 + \sqrt{1-\rho}} = \frac{\rho}{4} + O(\rho^2).$$

The rate is read off the Green function g of the plane cut along $[0, f^\star]$, with its pole at infinity, at the end λ of the segment that carries u: the farther λ lies from $[0, f^\star]$, the faster positivity separates the values from the values plus a multiple of u. For a recurrence of order two, with the coordinate M of Theorem 41.3(iv) and $u = x^{(1)}$ of this form, E_N is the bracket of degree N of M less the value of M.

Proposition 41.6 (What positivity cannot see)**.** *Let a ray be as in Proposition 41.4, K a real at which $\langle 1\rangle_K$ converges, and ν a real signed measure on $[0, f^\star]$ with $|\nu| \le C\mu_f$ for a constant C; put $u(k) = \int t^k \nu(dt)$ for $k \ge K$.*

(i) For $|\varepsilon| \le 1/C$, $\langle 1\rangle + \varepsilon u$ is from K on the moment sequence of the positive measure $\mu_f + \varepsilon\nu$, and $L_{K',p}(\langle 1\rangle + \varepsilon u) \ge 0$ for every real $K' \ge K$ and every real $p \ge 0$ on $[0, f^\star]$.

(ii) *If on an open interval $J \subseteq (0, f^\star)$ the measure ν has a density that agrees almost everywhere with no real-analytic function on J, then for $\varepsilon \neq 0$ the measure $t^K(\mu_f + \varepsilon\nu)$, the only finite measure on $[0, f^\star]$ whose moments are the $\langle 1\rangle_{K+m} + \varepsilon u(K+m)$, $m \in \mathbb{N}$, has no density on $(0, f^\star)$ that is real-analytic, while $t^K\mu_f$ has one (Proposition 40.3(i)).*

(iii) *Let the origin be 0, let $\mathbf{p} = (p_0, \dots, p_h)$ satisfy the conditions of Proposition 40.5, and let ν have a density that is bounded near 0, with $\mathfrak{D}_{\mathbf{p}}\nu = 0$ as distributions on $(0, \infty)$. Then $u(k) = \int t^k \nu(dt)$ converges at every k with $\operatorname{Re} k > -1$, $\sum_i p_i(k)u(k+i) = 0$ there, and $\sum_{i=1}^{h} p_i(0)\, u(i) = 0$: u satisfies the recurrence and contributes nothing to the low-end relation.*

So a sequence u as in (i) and (iii), a solution of the recurrence carried by $[0, f^\star]$ and dominated by the stride's law, is invisible to the recurrence, to the low-end relation and to positivity together: read as conditions on candidates, they leave the direction of u free. For a root λ of the symbol on the slit, a density ν on $(0, \lambda)$ with $\mathfrak{D}_{\mathbf{p}}\big(\nu\, \mathbf{1}_{(0,\lambda)}\big) = 0$ as distributions on $(0, \infty)$, a solution of the density equation on $(0, \lambda)$ that extends by zero at λ (Definition 40.4), bounded near 0 and with $|\nu| \leq C\varrho_f$ on $(0, \lambda)$, gives such a u. The gauge end does not choose among candidates: it constructs the density, and by (ii) the analyticity of the density on the open support is as much a property of the stride's law as its positivity.

Proposition 41.7 (A recurrence of order two is the volume of the direction times a continued fraction)**.** *Let a ray have the origin 0 and $\kappa_{1,S} > 0$ for every nonempty proper S, with $f^\star = f(\alpha^\star)$, and let $p_0, p_1, p_2 \in \mathbb{R}[k]$ satisfy $p_0(k)\langle 1\rangle_k + p_1(k)\langle 1\rangle_{k+1} + p_2(k)\langle 1\rangle_{k+2} = 0$ for all large integers k; put $a = [k^{n-1}]p_0$ and $\rho_k = \langle 1\rangle_{k+1}/\langle 1\rangle_k$ for the integers $k \geq 1$.*

(i) *$0 < \rho_k < f^\star$, and $\rho_k\big(p_1(k) + p_2(k)\rho_{k+1}\big) = -p_0(k)$ for every integer $k \geq 1$.*

(ii) *$\langle 1\rangle_1\big(p_1(0) + p_2(0)\rho_1\big) = -a\, V_1$. When $-a/p_1(0)$ and $-a/(p_1(0) + f^\star p_2(0))$ are finite and positive, $\langle 1\rangle_1/V_1$ lies between them, strictly when they differ.*

(iii) *Let the hypotheses of Theorem 41.3(iii) hold with $h = 2$ and $k_1 = 1$, so that $\lambda' = |\lambda_2|$, and let $a \neq 0$; put $\mathsf{M}_k(r) = -p_0(k)/\big(p_1(k) + p_2(k)\, r\big)$. There are K_0, C and C' such that for every $K \geq K_0$ and every $r \in [0, f^\star]$ the composite $\mathsf{M}_1 \circ \cdots \circ \mathsf{M}_K(r)$ is defined and lies within $C(f^\star/\lambda')^K K^{C'}$ of ρ_1. So ρ_1 is the value of a continued fraction in the coefficients of the recurrence, and $\langle 1\rangle_1 = -aV_1/(p_1(0) + p_2(0)\rho_1)$. The sets of the $\mathsf{M}_1 \circ \cdots \circ \mathsf{M}_K(r)$ over the $r \in (0, f^\star)$ whose intermediate values $\mathsf{M}_k \circ \cdots \circ \mathsf{M}_K(r)$, $2 \leq k \leq K$, lie in $(0, f^\star)$ are nested in K and contain ρ_1.*

The low-end relation fixes the value at $k = 1$ through the volume of the direction once the ratio ρ_1 is known, and positivity alone places every ρ_k in $(0, f^\star)$. The bracket of (ii) is the image of $\rho_1 \in (0, f^\star)$ under $\rho \mapsto -a/(p_1(0) + p_2(0)\rho)$; the nested sets of (iii) sharpen that condition with the conditions $\langle 1\rangle_k > 0$ and $f^\star\langle 1\rangle_k > \langle 1\rangle_{k+1}$ at every $k \leq K+1$, and they shrink to ρ_1 at the rate $(f^\star/\lambda')^K$, up to a power of K. The exercises work the brackets and the rate of Theorem 41.5 on the centre of three marks (Exercises 54.1 and 54.19), and the continued fraction on W_3 at $(\mathbf{1}; 0, 2)$ (Exercise 54.18).

41.4 The procedure

Definition 41.8 (The procedure that reads a ray from its list)**.** Input: a family whose weights lie in a field $\Bbbk \subseteq \mathbb{R}$, $\mathbb{Q}$ for a list; a ray of it with $\kappa_{1,S} > 0$ for every nonempty proper S and its origin in $\Bbbk$, the origin 0 unless stated; the precision wanted. Output: a spanning set and its one-step matrix with a certificate, a recurrence of the values that holds at every strength, the values at the positive integers, and brackets for them.

(1) *Walls and symmetries.* The walls $\kappa_{1,S}$ and the volume $V_1 = \sum_\pi \prod_{l=2}^{n} \kappa_{1,U_l}^{-1}$ of the direction (Proposition 39.34); a finite group G generated by maps of the four kinds of Proposition 39.11(ii) that are symmetries of the ray.

(2) *The box.* Through the boxes $\mathfrak{B}_{\mathfrak{t}}(\bar{\mathbf{a}}, \bar{\mathbf{b}})$ with level bounds kept by G, each with a ranking, and the $\mathfrak{s} < \mathfrak{t}$, in an order that reaches each, the first box accepted at some $\mathfrak{s}$, with its spanning set and its stems (Definition 39.20); the search stops (Theorem 39.22). Acceptance is decided by eliminations of the relations at strengths drawn at random, for a list modulo a prime (Proposition 41.10(iii) and (v), below).

(3) *The one-step matrix.* At strengths drawn at random, for a list modulo primes, the reductions of the targets, from the relations they need (Proposition 41.10(vi)); the entries of $\mathbf{B}$ over $\Bbbk(k)$ by rational reconstruction from these values (Proposition 41.10(ii)), for a list with Chinese remaindering and rational reconstruction of the coefficients over the primes; a check against eliminations of the whole box at strengths and primes drawn afresh (Proposition 41.10(iv) and (v)). A certificate supported on the stems exists (Theorem 39.21(ii)), and every solution, the values among them, satisfies $\varsigma^{-1} v_V = \mathbf{B} v_V$ (Theorem 39.21(iii)).

(4) *The recurrence.* The first dependence of the rows $w_i(k) = w_{i-1}(k-1)\,\mathbf{B}(k)$ (Proposition 39.6(ii)), read at points and reconstructed as in step (3), its coefficients being proportional to signed maximal minors (Proposition 39.6(iii)): $\sum_j p_j(k) f^j \in \mathcal{L}$, the law of [1] when the spanning set is independent (Theorem 39.21(iv)), as it is when the values of the spanning set at the nondegenerate native gauges span (Proposition 39.42(i)). Its end coefficient p_0 vanishes only at the shifted zeros of the denominator of $\mathbf{B}$ and at the strengths where the rows line up (Proposition 39.6(iii)).

(5) *The values.* Either the gauge end, from the recurrence, $\alpha^\star$ and $\det H$, when $f(\alpha^\star)$ is a simple root of its symbol (Definition 40.10); or, when the hypotheses of Theorem 41.3(iii) hold, positive selection with the low-end relation (Theorem 41.3(iv)), with brackets from positivity (Proposition 41.4).

(6) *Checks, outside the construction.* When the origin is integral and every letter exponent of the direction is at least 1, the closings of the spanning set satisfy $\mathsf{C}_{j+1}(\mathbf{b}) = \mathbf{B}(-j)\,\mathsf{C}_j(\mathbf{b})$ for all large j (Theorem 39.33, Theorem 39.21(iii)); for the origin 0, the constant terms of the f^{-j} satisfy the reflected recurrence (Corollary 39.38(i)); when $\mathbf{B}$ is regular at ∞, the native values of nondegenerate native gauges found by other means are reciprocal eigenvalues of $\mathbf{B}(\infty)$ (Proposition 39.42(ii)); the exponent at $f(\alpha^\star)$ is $\frac{n-3}{2}$ (Theorem 40.6(iii)); the low-end relation returns V_1 from the values read; two readings from different depths agree.

Every relation of a box is a relation of the module, so every identity that the elimination gives over $\Bbbk(k)$ holds at every strength (Proposition 39.18, Theorem 39.21), and the recurrence of step (4) holds for the values at every strength at which they converge (Proposition 40.5). Chance enters only through the strengths and primes at which steps (2) to (4) evaluate: Proposition 41.10 bounds it by degrees that the box fixes, and enough strengths remove it. The procedure needs no bound on the box: the search stops (Theorem 39.22).

The procedure of Section 39.12 reads the same module from its solutions, with no box reduced. Its output is certified when the solutions supplied annihilate no submodule (Corollary 39.46), and the closings alone certify it exactly when the native gauge of the direction sees every nonzero submodule (Corollary 39.59); otherwise a unique solution of its equations is evidence. The procedure above certifies the matrix of its spanning set by construction: the certificate of the box is an identity of the relations, whatever any solution sees, and the matrix is the one-step matrix of the

module exactly when the spanning set is independent. The two check each other: every solution that Section 39.12 uses satisfies $\varsigma^{-1}v_V = \mathbf{B}v_V$ on the spanning set of the box (Theorem 39.21(iii)), which is step (6) for the closings, and where the supplied solutions annihilate a submodule, the matrix of the box is still certified by its certificate. Section 39.12 ends with the law of [1]; the procedure above goes on to the values, at the gauge end or by positive selection. A recurrence read off the closings is a recurrence of the values when it holds for all large j and every letter exponent of the direction is positive (Corollary 39.60); finitely many closings do not show that, while the recurrence of step (4) carries a certificate.

Proposition 41.9 (The relations of a box are difference equations)**.** *Let a box $\mathfrak{B} = \mathfrak{B}_{\mathfrak{t}}(\bar{\mathbf{a}}, \bar{\mathbf{b}})$ of a ray be given (Definition 39.15).*

(i) The symbols at a level $(\mathbf{a}, \mathbf{b})$ are the points of the affine lattice $\{u \in \mathbb{Z}^{\mathcal{E}} : u_{\mathcal{E}} = \sum_j (a_j r_j + b_j r_j^*)\}$, of rank $n-1$. There is a constant C, depending on the ray and the level, such that the coordinates u_e, $e \neq e_0$, of the symbols of wall degree at most $\mathfrak{t}$ at that level lie in intervals of length at most $C(1+\mathfrak{t})$; so they number at most $\big(C(1+\mathfrak{t})+1\big)^{n-1}$.

(ii) A letter identity of table j ties a symbol to the $|\mathcal{B}_j|$ symbols one unit of that letter up, with weights as coefficients; the mark relation of a symbol at a mark ties it to at most $\sum_j |\mathcal{B}_j|$ symbols one unit of a letter up, with coefficients affine in k. The shifts of $(u; \mathbf{a}, \mathbf{b})$ that occur lie in one finite set that does not depend on the symbol.

(iii) In the basis of the symbols the relations of the box form a matrix $A(k) = A_0 + kA_1$ with entries in the field of the weights and the origin; A_1 vanishes outside the rows of the mark relations, where its entries are $m_{1,e}$, $-s_{1j}\theta_{j,T}$ and $-t_{1j}\theta_{j,T}$. The same holds for the orbit averages of the relations modulo a finite group of symmetries that keeps the box, in the basis of the orbit averages of the symbols.

Proposition 41.10 (What a reading by evaluation certifies)**.** *Let a finite group G of symmetries keep a box $\mathfrak{B}$ of a ray, with the field $\Bbbk$ of Definition 39.15 and a ranking (Definition 39.20). Let $A(k)$ be the matrix whose rows are the orbit averages of the letter identities and of the mark relations that span $\mathcal{R}_{\mathfrak{B}}$, in the basis of the orbit averages ordered by the ranking, so that its rows span $\mathcal{R}_{\mathfrak{B}}^G$ and its entries are affine in k (Proposition 41.9(iii)). Let P be the pivot orbits and F the free orbits, $r = |P|$, and let $A_P(k)$ and $A_F(k)$ be r rows of A that are independent over $\Bbbk(k)$, read on the columns P and F.*

(i) r is the rank of A, $A_P(k)$ is invertible over $\Bbbk(k)$, and the reduction of $x \in \mathcal{F}_{\mathfrak{B}}^G$ with coefficients in $\Bbbk$ is $x_F - x_P A_P(k)^{-1} A_F(k)$; $\det A_P$ is a nonzero polynomial of degree at most r. At $k_0 \in \Bbbk$ the elimination of all the rows of $A(k_0)$ in the order of the ranking has the pivots P exactly when some minor of order r of $A(k_0)$ on the columns P is nonzero, as when $\det A_P(k_0) \neq 0$; then the reduction it gives of every such x is the value at k_0 of the reduction over $\Bbbk(k)$.

(ii) When the box is accepted, every entry of its matrix $\mathbf{B}$ is a polynomial of degree at most r divided by $\det A_P$. A rational function whose numerator and denominator have degrees at most d_1 and d_2 is fixed, among such functions, by its values at any $d_1 + d_2 + 1$ points at which the denominators do not vanish; with a common denominator known, a numerator of degree at most d_1 is fixed by $d_1 + 1$ values.

(iii) The verdict of the elimination at k_0 on acceptance at $\mathfrak{s}$, whether the reductions of the targets are combinations of the free Laurent orbits of wall degree at most $\mathfrak{s}$, is the verdict over $\Bbbk(k)$ except at no more than $2r$ strengths k_0.

(iv) Let the box be accepted, and let $\mathbf{B}'$ *be a matrix over* $\Bbbk(k)$ *whose entries have a common denominator* Q'*, with* Q' *and the numerators of degree at most* d*. If* $\mathbf{B}' \neq \mathbf{B}$*, then* $\mathbf{B}'(k_0)$ *agrees with the matrix that the elimination at* k_0 *gives at no more than* $r+d$ *strengths* k_0 *with* $Q'(k_0) \neq 0$ *at which the elimination has the pivots* P*. So agreement at* $r+d+1$ *such strengths proves* $\mathbf{B}' = \mathbf{B}$*, and a wrong* $\mathbf{B}'$ *passes the check at a strength drawn uniformly from a finite set* $S \subseteq \Bbbk$ *with probability at most* $(r+d)/|S|$*.*

(v) Let $\Bbbk = \mathbb{Q}$*, and let* q *be a prime that divides no denominator of an entry of* A*, with* $\det A_P$ *not identically* 0 *modulo* q*. Then* A *modulo* q *has the rank* r *and the pivots* P *over* $\mathbb{F}_q(k)$*, its reductions are those over* $\mathbb{Q}(k)$ *taken modulo* q*, and (i) to (iv) hold over* $\mathbb{F}_q$ *with strengths in* $\mathbb{F}_q$*. A* $\mathbf{B}'$ *over* $\mathbb{Q}(k)$ *with* $\mathbf{B}' \neq \mathbf{B}$ *passes the check modulo* q *at a strength drawn uniformly from* $\mathbb{F}_q$ *with probability at most* $(r+d)/q$*, for every prime* q *outside a finite set fixed by* A *and* $\mathbf{B}'$*.*

(vi) If a subspace $\mathcal{R}' \subseteq \mathcal{R}^G_{\mathfrak{B}}$ *contains* $x - \bar{x}$ *for every target* x*,* $\bar{x}$ *its reduction, then the reduction of every target modulo* $\mathcal{R}'$*, defined as in Definition 39.20(ii) with* $\mathcal{R}'$ *in place of* $\mathcal{R}^G_{\mathfrak{B}}$*, is* $\bar{x}$*.*

An elimination over $\Bbbk(k)$ carries polynomials whose degrees are bounded only by the number r of pivots, which grows with the box. By (ii) a reconstruction from evaluations needs only as many strengths as the degrees of the entries of $\mathbf{B}$ ask, and by (iv) a check at one fresh strength drawn from a set S bounds the chance of a wrong result by $(r+d)/|S|$, while $r+d+1$ checks remove it.

A ray with a real origin is read in the same way: the box carries the origin in its mark relations (Definition 39.15(iii)), and the stride's law, its density and the gauge end are those of Chapter 40, which allow a real origin, the constant $g(0)$ carrying the factor $(\omega_0/dy)(\alpha^\star)$ (Proposition 40.3(ii)); the low-end relation and Theorem 41.3(iii) and (iv) ask for the origin 0. Data with rational masses are read through an origin.

Proposition 41.11 (Data with rational masses)**.** *Let data* $(\mathbf{m};\mathbf{s},\mathbf{t})$ *of a family on the balance wall have* $\mathbf{m} \in \mathbb{Q}^{\mathcal{E}}$*,* $\mathbf{s},\mathbf{t} \in \mathbb{N}^N$ *and every wall* κ_U*,* U *nonempty and proper, positive, and put* $f_{\mathbf{m}} = \alpha^{\mathbf{m}} \prod_j K_j^{-s_j} \Psi_j^{-t_j}$ *on the positive orthant.*

(i) Let $\mathbf{m}' \in \mathbb{Z}^{\mathcal{E}}$ *put* $(\mathbf{m}';\mathbf{s},\mathbf{t})$ *on the balance wall with every wall positive. Then the ray with the origin* $(\mathbf{m}-\mathbf{m}';\mathbf{0},\mathbf{0})$ *and the direction* $(\mathbf{m}';\mathbf{s},\mathbf{t})$ *has positive walls at every real* $k \geq 1$*, its values converge there, and* $\langle 1\rangle_1 = P_F(\mathbf{m};\mathbf{s},\mathbf{t})$*.*

(ii) Let $N \geq 1$ *be an integer with* $N\mathbf{m} \in \mathbb{Z}^{\mathcal{E}}$*. Then the ray with the origin* 0 *and the direction* $N(\mathbf{m};\mathbf{s},\mathbf{t})$ *has positive walls, its stride is* $f_{\mathbf{m}}^N$*,* $\langle 1\rangle_{1/N} = P_F(\mathbf{m};\mathbf{s},\mathbf{t})$*, and the wall degree of a symbol* g *for it is* $\frac{1}{N}\max_U\big(-\kappa_U(g)/\kappa_U\big)$*, the maximum over the nonempty proper* U*.*

So data with rational masses are read at $k=1$ on a ray with an origin, by the gauge end, or at $k=\frac{1}{N}$ on a ray from the origin 0, whose box of wall degree $\mathfrak{t}$ holds the symbols of wall degree $N\mathfrak{t}$ read on the walls of the data.

41.5 What a reading costs

A box has at most $\big(C(1+\mathfrak{t})+1\big)^{n-1}$ symbols at each level (Proposition 41.9(i)), and modulo a group G of symmetries its orbits number at least its symbols divided by $|G|$; one evaluation in step (3) of Definition 41.8 is one elimination of its relations, and the number of evaluations is set by the degrees of $\mathbf{B}$ (Proposition 41.10(ii)). The relations are affine in the strength, so one factorization at one strength gives every Taylor coefficient there.

Proposition 41.12 (One factorization serves every coefficient)**.** *In the setting of Proposition 41.10, let $k_0 \in \Bbbk$ have $\det A_P(k_0) \neq 0$, and put $M = A_P(k_0)$ and $E = A_P(k_0+1) - A_P(k_0)$, the part of A_1 on the rows and columns of A_P, so that $A_P(k_0+\epsilon) = M + \epsilon E$. For every row x_P over $\Bbbk$, as power series in ϵ convergent for small $|\epsilon|$,*

$$x_P\, A_P(k_0+\epsilon)^{-1} = \sum_{j\geq 0} \lambda_j \epsilon^j, \qquad \lambda_0 = x_P M^{-1}, \quad \lambda_j = -\lambda_{j-1} E M^{-1}.$$

So the Taylor coefficients at k_0 of the reductions, and of the entries of $\mathbf{B}$, up to any order J come from one factorization of M and J products by EM^{-1}; and a rational function whose numerator and denominator have degrees at most d_1 and d_2, the denominator not vanishing at k_0, is fixed, among such functions, by its Taylor coefficients of order at most $d_1 + d_2$ at k_0.

So one factorization at one strength can replace many evaluations; each step of the series is one solve with the factorization of M, and what it saves depends on the fill of that factorization.

Proposition 41.13 (The densities of a spanning set)**.** *Let a ray have a real origin and $\kappa_{1,S} > 0$ for every nonempty proper S, with $\alpha^\star$, $f^\star = f(\alpha^\star)$ and the function g of Proposition 40.3, and let $b_1, \dots, b_{\mathfrak{m}}$ be Laurent insertions with real coefficients and Q, $\tilde{P}_{il}$ polynomials with $Q(k)\langle b_i\rangle_{k-1} = \sum_l \tilde{P}_{il}(k)\langle b_l\rangle_k$ as meromorphic functions, as a box gives with $\mathbf{B} = \tilde{P}/Q$ (Theorem 39.21(iii)). For a Laurent insertion b with real coefficients let $\mu_{f,b}$ be the image under f of the signed measure $b\,\omega_0$ on the positive part of the chart, a signed measure on $(0, f^\star]$, finite on $[t, f^\star]$ for $t > 0$.*

- *(i) $\langle b\rangle_k = \int t^k \mu_{f,b}(dt)$ wherever $\langle b\rangle_k$ converges absolutely; $\mu_{f,b}$ has a density $\varrho_{f,b}$, real-analytic on $(0, f^\star)$, and near $f^\star$, $\varrho_{f,b}(t) = (f^\star - t)^{\frac{n-3}{2}} g_b(f^\star - t)$ with g_b holomorphic at 0 and $g_b(0) = b(\alpha^\star)\, g(0)$.*
- *(ii) As distributions on $(0,\infty)$, $Q(-1-\theta)\big(t^{-1}\mu_{f,b_i}\big) = \sum_l \tilde{P}_{il}(-1-\theta)\,\mu_{f,b_l}$ for every i, $\theta = t\frac{d}{dt}$: a system of order at most $\max(\deg Q, \deg \tilde{P}_{il})$ for the $\mathfrak{m}$ densities.*
- *(iii) With $v(k) = (\langle b_l\rangle_k)_l$ and every $K \geq 2$ at which $\mathbf{B}(2), \dots, \mathbf{B}(K)$ are finite and $v(K)$ converges, the continuation of v is finite at 1 and $v(1) = \mathbf{B}(2)\mathbf{B}(3)\cdots\mathbf{B}(K)\, v(K)$: the values of the spanning set run back from K with no scalar recurrence.*

The density operator of a scalar recurrence has the order of the degree of its coefficients, which carry the strengths where the rows line up (Proposition 39.6(iii)); the system of (ii) has the order of the degrees of the entries of $\mathbf{B}$, for $\mathfrak{m}$ densities whose germs at $f^\star$ start from the values $b_l(\alpha^\star)$ times the one constant $g(0)$.

Proposition 41.14 (The native gauges of all exponents)**.** *Let a family of N tables on $n \geq 2$ marks have the letter complement X_F (Definition 38.1), and for $\alpha \in X_F$ and complex exponents $(\mathbf{s}, \mathbf{t}) \in \mathbb{C}^{2N}$ write $\mathbf{u}(\alpha; \mathbf{s}, \mathbf{t}) = \sum_j \big(s_j R_j(\alpha) + t_j R_j^*(\alpha)\big) \in \mathbb{C}^{\mathcal{E}}$ for the usage (Definition 8.17).*

- *(i) The data $\big(\mathbf{u}(\alpha; \mathbf{s}, \mathbf{t}); \mathbf{s}, \mathbf{t}\big)$ lie on the balance wall. Call $\alpha \in X_F$* native for *data $(\mathbf{m}; \mathbf{s}, \mathbf{t})$ on the balance wall when $\mathbf{m} = \mathbf{u}(\alpha; \mathbf{s}, \mathbf{t})$: the native gauges of a ray are the points native for its direction (Definition 38.4), and for $m_{\mathcal{E}} \neq 0$ the points native for data are its native points (Definition 8.17). So the set of the $(\alpha, \mathbf{m}, \mathbf{s}, \mathbf{t})$ with α native for $(\mathbf{m}; \mathbf{s}, \mathbf{t})$ is the graph of the map $(\alpha, \mathbf{s}, \mathbf{t}) \mapsto \mathbf{u}(\alpha; \mathbf{s}, \mathbf{t})$ on $X_F \times \mathbb{C}^{2N}$, a smooth irreducible variety of dimension $n-1+2N$, and every $\alpha \in X_F$ is native for the data $\big(\mathbf{u}(\alpha; \mathbf{s}, \mathbf{t}); \mathbf{s}, \mathbf{t}\big)$, whatever $(\mathbf{s}, \mathbf{t})$.*
- *(ii) A ray of F with $\kappa_{1,S} > 0$ for every nonempty proper S has at most $(-1)^{n-1}\,\mathrm{eu}(X_F)$ nondegenerate native gauges, the number of native gauges of the directions outside the exceptional set of Theorem 38.31(i).*

The nondegenerate native gauges bound the sizes of a reading from below: the dimension of the invariant module is at least the number of their orbits (Theorem 39.12(iii)), and the order of the law of [1] at least the number of their distinct native values (Corollary 38.7 at $g = 1$); Proposition 41.14(ii) bounds their number from above. These are inequalities, with X_F inverting every letter whatever its exponent along the ray (Definition 38.1).

Definition 41.15 (The procedure that finds native gauges by continuation)**.** Input: a family and a ray of it with $\kappa_{1,S} > 0$ for every nonempty proper S. Output: nondegenerate native gauges of the ray, each with a certificate, and their native values.

(1) *A start.* Draw $(\alpha_0, \mathbf{s}_0, \mathbf{t}_0) \in X_F \times \mathbb{C}^{2N}$ at random; α_0 is native for the data $w_0 = \big(\mathbf{u}(\alpha_0; \mathbf{s}_0, \mathbf{t}_0); \mathbf{s}_0, \mathbf{t}_0\big)$ (Proposition 41.14(i)).

(2) *More points native for w_0.* Follow the points native for w_0 found so far along closed loops $w_0 \to w_1 \to w_2 \to w_0$ of random data on the balance wall, by Newton's method along the segments, and add every new endpoint; stop when several loops in a row add nothing.

(3) *To the direction.* Follow each point native for w_0 by Newton's method along a path of data from w_0 to the direction of the ray, and keep the endpoints that lie in X_F.

(4) *Certificates.* Around each endpoint, a box in the coordinates α_e, $e \neq e_0$, of the chart on which interval enclosures of the letters exclude 0; Krawczyk's interval Newton test on the equations $c_e^{(1)} = 0$, $e \neq e_0$, in the box, and an interval enclosure of the determinant of the Hessian of $\log f$ on the box that excludes 0. When both succeed, the box holds a native gauge of the ray, and every native gauge in it is nondegenerate. Disjoint boxes hold distinct native gauges, and disjoint enclosures of f on them prove distinct native values.

The certified native gauges of step (4) are distinct nondegenerate native gauges of the ray, so their number bounds the dimension of the ray from below (Theorem 38.6(iii)), the number of their orbits under a finite group of symmetries bounds $\dim \mathfrak{M}^G$ from below (Theorem 39.12(iii)), and the number of their distinct native values bounds the order of every recurrence that follows from the relations (Corollary 38.7); by Proposition 41.14(ii) their number is at most $(-1)^{n-1}\,\mathrm{eu}(X_F)$. The stopping rule of step (2) is not a certificate that every point native for w_0 was found, so the procedure gives lower bounds. Nothing in it writes a relation of a box. Exercise 55.10 reads the dimensions and the orders of the laws by the box, ray by ray.

Chapter 42

Inputs along a ray

A function that satisfies a recurrence with polynomial coefficients in its argument, above all the values of 1 along a ray continued in the strength, gives two live inputs on a lattice: its values and its slopes. The slopes satisfy the same recurrence, inhomogeneous by the values read through the derivatives of its coefficients. A Trailmoment at index zero of a polynomial word against either input is closed by summation by parts in the adjoint form of the recurrence: what crosses the cut is read off the Laurent data of the function at the low end, for a ray the low-end relation and its derivative, and when the symbol does not vanish at 1 everything else lands on a fixed block of $2D$ Trailmoments, D the degree of the recurrence. A mark of a list opened on its share side and closed at an integer strength is such a pairing: a polynomial word against the slope input of the room, less its derivative against the values input. The recurrence read at the poles of an input ties its initial slopes to residues and finite parts, and minimality, the root rate of the input, removes the components along the faster solutions. A recurrence of the values that is self-adjoint under the reflection of the strength pairs the values with the closings in one constant, the low-end relation, whose limit at high strength ties the volume of the direction to the Hessian at its native gauge through the native values. Section 42.6 reads all of this on the centre ray of the list $\binom{\mathcal{E}}{1}$, for every number n of marks: its native gauges are the signs, and at a lean the points whose occupations take two values; a parallel class enters a list through the closings and the signs of $\binom{P}{1}$; a mark is added by closing the critical-line kernel against the slopes of n marks; the law of the values is the n-th symmetric power of the second-order relation that the Gramma of one mark satisfies in its coefficient, read in the index, of order $\lceil n/2 \rceil$, with the native values $(n-2j)^{-2}$ as the roots of its symbol, and one identity carries it from n marks to $n+1$; the lowered settings are its solutions without low-end coefficient; and the exact pairing holds at every strength. The n-th power of the Gramma of one mark is a mixture of its dilations by the stride's law, and the balanced directions with one total and one multiset of offsets have one value up to Beta corners. The sections after it read a table built by substitution against its cells: its reciprocal stride factors over them, its closings average those of its core over the norms of its cells, its native gauges are read down the hinge tree, and its value at every strength, with norms on its marks, is the word of its core with the word of each cell set at the load of its marker. The law of a class is read for every size, at silence, at infinity and on its hinge plane, and the sources of a substitution of classes are counted in its hinge space.

42.1 Inputs read from a ray

Definition 42.1 (Recurrences; the values input and the slope input)**.** A *recurrence* of order h is an operator $(L\varphi)(x) = \sum_{i=0}^{h} c_i(x)\,\varphi(x+i)$ with polynomials $c_i \in \mathbb{C}[x]$ and $c_0 c_h \neq 0$. Its *adjoint* and its *derivative* are

$$(L^*\varphi)(x) = \sum_{i=0}^{h} c_i(x-i)\,\varphi(x-i), \qquad (L'\varphi)(x) = \sum_{i=0}^{h} c_i'(x)\,\varphi(x+i),$$

L'^* is the adjoint of L', its *degree* is $D = \max_i \deg c_i$, and its *symbol* is $\chi(\lambda) = \sum_i [x^D] c_i\,\lambda^i$, as in Corollary 38.7. Let p be meromorphic on $\mathbb{C}$ with $Lp = 0$ identically, holomorphic at the points of a coset $b+\mathbb{Z}$ beyond a cut N, and put $\tilde{p} = -p'$. The *values input* of p is $p\,\mathbb{I}_{b+\mathbb{Z}}$ and its *slope input* is $\tilde{p}\,\mathbb{I}_{b+\mathbb{Z}}$ (Definition 5.4), both read beyond the cut N. When p continues the values $\langle 1\rangle_k$ of a ray and L is a recurrence of these values, they are the *inputs read from the ray.*

Proposition 42.2 (The values of a ray as an input)**.** *Let a ray of a family on $n \geq 2$ marks have origin 0, every letter exponent of its direction positive and $\kappa_{1,S} > 0$ for every nonempty proper S, and let L be a recurrence of order h with $\sum_{i=0}^{h} c_i(k)\langle 1\rangle_{k+i} = 0$ for all large integers k.*

(i) $\langle 1\rangle_k$ is holomorphic in k on $\operatorname{Re} k > 0$ and continues to a meromorphic function p on $\mathbb{C}$ with $Lp = 0$ identically. At every $j \in \mathbb{N}$, $\lim_{k\to -j}(k+j)^{n-1}p(k) = V_1\,\mathsf{C}_j(1)$, with V_1 of Proposition 39.34, and $\sum_{i=0}^{\min(h,j)} c_i(-j)\,\mathsf{C}_{j-i}(1) = 0$.

(ii) The slope input satisfies $L\tilde{p} = L'p$ identically: a recurrence of the same order, inhomogeneous by the values read through the derivative of L.

(iii) Along the positive integers p has the root rate $f(\alpha^\star)$, the native value of the native gauge $\alpha^\star$ of the direction on the positive orthant, and $\tilde{p}$ a root rate at most $f(\alpha^\star)$.

The values of a ray are therefore an input of the kind of Chapter 6: their density is read from the serif family, and the recurrence gives the values input and the slope input recurrences of one finite order. The slope input carries what the derivative in the strength adds, and the values input enters its recurrence only through L'.

42.2 Closing an input

Proposition 42.3 (Summation by parts at the cut)**.** *Let p and L be as in Definition 42.1, p holomorphic at the integers $x \geq 1$, with p and $\tilde{p}$ of root rate below one along them, and for $0 \leq j < h$ put $\beta_j(x) = \sum_{i=0}^{j} c_i(x)\,p(x+i)$, which is holomorphic at $x = -j$ because $\beta_j = -\sum_{i>j} c_i(x)\,p(x+i)$. For every polynomial R,*

$$(\mathsf{T}_{0;(1)}[x]\,(L^*R)\,p\,\mathbb{I}_{\mathbb{Z}})((0,\infty)) = -\sum_{j=0}^{h-1} R(-j)\,\beta_j(-j),$$

$$(\mathsf{T}_{0;(1)}[x]\,(L^*R)\,\tilde{p}\,\mathbb{I}_{\mathbb{Z}})((0,\infty)) = (\mathsf{T}_{0;(1)}[x]\,(L'^*R)\,p\,\mathbb{I}_{\mathbb{Z}})((0,\infty)) + \sum_{j=0}^{h-1} R(-j)\,\beta_j'(-j).$$

If every c_i vanishes to order two at the integers $-j$ with $1 \leq j < i$, only $j = 0$ remains, with $\beta_0 = c_0\,p$: the boundary is the value and the derivative of $c_0 p$ at the cut.

What a summation by parts puts on the inputs beyond the cut is the adjoint word; what it leaves at the cut is read off p at $0, -1, \dots, -(h-1)$, where for the values of a ray the poles sit. The same move closes the slope input, once through L and once through L'.

Proposition 42.4 (The fixed block)**.** *Let L be a recurrence of degree D whose symbol has $\chi(1) \neq 0$, and let $\Bbbk$ be a field containing the coefficients of the c_i.*

(i) L^* raises the degree of every nonzero polynomial by exactly D, and $\Bbbk[x] = L^*(\Bbbk[x]) \oplus \{r \in \Bbbk[x] : \deg r < D\}$.

(ii) In the setting of Proposition 42.3, for every polynomial $W \in \Bbbk[x]$ the two Trailmoments

$$(\mathsf{T}_{0;(1)}[x]\, W\, p\, \mathbb{I}_{\mathbb{Z}})((0,\infty)), \qquad (\mathsf{T}_{0;(1)}[x]\, W\, \tilde{p}\, \mathbb{I}_{\mathbb{Z}})((0,\infty))$$

lie in the $\Bbbk$-span of the $2D$ block values

$$(\mathsf{T}_{0;(1)}[x]\, (x-1)^a\, p\, \mathbb{I}_{\mathbb{Z}})((0,\infty)), \qquad (\mathsf{T}_{0;(1)}[x]\, (x-1)^a\, \tilde{p}\, \mathbb{I}_{\mathbb{Z}})((0,\infty)) \qquad (0 \le a < D)$$

and of the boundary numbers $\beta_j(-j)$ and $\beta'_j(-j)$, $0 \le j < h$.

This is the counterpart at the index zero of Theorem 6.9: the words of a closing are polynomials, the shifts of the input are moved onto the word, and the input is read on one block of evaluations fixed once for the recurrence. When the boundary numbers are known, as they are at the cut of a ray from the low-end relation, a closing lands on the block plus a number of $\Bbbk$.

42.3 A mark opened at an integer strength

A mark that is neither a loop nor a coloop is a bunch of width one, and Theorem 19.13 opens the centre on it: at the strength s the period is the integral over one even share d of $\Gamma_2^4 \begin{bmatrix} d,\ d,\ s-d,\ s-d \\ s,\ s \end{bmatrix}$ against the period of the room family, the deletion at the share d and the contraction at $s-d$. Closing the share (Corollary 19.21) at an integer strength turns its heads into one polynomial word.

Corollary 42.5 (A mark opened at an integer strength)**.** *Let $\mathcal{B}$ be a connected list on $\mathcal{E}$, $|\mathcal{E}| \ge 3$, and e a mark that is neither a loop nor a coloop; on the chart $y_{e_0} = 0$ of $R = \mathcal{E} - e$ let $X_\backslash = K_{\mathcal{B}\backslash e}(\alpha) K_{\mathcal{B}\backslash e}(\alpha^{-1})$ and $X_/ = K_{\mathcal{B}/e}(\alpha) K_{\mathcal{B}/e}(\alpha^{-1})$, the even letters of the deletion and of the contraction over α^R. Suppose that one lies below the other: $\{X_\flat, X_\sharp\} = \{X_\backslash, X_/\}$ with $\rho = \sup X_\flat / X_\sharp < 1$ on the chart. For $s \in \{1, 2, \dots\}$ and $x \ge 0$ put*

$$q_s(x) = \int_{y_{e_0}=0} \Big(\frac{X_\flat}{X_\sharp}\Big)^x X_\sharp^{-s}\, dy, \qquad \tilde{q}_s = -\partial_x q_s, \qquad V_s(x) = \big((x+1)(x+2)\cdots(x+s-1)\big)^2.$$

Then q_s converges and is holomorphic on a neighbourhood of $[0,\infty)$, and

$$\Gamma(s)^2\, P_{\mathcal{B}}(s\mathbf{1}; s, s) = \sum_{x \in \mathbb{N}} \big(V_s(x)\, \tilde{q}_s(x) - V'_s(x)\, q_s(x)\big),$$

the terms of root rate at most ρ: the centre at the strength s is a polynomial word against the slope input of q_s less its derivative against its values input, read on $\mathbb{N}$.

The function q_s is read along the direction of the ratio $X_\flat / X_\sharp$ of the two even letters, with the origin form $X_\sharp^{-s} dy$, which decays where the ratio does not; where it satisfies a recurrence in x, Sections 42.2 and 42.4 close it, and its values half $\sum_x V_s(x)\, q_s(x)$ with it.

42.4 Boundaries and minimality

Proposition 42.6 (Boundary relations)**.** *Let p and L be as in Definition 42.1, let $x_0 \in \mathbb{C}$ and $0 \le j < h$, and let p be holomorphic at $x_0 + i$ for $j < i \le h$. Then $\beta_{x_0,j}(x) = \sum_{i=0}^{j} c_i(x)\, p(x+i)$ is holomorphic at x_0, its value and its derivative there are read off the Laurent expansions of p at $x_0, \dots, x_0 + j$ and the Taylor expansions of $c_0, \dots, c_j$ at x_0, and*

$$\sum_{i=j+1}^{h} c_i(x_0)\, p(x_0+i) = -\beta_{x_0,j}(x_0),$$

$$\sum_{i=j+1}^{h} \big(c_i(x_0)\, \tilde{p}(x_0+i) - c_i'(x_0)\, p(x_0+i)\big) = \beta_{x_0,j}'(x_0).$$

Where c_h has no zero at the integers $x \ge 1$, the slope input on these integers is fixed by its initial slopes $\tilde{p}(1), \dots, \tilde{p}(h)$ through $L\tilde{p} = L'p$, and every second relation at an integer x_0 with $x_0 + j \ge 0$ is an affine relation among them; at $x_0 = -j$ its right side is read off the Laurent data of p at the nonpositive integers $-j, \dots, 0$ alone. At the cut of the values of a ray (Proposition 42.2), with $c_0(x) = \sum_m \gamma_m x^m$ and $p(x) = \sum_{i \ge 0} \mathsf{L}_i x^{i-n+1}$ near $x = 0$, the low-end coefficients of Definition 39.37, c_0 vanishes to order at least $n-1$ at 0, $\mathsf{L}_0 = V_1$, and at $x_0 = 0$, $j = 0$ the two relations are

$$\sum_{i=1}^{h} c_i(0)\, p(i) = -\gamma_{n-1} V_1, \qquad \sum_{i=1}^{h} \big(c_i(0)\, \tilde{p}(i) - c_i'(0)\, p(i)\big) = \gamma_{n-1}\mathsf{L}_1 + \gamma_n V_1,$$

the low-end relation (Corollary 39.38(ii), which holds for every recurrence of the values at the large integers by Proposition 40.5) and its derivative; when every table of the family has unit weights, $\mathsf{L}_1 = 0$.

At a pole of the input that a wall or a zero share puts on the lattice, the right sides are its principal part and its finite part: at a simple pole x_0 where c_0 has a simple zero, $\beta_{x_0,0}(x_0) = c_0'(x_0) \operatorname{Res}_{x_0} p$ and $\beta_{x_0,0}'(x_0) = c_0'(x_0)\, a + \frac{1}{2} c_0''(x_0) \operatorname{Res}_{x_0} p$, a the constant term of p at x_0. Each independent relation removes one direction from the initial slopes; what the relations leave free, the root rate of the input fixes in the directions that grow faster than the input.

Proposition 42.7 (Minimality)**.** *Let p and L be as in Definition 42.1, p holomorphic at the integers $x \ge 1$, with $c_0(x) c_h(x) \ne 0$ at these integers, every c_i of degree at most $\deg c_0 = \deg c_h$, and the roots $\lambda_1, \dots, \lambda_h$ of the symbol of distinct moduli. Let $\lambda > 0$ be at least the root rates of p and of $\tilde{p}$ along the positive integers (Definition 1.1(vii)).*

(i) The solutions u of $Lu = 0$ on the integers $x \ge 1$ of root rate at most λ form a space U_λ of dimension $\#\{c : |\lambda_c| \le \lambda\}$, and every nonzero $u \in U_\lambda$ has $u(x+1)/u(x) \to \lambda_c$ for one of these roots, so the root rate $|\lambda_c|$.

(ii) The functions φ on the integers $x \ge 1$ with $L\varphi = L'p$ and root rate at most λ are the $\tilde{p} + u$, $u \in U_\lambda$, and those with $L\varphi = 0$ are the $p + u$. So the slope input is the only one of them that satisfies a set of second relations of Proposition 42.6 whose left sides, read on u, vanish together on no nonzero $u \in U_\lambda$; the values input is singled out by the first relations in the same way.

So the initial slopes are fixed by as many boundary relations as there are roots of the symbol of modulus at most the root rate of the input; the roots beyond it are removed by the root rate alone.

42.5 The two ends paired

Proposition 42.8 (The two ends paired)**.** *Let a ray be as in Proposition 42.2, with a recurrence L of its values whose coefficients satisfy $c_i(-x-i) = \epsilon\, c_i(x)$ for every i, $\epsilon \in \{1,-1\}$, and put $\mathsf{C}_j = \mathsf{C}_j(1)$ for $j \geq 0$ and $\mathsf{C}_j = 0$ for $j < 0$.*

(i) $\sum_{i=0}^{h} c_i(\sigma - i)\, \mathsf{C}_{\sigma-i} = 0$ *for every integer σ: the closings, read at the strength σ, solve the adjoint recurrence.*

(ii) The concomitant

$$B(\sigma) = \sum_{i=1}^{h} \sum_{j=1}^{i} c_i(\sigma - j)\, \mathsf{C}_{\sigma-j}\, \langle 1 \rangle_{\sigma-j+i}$$

takes one value at every integer $\sigma \geq 1$, $B(\sigma) = \sum_{i=1}^{h} c_i(0)\langle 1\rangle_i = -\gamma_{n-1} V_1$ with $\gamma_{n-1} = [x^{n-1}]c_0$: the low-end relation, carried to every strength.

(iii) On the centre ray of a family (Definition 38.13), if every c_i has degree at most $n-1$, then $c_0 = \chi(0)\, x^{n-1}$, $\lambda_\star = f(\alpha^\star)$ is a simple root of the symbol, and

$$V_1 \det H = -\frac{\lambda_\star\, \chi'(\lambda_\star)}{\chi(0)} = \prod_{c \neq \star} \Big(1 - \frac{\lambda_\star}{\lambda_c}\Big),$$

with H the Hessian of $-\log f$ at $\mathbf{1}$ on the chart (Theorem 38.15) and λ_c the roots of the symbol, counted with multiplicity.

The values at the high end and the closings at the low end are two solutions of one recurrence and of its adjoint, and their concomitant is the constant that the low end fixes. At high strength the two decay and grow at the reciprocal rates $f(\alpha^\star)^{\pm k}$ with the Gaussian constants of the native gauge of the direction, and the constant becomes an identity between the volume V_1 of the direction, read by its walls, and the Hessian at its native gauge, through the other native values.

42.6 The centre ray of $\binom{\mathcal{E}}{1}$

For the list $\binom{\mathcal{E}}{1}$ on n marks, whose bases are the singletons, $K(\alpha) = \sum_e \alpha_e$ and $\Psi(\alpha) = \alpha^{\mathcal{E}} K(\alpha^{-1})$, and the stride of the centre ray at the strength σ is $\big(K(\alpha)K(\alpha^{-1})\big)^{-\sigma} = \big(\sum_{e,e'} \alpha_e/\alpha_{e'}\big)^{-\sigma}$. Its widths are all one, so $V_1 = n!$ at the strength one. Its share side is one Gramma read n times: by Corollary 18.24 for the dual table, whose bases are the sets $\mathcal{E} - e$, and Proposition 8.15, for masses $\mathbf{m}$ on the balance wall, $m_{\mathcal{E}} = s + (n-1)t$, with $m_S > t(|S|-1)$ for every nonempty proper S,

$$\Gamma(s)\,\Gamma(t)\, P_{\binom{\mathcal{E}}{1}}(\mathbf{m}; s, t) = \int_0^\infty y^{t-1} \prod_{e \in \mathcal{E}} \mathsf{G}_{m_e - t;(1,-1)}(1, y)\, dy,$$

and at the centre $\Gamma(s)^2 P_{\binom{\mathcal{E}}{1}}(s\mathbf{1}; s, s) = \int_0^\infty y^{s-1} \mathsf{G}_{0;(1,-1)}(1,y)^n\, dy$. With $\vartheta = y\, d/dy$, the ladder and the exchange relation of the Gramma (Theorem 2.4) give $\vartheta^2 \mathsf{g} = y\, \mathsf{g}$ for $\mathsf{g}(y) = \mathsf{G}_{0;(1,-1)}(1,y)$, and the partner $\mathsf{h}(y) = \sum_{m \geq 0} y^m/m!^2$ of its lattice expansion (Lemma 20.29(i), $\mathsf{g} = -\mathsf{h}\log y + \sum_m 2(\log\Gamma)'(1+m)\, y^m/m!^2$) satisfies the same relation. The statements below read the centre ray from these two functions.

Proposition 42.9 (The native gauges of $\binom{\mathcal{E}}{1}$)**.** *Let $n \geq 2$, let $s, t \geq 1$ and m be integers with $nm = s + (n-1)t$, and read a ray of $\binom{\mathcal{E}}{1}$ in the direction $(m\mathbf{1}; s, t)$; in this statement $u_e(\alpha) = \alpha_e/K(\alpha)$ is the occupation of the mark e and $\lambda(\alpha) = \big(K(\alpha)K(\alpha^{-1})\big)^{-1}$.*

(i) A point α of X_F is a native gauge exactly when its occupations take at most two values, u_+ on $n-j$ marks and u_- on j marks, $0 \le j \le n$, $2j \ne n$, with

$$(n-2j)\,u_+ = 1 - j\,\frac{s-t}{ns}, \qquad u_+ + u_- = \frac{s-t}{ns}, \qquad u_+u_- \ne 0;$$

then $\lambda(\alpha) = -s\,u_+u_-/t$ and the native value is $f(\alpha) = \big(\prod_e u_e\big)^{m-t}\lambda(\alpha)^t$. Up to scale these points are $\alpha = (u_e)_e$, one for each set of j marks, a set and its complement giving the same point.

(ii) At the centre, $s = t = \sigma$, $m = \sigma$, the native gauges are exactly the signs η with $K(\eta) = \sum_e \eta_e \ne 0$, of the native values $K(\eta)^{-2\sigma} = (n-2j)^{-2\sigma}$, j the number of marks at -1: there are $\lceil n/2 \rceil$ native values. Each of these signs is nondegenerate: on the chart $\alpha_e = \eta_e e^{y_e}$, $y_{e_0} = 0$, the Hessian of $-\log f$ at $y = 0$ has the determinant $(2\sigma)^{n-1}\prod_e \eta_e/K(\eta)^n$.

A lean moves every sign to a real point with the same pattern: the occupations keep two values, on the same marks, and only the two values change. Every list has the signs with $K(\eta) \ne 0$ among the native gauges of its centre ray (Theorem 38.17); the list $\binom{\mathcal{E}}{1}$ has nothing else.

Proposition 42.10 (A parallel class enters through its list)**.** *Let $\mathcal{H}$ be a connected list on the marks $1, \dots, q$, $q \ge 2$, and replace every mark i by a parallel class P_i of $s_i \ge 1$ marks by the first rule of Theorem 21.5: the list $\mathcal{B}$ on $\mathcal{E} = \bigsqcup_i P_i$ whose bases are the sets with one mark in P_i for every $i \in T$ and none in the other classes, T a basis of $\mathcal{H}$. Write $A_i = \sum_{e \in P_i} \alpha_e$.*

(i) $K_{\mathcal{B}}(\alpha) = K_{\mathcal{H}}(A_1, \dots, A_q)$, and for $v \in \mathbb{N}^{\mathcal{E}}$, with $w_i = v_{P_i}$, $[\alpha^v]K^k_{\mathcal{B}} = \big([A^w]K^k_{\mathcal{H}}\big)\prod_i \binom{w_i}{v|_{P_i}}$, with the multinomial coefficients $\binom{w_i}{v|_{P_i}}$.

(ii) The closings of the centre ray of $\mathcal{B}$ at the strength one (Definition 39.30) are

$$\mathsf{C}^{\mathcal{B}}_k(1) = \sum_{w \in \mathbb{N}^q} \big([A^w]K^k_{\mathcal{H}}\big)^2 \prod_{i=1}^{q} \mathsf{C}^{\binom{P_i}{1}}_{w_i}(1), \qquad \mathsf{C}^{\binom{P}{1}}_{w}(1) = \sum_{v \in \mathbb{N}^P,\ |v| = w} \binom{w}{v}^2,$$

the second the closings of the centre ray of $\binom{P}{1}$ at the strength one, read as 1 when $|P| = 1$.

(iii) At a sign η of $\mathcal{B}$, $K_{\mathcal{B}}(\eta) = K_{\mathcal{H}}(a_1, \dots, a_q)$ with $a_i = \sum_{e \in P_i}\eta_e \in \{s_i, s_i - 2, \dots, -s_i\}$, the sign values of $\binom{P_i}{1}$: on the centre ray of $\mathcal{B}$ at the strength σ the native values of the signs with $K_{\mathcal{B}}(\eta) \ne 0$ (Theorem 38.17(ii)) are the $K_{\mathcal{H}}(\mathbf{a})^{-2\sigma}$ at these points $\mathbf{a}$.

A parallel class enters the closings of a list only through the closings of its own list $\binom{P}{1}$, and the signs only through the sign values of that list, as a parallel block is read by K through its total and by Ψ through its hinge value (Corollary 21.7(i)).

Proposition 42.11 (A mark added is a closing of the critical-line kernel)**.** *Let $n \ge 2$; in this statement $p_n(s) = P_{\binom{\mathcal{E}}{1}}(s\mathbf{1}; s, s) = \int_{y_{e_0}=0} \big(K(\alpha)K(\alpha^{-1})\big)^{-s} dy$ for $|\mathcal{E}| = n$ and $\operatorname{Re} s > 0$, $\tilde{p}_n = -p_n'$, and $W_s(x) = \prod_{j=1}^{s-1}(x-j)^2$.*

(i) For $\operatorname{Re} s > 0$ and $0 < c < \operatorname{Re} s$, $\Gamma(s)^2 p_{n+1}(s) = \frac{1}{2\pi i}\int_{(c)} \Gamma(d)^2\,\Gamma(s-d)^2\,p_n(d)\,dd$. At $s = 1$ the kernel on the line $\operatorname{Re} d = \frac{1}{2}$ is 2π times the critical-line density (Definition 36.1): $p_{n+1}(1) = \mathbb{E}\big[p_n(\frac{1}{2} + iY)\big]$, $Y \sim \mathbb{P}_{\mathrm{crit}}$.

(ii) For $s \in \{1, 2, \dots\}$,

$$\Gamma(s)^2 p_{n+1}(s) = \big(\mathsf{T}_{0;(1)}[x]\,(W_s\tilde{p}_n - W_s' p_n)\,\mathbb{I}_{\mathbb{Z}}\big)((0,\infty)),$$

$$\int_0^\infty y^{s-1}\mathsf{G}_{0;(1,-1)}(1,y)^n\sum_{m\ge0}\frac{y^m}{m!^2}\,dy=(\mathsf{T}_{0;(1)}[x]\,W_s\,p_n\,\mathbb{I}_{\mathbb{Z}})((0,\infty));$$

at $s=1$, $p_{n+1}(1)=(\mathsf{T}_{0;(1)}[x]\,\tilde p_n\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$: the centre of $n+1$ marks at the strength one is the slope input of n marks summed over the positive integers.

(iii) On the share side every mark carries on average the share $\frac{1}{n+1}$ of the strength:

$$(n+1)\Big((\mathsf{T}_{0;(1)}[x]\,p_n\,\mathbb{I}_{\mathbb{Z}})((0,\infty))-(\mathsf{T}_{0;(1)}[x]\,(x-1)\,\tilde p_n\,\mathbb{I}_{\mathbb{Z}})((0,\infty))\Big)=(\mathsf{T}_{0;(1)}[x]\,\tilde p_n\,\mathbb{I}_{\mathbb{Z}})((0,\infty)).$$

Theorem 42.12 (The law of the values of $\binom{\mathcal{E}}{1}$)**.** *Let $n\ge1$ and $h=\lceil n/2\rceil$; in this statement $\vartheta=y\,d/dy$, and the operators $\mathbf{R}_i$ are $\mathbf{R}_0=1$, $\mathbf{R}_1=\vartheta$ and $\mathbf{R}_{i+1}=\vartheta\mathbf{R}_i-i(n+1-i)\,y\,\mathbf{R}_{i-1}$.*

(i) $\mathbf{Q}_n=\mathbf{R}_{n+1}$ annihilates every product of n solutions of $\vartheta^2u=yu$. Written $\mathbf{Q}_n=\sum_{k\ge0}y^kq_{n,k}(\vartheta)$ with polynomials $q_{n,k}$, $q_{n,0}=\vartheta^{n+1}$ and $\deg q_{n,k}\le n+1-2k$, so that $q_{n,k}=0$ for $k>h$; with $a_{n,k}$ the coefficient of ϑ^{n+1-2k} in $q_{n,k}$,

$$\sum_k a_{n,k}\,\eta^k\xi^{n+1-2k}=\prod_{j=0}^{n}\big(\xi-(n-2j)\sqrt{\eta}\big)=\xi^{n+1-2h}\prod_{0\le j<n/2}\big(\xi^2-(n-2j)^2\eta\big),$$

so $q_{n,h}\ne0$. The formal adjoint for the measure dy/y is $\mathbf{Q}_n^*=(-1)^{n+1}\mathbf{Q}_n$: $q_{n,k}(-\vartheta-k)=(-1)^{n+1}q_{n,k}(\vartheta)$.

(ii) Put $c_{n,0}(s)=(-1)^{n+1}s^{n-1}$ and $c_{n,k}(s)=q_{n,k}(-s-k)\big((s+1)(s+2)\cdots(s+k-1)\big)^2$ for $1\le k\le h$. Every $c_{n,k}$ has degree $n-1$, $c_{n,k}(-s-k)=(-1)^{n+1}c_{n,k}(s)$, $c_{n,k}$ vanishes to order two at $s=-1,\dots,-(k-1)$, $c_{n,h}$ has no zero at the integers $s\ge0$, and the symbol is

$$\chi_n(\lambda)=(-1)^{n+1}\prod_{0\le j<n/2}\big(1-(n-2j)^2\lambda\big),$$

whose roots are the native values $(n-2j)^{-2}$ of the signs (Proposition 42.9). For $n\ge2$ the values satisfy

$$\sum_{k=0}^{h}c_{n,k}(s)\,P_{\binom{\mathcal{E}}{1}}\big((s+k)\mathbf{1};s+k,s+k\big)=0$$

identically in s.

(iii) For $n\ge2$ the values $P_{\binom{\mathcal{E}}{1}}(k\mathbf{1};k,k)$ satisfy no recurrence of order less than h: their tier (Proposition 38.11) is h, and the recurrence of (ii) is their least recurrence. The closings $\mathsf{C}_j(1)=\sum_{|v|=j}\binom{j}{v}^2$ satisfy $\sum_{k=0}^{\min(h,j)}c_{n,k}(-j)\,\mathsf{C}_{j-k}(1)=0$ for every $j\in\mathbb{N}$ and no recurrence of order less than h, and the cyclic submodule of $[1]$ in the value module (Definition 39.58) has dimension h.

The law of the values of $\binom{\mathcal{E}}{1}$ is the relation of one mark raised to the n-th symmetric power and read in the index, where ϑ becomes $-s$ and y the shift. Its leading coefficients are those of the product of the $n+1$ factors $\xi-(n-2j)\sqrt{\eta}$, which pair into the native values of the signs, the tie $n=2j$ at even n leaving the factor ξ; every coefficient $c_{n,k}$ carries the square of a rising factorial, which is why the boundaries below the cut vanish. One identity carries it from n marks to $n+1$.

Proposition 42.13 (A mark added carries the law of the values)**.** *In the notation of Theorem 42.12, for every $n\ge1$:*

(i) For every solution u of $\vartheta^2 u = yu$ and every smooth function F on $(0,\infty)$,

$$\mathbf{Q}_{n+1}(uF) = u\,\vartheta\,\mathbf{Q}_n(F) + (n+2)\,(\vartheta u)\,\mathbf{Q}_n(F).$$

(ii) With $\binom{a}{b} = \Gamma(a+1)/\big(\Gamma(b+1)\Gamma(a-b+1)\big)$ and $A_s(x) = \big((n+1)x-(n+2)s\big)\binom{x}{s}^2$,

$$\sum_{k=0}^{\lceil (n+1)/2\rceil} c_{n+1,k}(s)\binom{x-1}{s+k-1}^2 = \sum_{j=0}^{\lceil n/2\rceil} c_{n,j}(x-j)\,A_s(x-j),$$

an identity of rational functions of (x,s) after division by $\binom{x}{s}^2$. At integers $s, x \geq 1$ the words $\binom{x-1}{s+k-1}^2$ are the words $W_{s+k}(x)/\Gamma(s+k)^2$ of the closing of Proposition 42.11(ii): weighted by the coefficients $c_{n+1,k}(s)$, they are the adjoint of the recurrence of n marks applied to the one word A_s, which vanishes at $x = 0, 1, \ldots, s-1$.

Proposition 42.14 (The lowered settings)**.** *Let $n \geq 2$ and $h = \lceil n/2\rceil$, with $c_{n,k}$ of Theorem 42.12; in this statement $\mathsf{g}(y) = \mathsf{G}_{0;(1,-1)}(1,y)$ and $\mathsf{h}(y) = \sum_{m\geq 0} y^m/m!^2$, and for $0 \leq j < n/2$ the* lowered setting *with j marks lowered is*

$$\xi_{n,j}(s) = \Gamma(s)^{-2}\int_0^\infty y^{s-1}\,\mathsf{g}(y)^{n-j}\,\mathsf{h}(y)^j\,dy \qquad (\operatorname{Re} s > 0),$$

so that $\xi_{n,0}(s) = P_{\binom{\mathcal{E}}{1}}(s\mathbf{1}; s, s)$, $|\mathcal{E}| = n$.

(i) Every $\xi_{n,j}$ satisfies the recurrence of Theorem 42.12(ii) on $\operatorname{Re} s > 0$.

(ii) For $j \geq 1$, $s^{n-1}\xi_{n,j}(s) \to 0$ as $s \downarrow 0$, and $\sum_{k=1}^h c_{n,k}(0)\,\xi_{n,j}(k) = 0$, against $\sum_{k=1}^h c_{n,k}(0)\,\xi_{n,0}(k) = (-1)^n n!$: the lowered settings have no low-end coefficient.

(iii) $\xi_{n,j}(k+1)/\xi_{n,j}(k) \to (n-2j)^{-2}$ along the integers, so $\xi_{n,j}$ has the root rate $(n-2j)^{-2}$: the setting with j marks lowered carries the native value of the signs with j marks at -1.

(iv) The h sequences $(\xi_{n,j}(k))_{k\geq 1}$ are a basis of the solutions of the recurrence on the integers $k \geq 1$, and its solutions x with $\sum_{k=1}^h c_{n,k}(0)\,x(k) = (-1)^n n!$ are the $\xi_{n,0} + \sum_{j=1}^{h-1} b_j\,\xi_{n,j}$, $b_j \in \mathbb{C}$.

So the recurrence and the low-end relation fix the values only up to the $h-1$ lowered settings with $j \geq 1$, which satisfy both with the right side zero; $h-1$ further numbers fix them, for instance the first $h-1$ values (Corollary 42.15). The integrand $\mathsf{g}^{n-j}\mathsf{h}^j$ of the setting with j marks lowered decays like $e^{-2(n-2j)\sqrt{y}}$ up to powers of y, and its integral converges on all of $\operatorname{Re} s > 0$ exactly when $j < n/2$: at even n the tie $j = n/2$, the sign with $K(\eta) = 0$, is no native gauge and gives no setting.

Corollary 42.15 (The value span of $\binom{\mathcal{E}}{1}$)**.** *Let $n \geq 2$, $h = \lceil n/2\rceil$ and $p_n(s) = P_{\binom{\mathcal{E}}{1}}(s\mathbf{1}; s, s)$, $|\mathcal{E}| = n$, with $c_{n,k}$ of Theorem 42.12.*

(i) $\sum_{k=1}^h c_{n,k}(0)\,p_n(k) = (-1)^n n!$, and every value $p_n(k)$, $k \geq 1$, lies in $\mathbb{Q} + \sum_{i=1}^{h-1}\mathbb{Q}\,p_n(i)$; so do the values $p_n(k\sigma)$ of the centre ray at every strength σ.

(ii) For even n the symbol has $\chi_n(1) \neq 0$, and for every polynomial W with rational coefficients, $(\mathsf{T}_{0;(1)}[x]\,W\,p_n\,\mathbb{I}_\mathbb{Z})((0,\infty))$ and $(\mathsf{T}_{0;(1)}[x]\,W\,\tilde{p}_n\,\mathbb{I}_\mathbb{Z})((0,\infty))$, $\tilde{p}_n = -p_n'$, lie in $\mathbb{Q}$ plus the $\mathbb{Q}$-span of the $2(n-1)$ block values $(\mathsf{T}_{0;(1)}[x]\,(x-1)^a\,p_n\,\mathbb{I}_\mathbb{Z})((0,\infty))$ and $(\mathsf{T}_{0;(1)}[x]\,(x-1)^a\,\tilde{p}_n\,\mathbb{I}_\mathbb{Z})((0,\infty))$, $a < n-1$. In particular so do $\Gamma(s)^2 P_{\binom{[n+1]}{1}}(s\mathbf{1}; s, s)$ and $\Gamma(s)^2\xi_{n+1,1}(s)$ at every integer $s \geq 1$.

Corollary 42.16 (The exact pairing of $\binom{\mathcal{E}}{1}$)**.** *Let $n \geq 2$, $h = \lceil n/2 \rceil$, and p_n and $c_{n,k}$ as in Corollary 42.15; put $\mathsf{C}_l = \sum_{v \in \mathbb{N}^{\mathcal{E}},\ |v|=l} \binom{l}{v}^2$ for $l \geq 0$ and $\mathsf{C}_l = 0$ for $l < 0$. For every integer $\sigma \geq 1$,*

$$\sum_{i=1}^{h} \sum_{j=1}^{i} c_{n,i}(\sigma - j)\, \mathsf{C}_{\sigma - j}\, p_n(\sigma - j + i) = (-1)^n n!,$$

and its limit at high strength is the identity

$$n! \cdot \frac{2^{n-1}}{n^n} = \prod_{j=1}^{h-1} \Big(1 - \frac{(n-2j)^2}{n^2}\Big) = \prod_{j=1}^{h-1} \frac{4j(n-j)}{n^2}$$

of Proposition 42.8(iii), with $V_1 = n!$, $\det H = 2^{n-1}/n^n$, $\lambda_\star = n^{-2}$ and the other roots $(n-2j)^{-2}$.

Proposition 42.17 (The power of one mark as a mixture)**.** *Let $n \geq 2$; in this statement $\mathsf{g}(y) = \mathsf{G}_{0;(1,-1)}(1, y)$, and f_n, f_{n+1} are the strides $\big(K(\alpha)K(\alpha^{-1})\big)^{-1}$ of the centre rays of $\binom{\mathcal{E}}{1}$ at the strength one for $|\mathcal{E}| = n$ and for $|\mathcal{E}| = n+1$, with the stride's laws μ_{f_n} and $\mu_{f_{n+1}}$ (Definition 40.1): the images of the Lebesgue measure dy of the chart $y_{e_0} = 0$ under the strides, carried by $(0, n^{-2}]$ and by $(0, (n+1)^{-2}]$.*

(i) $\mathsf{g}(y)^n = \int \mathsf{g}(y/t)\, \mu_{f_n}(dt)$ *for every $y > 0$: the n-th power of the Gramma of one mark is a mixture of its dilations by the stride's law.*

(ii) For $t > 0$ let $\phi_t(x) = x/\big((x + t^{-1/2})(1 + t^{-1/2}x)\big)$ on $(0, \infty)$, the stride of the centre ray at the strength one of the table $\binom{\{1,2\}}{1}$ with the weights $t^{-1/2}$ on its basis $\{1\}$ and 1 on $\{2\}$, on the chart $\alpha_1 = 1$, $\alpha_2 = x$; its stride's law μ_{ϕ_t} is the image of dx/x under ϕ_t. Then $\mu_{f_{n+1}} = \int \mu_{\phi_t}\, \mu_{f_n}(dt)$: adding a mark mixes the stride's law of two marks over the stride's law of n.

Proposition 42.18 (Balanced directions of $\binom{\mathcal{E}}{1}$)**.** *Let $|\mathcal{E}| = n \geq 2$, let $s, t \geq 1$ be integers and $\mathbf{m} \in \mathbb{Z}^{\mathcal{E}}$ with $m_{\mathcal{E}} = s + (n-1)t$ and $m_S > t(|S| - 1)$ for every nonempty proper S, and put $c_e = m_e - t$, so that $\sum_e c_e = s - t$. For real $k > 0$, with $P(k) = P_{\binom{\mathcal{E}}{1}}(k\mathbf{m}; ks, kt)$,*

$$\Gamma(sk)\, \Gamma(tk)\, P(k) = \int_0^\infty y^{\frac{(s+t)k}{2} - 1} \prod_{e \in \mathcal{E}} \mathsf{G}_{c_e k;(1,-1)}\big(\sqrt{y}, \sqrt{y}\big)\, dy,$$

which depends on the direction only through $s + t$ and the multiset $\{|c_e|\}_e$. Two such directions $(\mathbf{m}; s, t)$ and $(\mathbf{m}'; s', t')$ with $s + t = s' + t'$ and the same multiset have, with $P'(k) = P_{\binom{\mathcal{E}}{1}}(k\mathbf{m}'; ks', kt')$,

$$\frac{P'(k)}{P(k)} = \Gamma_1^2 \begin{bmatrix} sk,\ tk \\ (s+t)k \end{bmatrix} \Big/ \Gamma_1^2 \begin{bmatrix} s'k,\ t'k \\ (s+t)k \end{bmatrix},$$

a quotient of Beta corners at one total, rational at the integers k, so that their values span one $\mathbb{Q}$-space; the inversion $\alpha \mapsto \alpha^{-1}$ carries the integrand at $(\mathbf{m}; s, t)$ to the integrand at $((s+t)\mathbf{1} - \mathbf{m}; t, s)$, which is $c \mapsto -c$.

The exercises work these statements on the lists of a few marks: the closings and the law of the values of $\binom{[n]}{1}$ for $n = 3, 4, 5$ (Chapter 54), the value at the centre of five marks as a Trailmoment of a ray input (Exercise 54.16), and the lean $(\mathbf{21}; 4, 1)$ of three marks (Exercise 54.5).

42.7 The centre ray of a substitution

A list built by substitution meets each of its cells through one number on each side of the Cremona, the hinge value of the cell at α and at α^{-1}. So its reciprocal stride is a product of one factor for each cell and one function of the core read at those hinge values, its closings are averages of the closings of the core with the cells read at their norms, its native gauges are read down the hinge tree, and its pencil module is a quotient of the direct image, under the core, of the modules of its cells. Throughout this section $\mathcal{B} = \mathcal{H}\langle \mathcal{A}_1, \dots, \mathcal{A}_q \rangle$ is a plain table built by substitution (Definition 21.1), every marker h_i of the core carrying a cell $\mathcal{A}_i$ on $B_i \sqcup \{g_i\}$, a mark left in place being the cell $\binom{\{h,g\}}{1}$, read on its centre ray at the strength one, $f^{-1} = K(\alpha)K(\alpha^{-1})$; $\gamma_i = \gamma^K_{\mathcal{A}_i}$ is the hinge value of the cell by K.

Definition 42.19 (Hinge pairs; norms; the two-sided core; the class density)**.** For a plain cell $\mathcal{A}$ on $B \sqcup \{g\}$ put $v_{\mathcal{A}}(\alpha) = K_{\mathcal{A}/g}(\alpha) K_{\mathcal{A}/g}(\alpha^{-1})$.

(i) The *hinge pair* of $\mathcal{A}$ at α is $(x, x') = \big(\gamma^K_{\mathcal{A}}(\alpha), \gamma^K_{\mathcal{A}}(\alpha^{-1})\big)$, and its *norm* is $t = xx'$. A parallel class $\binom{B\sqcup\{g\}}{1}$ has $(x, x') = (A, A')$ with the *totals* $A = \sum_{e\in B} \alpha_e$ and $A' = \sum_{e\in B} \alpha_e^{-1}$, $v = 1$, and its norm is AA'; a series class $\binom{B\sqcup\{g\}}{|B|}$ has $(x, x') = (1/A', 1/A)$ and $v = AA'$; a mark left in place has $(\alpha_h, \alpha_h^{-1})$, $v = 1$ and the norm 1. A mark of the *norm* $\mathsf{m} > 0$ left in place has the hinge pair $(\alpha_h, \mathsf{m}\alpha_h^{-1})$ and $v = 1$; a table with the norms $\mathsf{m} = (\mathsf{m}_e)_e$ on its marks is read with $K(\alpha)K(\mathsf{m}\alpha^{-1})$, $\mathsf{m}\alpha^{-1} = (\mathsf{m}_e\alpha_e^{-1})_e$, in the place of $K(\alpha)K(\alpha^{-1})$.

(ii) The *hinge quadruple* of $\mathcal{A}$ is

$$q_{\mathcal{A}}(\alpha) = (c, d, c', d') = \big(K_{\mathcal{A}/g}(\alpha),\, K_{\mathcal{A}\setminus g}(\alpha),\, K_{\mathcal{A}/g}(\alpha^{-1}),\, K_{\mathcal{A}\setminus g}(\alpha^{-1})\big),$$

a morphism from $(\mathbb{C}^\times)^B$ to $\mathbb{C}^4$, and its *hinge map* is $\alpha \mapsto (x, x', v) = (d/c,\, d'/c',\, cc')$, defined where $cc' \neq 0$. A parallel class and a mark left in place have $c = c' = 1$, and their hinge map is (x, x'), for a parallel class (A, A'), into the *hinge plane* $\mathbb{C}^2$, on which the scale $\alpha \mapsto \lambda\alpha$ acts by $(x, x') \mapsto (\lambda x, \lambda^{-1}x')$. The *hinge module* $\mathcal{H}_{\mathcal{A}}$ is the submodule generated by the class of $\prod_{e\in B} d\alpha_e/\alpha_e$ in the direct image of the functions along the hinge quadruple, read on the hinge plane for a parallel class.

(iii) The *two-sided core* is $\Phi_{\mathcal{H}}(x, x') = K_{\mathcal{H}}(x)\, K_{\mathcal{H}}(x')$ on $\prod_i \mathbb{C}^2_{(x_i, x_i')}$, and the *hinge space* of $\mathcal{B}$ is $\prod_i \mathbb{C}^2_{(x_i,x_i')}$ modulo the diagonal scale. At the norms 1, on $x' = x^{-1}$, the two-sided core is the reciprocal stride of the centre ray of $\mathcal{H}$. Read on the quadruples it is $\Phi^{\hom}_{\mathcal{H}}(q) = \mathcal{H}^{\hom}(\mathbf{c}, \mathbf{d})\, \mathcal{H}^{\hom}(\mathbf{c}', \mathbf{d}')$ (Definition 39.55), a polynomial, equal to $\prod_i c_i c_i' \cdot \Phi_{\mathcal{H}}(x, x')$ where every $c_i c_i' \neq 0$.

(iv) The *class density* ν_s is the law of $AA' = |\sum_e \alpha_e|^2$ for $\binom{[s]}{1}$ under the Haar probability of the compact torus $|\alpha_e| = 1$; ν_1 is the unit point mass at 1, and the moments of ν_s are the closings $\mathsf{C}_w^{\binom{[s]}{1}}(1) = \sum_{|v|=w} \binom{w}{v}^2$ (Proposition 42.10(ii)).

Theorem 42.20 (A list is its core read against its cells)**.** *(i) The reciprocal stride factors over the cells and the core:*

$$f^{-1}(\alpha) = \prod_i v_{\mathcal{A}_i}(\alpha) \cdot \Phi_{\mathcal{H}}\big(\gamma(\alpha), \gamma(\alpha^{-1})\big),$$

which on the whole torus is $\Phi^{\hom}_{\mathcal{H}}\big(q_{\mathcal{A}_1}(\alpha), \dots, q_{\mathcal{A}_q}(\alpha)\big)$.

(ii) If every cell is a parallel class, of sizes $s_1, \dots, s_q \geq 1$, then for every j

$$\mathsf{C}_j(1) = \int \operatorname*{CT}_x \Big[K_{\mathcal{H}}(x)^j \, K_{\mathcal{H}}\big(t_1 x_1^{-1}, \dots, t_q x_q^{-1}\big)^j \Big] \prod_i \nu_{s_i}(dt_i),$$

and the torus fibre integral $T_{\mathcal{B}}(\tau) = \sum_j \mathsf{C}_j(1)\tau^{-j-1}$ (Definition 39.47) is the average, against $\prod_i \nu_{s_i}(dt_i)$, of the torus fibre integrals of the two-sided core at the norms t_i.

(iii) The pencil is the composite of the hinge quadruples, read modulo the scale, with $\Phi_{\mathcal{H}}^{\hom}$, and the origin form dy is the image of the product of the forms $\prod_{e \in B_i} d\alpha_e/\alpha_e$. So $\mathcal{D}_{\mathcal{B}}[1]$ is a quotient of the submodule generated by the product of the generators in the direct image of $\boxtimes_i \mathcal{H}_{\mathcal{A}_i}$ under $\Phi_{\mathcal{H}}^{\hom}$, taken modulo the scale: every singular value of $\mathcal{D}_{\mathcal{B}}[1]$ is a singular value of that direct image, and its vanishing rank there is not larger. Theorem 39.56 gives the same at every depth of a hinge tree.

The class enters through its own module once, whatever the rest of the list is; a series class enters with the norm t_i^{-1} and the factor t_i^j by (i).

Corollary 42.21 (The pencil of a list along its canonical tree)**.** *Let $\mathcal{B}$ be a connected list on $n \geq 3$ marks, read on its centre ray at the strength one, with its canonical hinge tree (Theorem 23.16) rooted at a vertex o. In Theorem 39.56 the data of a vertex is the hinge quadruple (c, d, c', d') of its subtree cell (Definition 42.19(ii)), a mark has $(1, \alpha_e, 1, \alpha_e^{-1})$, the last coordinate is 1, the root map is $\mathcal{H}_o^{\hom}(\mathbf{c}, \mathbf{d})\, \mathcal{H}_o^{\hom}(\mathbf{c}', \mathbf{d}') = \Phi_{\mathcal{H}_o}^{\hom}$, and the node maps are of three kinds, each applied to the pairs (c, d) and (c', d') alike:*

(i) at a parallel node, $(c_l, d_l)_l \mapsto \big(\prod_l c_l,\ \sum_l d_l \prod_{l' \neq l} c_{l'}\big)$, so the hinge values add;

(ii) at a series node, $(c_l, d_l)_l \mapsto \big(\sum_l c_l \prod_{l' \neq l} d_{l'},\ \prod_l d_l\big)$, so the reciprocals of the hinge values add;

(iii) at a prime node $\mathcal{H}_v$, $(c, d) \mapsto \big((\mathcal{H}_v/g_v)^{\hom}(\mathbf{c}, \mathbf{d}),\ (\mathcal{H}_v \setminus g_v)^{\hom}(\mathbf{c}, \mathbf{d})\big)$.

A parallel node whose children are all marks is a parallel class, with the quadruple $(1, A, 1, A')$ and its hinge module on the hinge plane, and a series node whose children are all marks is a series class, with $(\alpha^B A', \alpha^B, \alpha^{-B} A, \alpha^{-B})$. So the pencil module of the centre ray of every connected list on n marks, and the law of every insertion along it, are generated from the module of one mark by the parallel and series rules and by the node maps of the prime lists on at most n marks, which up to the names of the marks are finitely many.

The tree decides what a list carries into its pencil. The series and parallel nodes act by the conductance rules, the same at every size; a class is a parallel node of marks; and the prime nodes are the only operations that depend on more than the number of their children.

Proposition 42.22 (The closings of a substitution)**.** *For every $j \in \mathbb{N}$,*

$$\mathsf{C}_j(1) = \sum_{w \in \mathbb{N}^q} \Big([x^w]\, K_{\mathcal{H}}(x)^j \Big)^2 \prod_{i=1}^{q} \mathsf{M}_j^{(i)}(w_i),$$

$$\mathsf{M}_j^{(i)}(w) = \operatorname{CT}\Big(\big(K_{\mathcal{A}_i \setminus g_i}(\alpha) K_{\mathcal{A}_i \setminus g_i}(\alpha^{-1})\big)^w \big(K_{\mathcal{A}_i/g_i}(\alpha) K_{\mathcal{A}_i/g_i}(\alpha^{-1})\big)^{j-w} \Big),$$

the constant term taken on the marks B_i alone. A parallel class of s marks has $\mathsf{M}_j(w) = \mathsf{C}_w^{\binom{[s]}{1}}(1)$, a series class of s marks has $\mathsf{M}_j(w) = \mathsf{C}_{j-w}^{\binom{[s]}{1}}(1)$, and a mark left in place has $\mathsf{M}_j = 1$. A cell that

is itself a substitution, $\mathcal{A} = \mathcal{A}_0\langle \mathcal{A}' \text{ at } x\rangle$ (Proposition 21.3(ii)), has

$$\mathsf{M}_j^{\mathcal{A}}(w) = \sum_u \Big([\alpha^u]\, K^{w}_{\mathcal{A}_0\backslash g} K^{j-w}_{\mathcal{A}_0/g} \Big)^2 \, \mathsf{M}_j^{\mathcal{A}'}(u_x),$$

so the arrays M *compose down the hinge tree, one for each edge.*

Proposition 42.10(ii) is the case of parallel classes. By Theorem 39.57 and Corollary 39.36 the least recurrence of the closings of 1 is read from these arrays, with no box.

Lemma 42.23 (The occupations of a substitution)**.** *Let $\rho_i(\alpha) = R^{\mathcal{H}}_{h_i}\big(\gamma(\alpha)\big)$ be the occupation of the marker h_i in the core read at the hinge values. On the marks of B_i the occupations of $\mathcal{B}$ are*

$$R_e = (1-\rho_i)\, R_e^{\mathcal{A}_i/g_i} + \rho_i\, R_e^{\mathcal{A}_i\backslash g_i},$$

and $\rho_i = \gamma_i\, K_{\mathcal{H}/h_i}(\gamma)/K_{\mathcal{H}}(\gamma)$, $K_{\mathcal{H}}$ being multilinear; on a mark left in place, $R_e = \rho_i$.

Theorem 42.24 (Native gauges along the hinge tree)**.** *Write $\rho_i = \rho_i(\alpha)$ and $\rho_i^* = \rho_i(\alpha^{-1})$, and where the hinge values are nonzero put $t_i = \gamma_i(\alpha)\gamma_i(\alpha^{-1})$ and $q_i = \gamma_i(\alpha)/\gamma_i(\alpha^{-1})$. A point $\alpha \in X_F$ with nonzero hinge values is a native gauge of the centre ray of $\mathcal{B}$ exactly when for every cell*

$$d_{B_i}\Big[\log v_{\mathcal{A}_i} + \tfrac{1}{2}(\rho_i + \rho_i^*)\log t_i + \tfrac{1}{2}(\rho_i - \rho_i^*)\log q_i \Big] = 0, \qquad (\star)$$

the differential taken along the marks of B_i in the logarithmic coordinates with ρ_i, ρ_i^* held fixed.

(a) Along the scale of the cell, under which $v_{\mathcal{A}_i}$ and t_i are invariant and q_i has the degree 2, $(\star)$ reads $\rho_i = \rho_i^*$; then $(\star)$ says that the cell sits at a critical point of $v_{\mathcal{A}_i} t_i^{\rho_i}$, with ρ_i fixed, on its torus modulo its scale.

(b) A parallel class $\mathcal{A}_i$ is, at every native gauge, hinge values zero or not, either empty, *$K_{\mathcal{H}/h_i}(\gamma(\alpha)) = K_{\mathcal{H}/h_i}(\gamma(\alpha^{-1})) = 0$, or* occupied, *$\alpha_e = \eta_e \tau_i$ on B_i with signs η_e and a scale τ_i. An occupied class of the sign value $a_i = \sum_{e\in B_i}\eta_e$ is read by the core as one mark of the variable τ_i and the weight a_i in both letters, $\gamma_i(\alpha) = a_i\tau_i$ and $\gamma_i(\alpha^{-1}) = a_i\tau_i^{-1}$, and for $a_i \neq 0$ its equations are the native-gauge equation of that weighted core at h_i. An empty class satisfies its own equations identically and enters the others only through its totals (A_i, A_i'), which the core fixes; for a pair the ratio r of its two scales solves $r + r^{-1} = A_i A_i' - 2$. For a series class the same holds with $K_{\mathcal{H}\backslash h_i}$ in the place of $K_{\mathcal{H}/h_i}$, the totals exchanged, the weight $1/a_i$, and the factor $v_{\mathcal{A}_i} = a_i^2$ of f^{-1} when it is occupied.*

(c) A cell $\mathcal{A} = \mathcal{H}'\langle \mathcal{A}_1', \dots, \mathcal{A}_p'\rangle$, its hinge a mark g of $\mathcal{H}'$, has as its hinge map the composite of the hinge maps $(\gamma_l', \gamma_l'^*, v_l')$ of its own cells with

$$\big(\gamma', \gamma'^*, v'\big) \mapsto \Big(\frac{K_{\mathcal{H}'\backslash g}(\gamma')}{K_{\mathcal{H}'/g}(\gamma')},\ \frac{K_{\mathcal{H}'\backslash g}(\gamma'^*)}{K_{\mathcal{H}'/g}(\gamma'^*)},\ \prod_l v_l'\, K_{\mathcal{H}'/g}(\gamma') K_{\mathcal{H}'/g}(\gamma'^*) \Big),$$

so the differentials in $(\star)$ are read from those of its cells by the chain rule, and $(\star)$ recurses down the hinge tree.

(d) For the series and parallel nodes these maps are the conductance rules: at a parallel node of p cells $\gamma = \sum_l \gamma_l'$ and $v = \prod_l v_l'$; at a series node $\gamma^{-1} = \sum_l \gamma_l'^{-1}$ and $v = \prod_l v_l' \cdot e_{p-1}(\gamma')\, e_{p-1}(\gamma'^*)$.

So the native gauges of a list of series and parallel nodes are found by choosing, class by class, occupied with a sign pattern or empty, and solving the native-gauge equation of the core in which an occupied class is one mark of weight a_i and an empty class a pair of free totals subject to the vanishing of the contraction letter of the core on both sides of the Cremona. Native gauges that are not signs come from emptiness: a marker whose contraction letter vanishes on both sides of the Cremona releases its class from the sign condition.

Corollary 42.25 (A class is a bubble of classes)**.** *For $a+b=s$, $a,b\ge 1$, $\binom{[s]}{1}=\binom{[2]}{1}\langle\binom{[a]}{1},\binom{[b]}{1}\rangle$, the two classes substituted as parallel classes. The two-sided core of $\binom{[2]}{1}$ at the norms (t_1,t_2) is $t_1+t_2+t_1r+t_2r^{-1}$, $r=x_2/x_1$, and*

$$T_s(\tau)=\iint\frac{\nu_a(dt_1)\,\nu_b(dt_2)}{\sqrt{(\tau-t_1-t_2)^2-4t_1t_2}},\qquad \sum_j \mathsf{C}_j^{\binom{[s]}{1}}(1)\,\frac{z^j}{j!^2}=\Big(\sum_k\frac{z^k}{k!^2}\Big)^s,$$

T_s the torus fibre integral of the centre ray of $\binom{[s]}{1}$ at the strength one and the root positive for large τ.

42.8 The value of a table as a closed serif word

The value of a connected table at every strength, with norms on its marks, is the word of the table with the norms entering as a monomial in the loads, and the value of a table built by substitution is the word of its core with the word of each cell set at the load of its marker. A cell enters through one Trailmoment of its law; down the hinge tree it is read through the family of the minors of its core, or, at a series or parallel node, on one scale through the transforms of the cells below it. Throughout this section $(\mathcal{B},\theta)$ is a connected table on $\mathcal{E}$, $|\mathcal{E}|=n$, of rank r, with N bases and the norms $\mathsf{m}_e>0$ on its marks (Definition 42.19(i)), and $k>0$. Its *value* at the strength k is

$$\mathsf{V}_{\mathcal{B}}(k;\mathsf{m})=\int_{\{h=1\}}\big(K(\alpha)K(\mathsf{m}\alpha^{-1})\big)^{-k}\alpha^{-\mathbf{1}}\,d\alpha,\qquad \mathsf{m}\alpha^{-1}=(\mathsf{m}_e\alpha_e^{-1})_e,$$

h any positive function homogeneous of degree one, and $\mathsf{V}_{\mathcal{B}}(k)=\mathsf{V}_{\mathcal{B}}(k;\mathbf{1})=P_{\mathcal{B}}(k\mathbf{1};k,k)$ is the period of its centre ray at the strength k (Definition 38.13).

Proposition 42.26 (The value of a table is a closed serif word)**.** *(i) $K(\mathsf{m}\alpha^{-1})=\alpha^{-\mathcal{E}}\Psi_{\theta\mathsf{m}}(\alpha)$, with $\Psi_{\theta\mathsf{m}}$ the cobasis letter of $(\mathcal{B},\theta\mathsf{m})$, $(\theta\mathsf{m})_T=\theta_T\prod_{e\in T}\mathsf{m}_e$: the norms are weights of the cobasis letter. So $\mathsf{V}_{\mathcal{B}}(k;\mathsf{m})$ is the period at the masses $k\mathbf{1}$ of the family F_{m} of the two tables $((\mathcal{B},\theta);k,0)$ and $((\mathcal{B},\theta\mathsf{m});0,k)$, which is on the balance wall with the walls $\kappa_S=k\big(r(S)+r(\mathcal{E}\setminus S)-r\big)>0$; it converges and has a native gauge, for all positive weights and norms.*

(ii) Fix $g\in\mathcal{E}$. Open K with one share a_T and $\Psi_{\theta\mathsf{m}}$ with one share b_T on each basis T, write $\ell_e(\mathbf{a})=\sum_{T\ni e}a_T$ for the load of K on the mark e, and let $\mathcal{X}_k$ be the fibre cut by $|\mathbf{a}|=|\mathbf{b}|=k$ and $\mathrm{load}_e=k$ for $e\ne g$ (Definition 12.24), of dimension $2(N-1)-(n-1)$. On every wall contour, among them the uniform split $a_T=b_T=k/N$, which lies on $\mathcal{X}_k$ whatever the weights and the norms,

$$\mathsf{V}_{\mathcal{B}}(k;\mathsf{m})=\int_{\mathcal{X}_k}\Gamma_{\substack{N\\1}}\begin{bmatrix}\mathbf{a}\\k\end{bmatrix}\Gamma_{\substack{N\\1}}\begin{bmatrix}\mathbf{b}\\k\end{bmatrix}\prod_T\theta_T^{-a_T-b_T}\prod_{e\in\mathcal{E}}\mathsf{m}_e^{-\ell_e(\mathbf{a})},$$

independent of g. A norm enters as a twist on the load of its mark, and at $\mathsf{m}=\mathbf{1}$ the word is the word of the table.

(iii) *Let $\mathcal{B} = \mathcal{H}\langle \mathcal{A}_1, \dots, \mathcal{A}_q \rangle$ be built by substitution with plain cells (Definition 21.1), the core $\mathcal{H}$ with $N_{\mathcal{H}}$ bases and the weights $\theta^{\mathcal{H}}$, the cell $\mathcal{A}_i$ on $B_i \sqcup \{g_i\}$, the norms 1 on the marks of the cells with $|B_i| \geq 2$, and the norm m_i on a mark left in place at h_i. For a cell $\mathcal{A}$ on $B \sqcup \{g\}$ with $|B| \geq 2$ and $0 < \operatorname{Re} \ell < k$ put*

$$\widehat{\mathsf{V}}_{\mathcal{A}}(k;\ell) = \int_{\{h=1\}} v_{\mathcal{A}}(\alpha)^{\ell-k} \big(K_{\mathcal{A}\setminus g}(\alpha) K_{\mathcal{A}\setminus g}(\alpha^{-1})\big)^{-\ell} \alpha^{-\mathbf{1}}\, d\alpha,$$

the period of the family of its two hinge minors, $\mathcal{A}/g$ at the strength $k-\ell$ and $\mathcal{A}\setminus g$ at the strength ℓ, which is on the balance wall of B and converges; for a mark of the norm m left in place put $\widehat{\mathsf{V}}(k;\ell) = \mathsf{m}^{-\ell}$. A parallel class of $s \geq 2$ marks has

$$\widehat{\mathsf{V}}(k;\ell) = \Gamma(\ell)^{-2} \int_0^\infty y^{\ell-1} \mathsf{G}_{0;(1,-1)}(1,y)^s\, dy.$$

Then, with the fibre $\mathcal{X}_k^{\mathcal{H}}$ and the loads ℓ_{h_i} of (ii) for the core,

$$\mathsf{V}_{\mathcal{B}}(k;\mathsf{m}) = \int_{\mathcal{X}_k^{\mathcal{H}}} \Gamma_{N_{\mathcal{H}}}\begin{bmatrix}\mathbf{a}\\ k\end{bmatrix} \Gamma_{N_{\mathcal{H}}}\begin{bmatrix}\mathbf{b}\\ k\end{bmatrix} \prod_T \big(\theta_T^{\mathcal{H}}\big)^{-a_T-b_T} \prod_{i=1}^q \widehat{\mathsf{V}}_{\mathcal{A}_i}\big(k;\ell_{h_i}(\mathbf{a})\big) :$$

the word of a table is the word of its core with the word of each cell set at the load of its marker.

(iv) The law of a cell. *A connected plain cell $\mathcal{A}$ on $B \sqcup \{g\}$, $|B| \geq 2$, at the exponents (k,k) with the masses k on B is a cell family with the hinge wall k, with its law $(\varrho_{\mathcal{A}})_*\phi_{\mathcal{A}}$, its transform $f_{\mathcal{A}}$ and its dual transform $\check{f}_{\mathcal{A}}$ (Definition 23.1). For $0 < \operatorname{Re}\ell < k$ and $0 < \operatorname{Re} z < k$,*

$$\widehat{\mathsf{V}}_{\mathcal{A}}(k;\ell) = \int_{\Delta_B} \varrho_{\mathcal{A}}^{\ell-k}\, d\phi_{\mathcal{A}} = \big(\mathsf{T}_{k-\ell;(1)}[x]\,(\varrho_{\mathcal{A}})_*\phi_{\mathcal{A}}\big)((0,\infty)),$$

$$\int_0^\infty y^{z-1} \check{f}_{\mathcal{A}}(y)\, dy = \Gamma(z)^2\, \widehat{\mathsf{V}}_{\mathcal{A}}(k;z), \qquad \int_0^\infty y^{z-1} f_{\mathcal{A}}(y)\, dy = \Gamma(z)^2\, \widehat{\mathsf{V}}_{\mathcal{A}}(k;k-z) :$$

a cell enters the word of a table through one Trailmoment of its law, at the index k less the load of its marker, and its two transforms are that word read back on a scale.

(v) Down the tree. *Let a cell $\mathcal{A}$ as in (iv) be built by substitution with plain cells, $\mathcal{A} = \mathcal{H}'\langle \mathcal{A}'_1, \dots, \mathcal{A}'_p \rangle$, its hinge g a mark of $\mathcal{H}'$ left in place at the marker h, the cell $\mathcal{A}'_i$ at the marker h_i, the norms 1 on all its marks, and a mark left in place counted as a cell with $\widehat{\mathsf{V}} = 1$. Let $\mathcal{C} = \mathcal{H}'/h$ and $\mathcal{D} = \mathcal{H}' \setminus h$ on $h_1, \dots, h_p$, with the inherited weights and $N_{\mathcal{C}}$ and $N_{\mathcal{D}}$ bases; open the letters K and Ψ of $\mathcal{C}$ with the shares a_T and b_T, and those of $\mathcal{D}$ with the shares c_T and d_T, one on each basis; write $\ell_x(\mathbf{a}) = \sum_{T \ni x} a_T$, and let $\mathcal{Y}_{k,\ell}$ be the fibre cut by $|\mathbf{a}| = |\mathbf{b}| = k-\ell$, $|\mathbf{c}| = |\mathbf{d}| = \ell$ and the load $\ell_x(\mathbf{a}) + \ell_x(\mathbf{c}) + \sum_{T \not\ni x}(b_T + d_T) = k$ at every marker x but one, of dimension $2(N_{\mathcal{C}} + N_{\mathcal{D}}) - p - 3$. On its uniform split $a_T = b_T = (k-\ell)/N_{\mathcal{C}}$, $c_T = d_T = \ell/N_{\mathcal{D}}$, at which every $\ell_{h_i}(\mathbf{a}) + \ell_{h_i}(\mathbf{c})$ has its real part in $(0,k)$, for $0 < \operatorname{Re}\ell < k$*

$$\widehat{\mathsf{V}}_{\mathcal{A}}(k;\ell) = \int_{\mathcal{Y}_{k,\ell}} \Gamma_{N_{\mathcal{C}}}\begin{bmatrix}\mathbf{a}\\ k-\ell\end{bmatrix} \Gamma_{N_{\mathcal{C}}}\begin{bmatrix}\mathbf{b}\\ k-\ell\end{bmatrix} \Gamma_{N_{\mathcal{D}}}\begin{bmatrix}\mathbf{c}\\ \ell\end{bmatrix} \Gamma_{N_{\mathcal{D}}}\begin{bmatrix}\mathbf{d}\\ \ell\end{bmatrix}$$
$$\times \prod_T \big(\theta_T^{\mathcal{C}}\big)^{-a_T-b_T} \prod_T \big(\theta_T^{\mathcal{D}}\big)^{-c_T-d_T} \prod_{i=1}^p \widehat{\mathsf{V}}_{\mathcal{A}'_i}\big(k;\ell_{h_i}(\mathbf{a}) + \ell_{h_i}(\mathbf{c})\big) :$$

the word of a cell is the word of the family of the two minors of its core at the marker of its hinge, with the word of each of its own cells set at the load of its marker.

(vi) Series and parallel nodes on one scale. *When the core of $\mathcal{A}$ in (v) is a parallel node $\binom{\{h,h_1,\dots,h_p\}}{1}$ or a series node $\binom{\{h,h_1,\dots,h_p\}}{p}$, with the weights* 1, *a mark left in place having the transforms $f = \check{f} = \mathsf{G}_{0;(1,-1)}(1,\cdot)$ (Definition 23.19(1)), respectively*

$$\widehat{\mathsf{V}}_{\mathcal{A}}(k;\ell) = \frac{1}{\Gamma(\ell)^2}\Big(\mathsf{T}_{1-\ell;(1)}[x]\prod_{i=1}^{p}\check{f}_{\mathcal{A}_i'}(x)\,\mathbb{I}_{(0,\infty)}\Big)((0,\infty)),$$

$$\widehat{\mathsf{V}}_{\mathcal{A}}(k;\ell) = \frac{1}{\Gamma(k-\ell)^2}\Big(\mathsf{T}_{1-k+\ell;(1)}[x]\prod_{i=1}^{p}f_{\mathcal{A}_i'}(x)\,\mathbb{I}_{(0,\infty)}\Big)((0,\infty)) :$$

one integral on one scale whatever the cells, equal cells entering as one transform to a power. A series class of $s \geq 2$ marks has $\widehat{\mathsf{V}}(k;\ell) = \Gamma(k-\ell)^{-2}\int_0^\infty y^{k-\ell-1}\mathsf{G}_{0;(1,-1)}(1,y)^s\,dy$.

(vii) The root on one scale. *When the core $\mathcal{H}$ of (iii) is a parallel node $\binom{\{h_1,\dots,h_q\}}{1}$ or a series node $\binom{\{h_1,\dots,h_q\}}{q-1}$, with the weights* 1, $\mathsf{m}_i = 1$ *at a cell of at least two marks and the transforms of (vi) at a mark left in place, respectively*

$$\mathsf{V}_{\mathcal{B}}(k;\mathsf{m}) = \frac{1}{\Gamma(k)^2}\Big(\mathsf{T}_{1-k;(1)}[x]\prod_{i=1}^{q}\check{f}_{\mathcal{A}_i}(\mathsf{m}_i x)\,\mathbb{I}_{(0,\infty)}\Big)((0,\infty)),$$

$$\mathsf{V}_{\mathcal{B}}(k;\mathsf{m}) = \frac{1}{\Gamma(k)^2}\Big(\mathsf{T}_{1-k;(1)}[x]\prod_{i=1}^{q}\mathsf{m}_i^{-k}f_{\mathcal{A}_i}(x/\mathsf{m}_i)\,\mathbb{I}_{(0,\infty)}\Big)((0,\infty)).$$

A cell enters the word of a table only through its own word, set at the load of its marker, and a mark with a norm is a cell whose word is a single power. The cells ride on the core's fibre in the same way for every substituted family (Theorem 22.4). The word of a cell is one Trailmoment of its law, and its two transforms are that word read back on a scale (iv). Down the hinge tree the root contributes the word (ii) of its own table and a node below it the word of the family of the two minors of its table at its hinge, with its own cells set at their loads (v); a series or parallel node can instead be read on one scale, through the product of the transforms of the cells directly below it, a repeated cell entering as one transform to a power (vi), (vii).

42.9 The class at silence

A class enters every list through its own pencil, $t = AA'$ on $(\mathbb{C}^\times)^s/\mathbb{C}^\times$, and it is silent at $t = 0$. Its law is the law of the values of $\binom{\mathcal{E}}{1}$ (Theorem 42.12); what the class carries into a list is the local system of that law, irreducible of rank $s-1$, with its local monodromies: one Jordan block at $t = \infty$, a reflection at every sign value, and $\lfloor s/2 \rfloor$ at silence.

Lemma 42.27 (The pencil of a class)**.** *For $\binom{[s]}{1}$, $s \geq 2$, with $\varphi = AA'$ on $T_s = (\mathbb{C}^\times)^s/\mathbb{C}^\times$:*

(i) the critical points of nonzero value are the signs η with $\sum_e \eta_e \neq 0$, of the value $(\sum_e \eta_e)^2$, nondegenerate; the critical points of the value 0 *are the points with $A = A' = 0$;*

(ii) φ has no asymptotic critical value in $\mathbb{C}^\times$: the centre ray of $\binom{[s]}{1}$ has no asymptotic native value (Definition 38.29);

(iii) the critical points of a value $a^2 \neq 0$ form one orbit of S_s, and the Cremona fixes each of them.

Theorem 42.28 (The class for every size)**.** *Let $s \geq 2$, $h = \lceil s/2 \rceil$, let $c_{s,k}$ be the coefficients of Theorem 42.12, and put*

$$\widetilde{A}_s = \sum_{k=0}^{h} c_{s,k}(t\partial_t + 1)\, t^{-k},$$

an operator of order $s-1$ in ∂_t. Let $T_s(t) = \sum_{j\geq 0} \mathsf{C}_j^{\binom{[s]}{1}}(1)\, t^{-j-1}$ be the torus fibre integral of $\binom{[s]}{1}$, and V_s the span of its continuations along the paths that avoid 0 and the sign values a^2, $0 < a \leq s$, $a \equiv s \bmod 2$.

(i) $\widetilde{A}_s T_s = 0$ exactly, and V_s is the whole space of the solutions of $\widetilde{A}_s$: a local system of rank $s-1$, irreducible.

(ii) At $t = \infty$ the monodromy of V_s is one Jordan block of size $s-1$ for the eigenvalue 1, with all exponents equal to 1 in $1/t$.

(iii) At every sign value a^2 the monodromy minus the identity has rank one; the exponents there are $0, 1, \ldots, s-3$ and $\frac{s-3}{2}$.

(iv) At $t = 0$, where the class is silent, $\operatorname{rank}(T_0 - 1) = \lfloor s/2 \rfloor$, and the exponents are $0, 0, 1, 1, \ldots, h-2, h-2$ and, for even s, one more, $\frac{s}{4} - 1$. For odd s, $(T_0 - 1)^2 = 0$: the monodromy is $\frac{s-1}{2}$ Jordan blocks of size 2. For even s the eigenvalue -1 has the multiplicity at most one, and on the unipotent part $(T_0 - 1)^3 = 0$ with $(T_0 - 1)^2$ of rank at most one.

At silence an odd class carries $\frac{s-1}{2}$ logarithms, $t^m \log t + \cdots$ beside $t^m + \cdots$ for $0 \leq m \leq \frac{s-3}{2}$; the fibre integral of the class at its norm $x = A_i A_i'$ enters a list through these germs.

Proposition 42.29 (The hinge module of a class)**.** *Let $s \geq 2$, with h and $c_{s,k}$ as in Theorem 42.28, write $c_{s,k}(x) = q_k(-x-k)\big((x+1)\cdots(x+k-1)\big)^2$ for $k \geq 1$ and $q_0(\vartheta) = \vartheta^{s+1}$, the polynomials $q_k = q_{s,k}$ of Theorem 42.12(i), and put on the hinge plane*

$$E = x\partial_x - x'\partial_{x'}, \qquad \widetilde{B} = \sum_{k=1}^{h} (\partial_x \partial_{x'})^{k-1} q_k(-x\partial_x - 1) + xx'(-x\partial_x - 1)^{s-1}.$$

(i) E and $\widetilde{B}$ annihilate the generator of the hinge module $\mathcal{H}_C$ of the class. On functions of $t = xx'$, $\widetilde{B}$ acts as $t\,\widetilde{A}_s$.

(ii) The periods of $[1]$ of the class are exactly V_s: the module $\mathcal{D}[1]$ of the centre ray of $\binom{[s]}{1}$ has rank $s-1$ and is irreducible off its singular values.

(iii) $\mathcal{H}_C$ is the intermediate extension of its local system, the pullback of V_s along $t = xx'$.

(iv) With $P = \mathbb{C}^2$, $H_a = \{xx' = a^2\}$ for the sign values, $X = \{x = 0\}$, $X' = \{x' = 0\}$ and $O = \{0\}$,

$$CC(\mathcal{H}_C) = (s-1)[T_P^*] + \sum_a [T_{H_a}^*] + \left\lfloor \frac{s}{2} \right\rfloor \big([T_X^*] + [T_{X'}^*]\big) + m_s(O)[T_O^*],$$

with $m_s(O) = 0$ for odd s and $m_s(O) = 1 + n_1$ for even s, n_1 the number of Jordan blocks of size one of T_0 for the eigenvalue 1.

Write $m_s(P) = s-1$, $m_s(H_a) = 1$, $m_s(X) = m_s(X') = \lfloor s/2 \rfloor$; a mark left in place has the single component H_1, with the multiplicity 1.

So the module through which a class enters every list is determined: on the hinge plane it is annihilated by the scale and by the law of the class with one factor removed, it is the intermediate extension of its local system, and its characteristic cycle is explicit. The values of every table a class enters, with norms on its marks, are serif words (Proposition 42.26). The periods of a class of at least three marks continue through a group whose Zariski closure has an identity component that is not solvable, so they are not combinations, with algebraic coefficients, of iterated integrals of logarithmic forms with algebraic letters, nor of any functions whose continuations become unipotent on a finite cover (Corollary 42.30). That is a statement about those functions, not about the class (Definition 18.19).

Corollary 42.30 (The periods of a class are not unipotent)**.** *For $s \geq 3$ the identity component of the Zariski closure of the monodromy group of V_s is not solvable, hence not unipotent. So no nonzero element of V_s is a function whose continuations span a local system with a unipotent subgroup of finite index in its monodromy, as are the combinations, with algebraic coefficients, of iterated integrals of logarithmic forms with algebraic letters.*

42.10 The sources of a substitution of classes

When every cell is a parallel class, the sources of the list are the critical points of one function, the two-sided core, on the strata of one space, the hinge space, with each class on one of five strata of its hinge plane, and their contributions to the vanishing ranks are counted there with the multiplicities of Proposition 42.29.

Theorem 42.31 (The sources in the hinge space)**.** *Let every cell of $\mathcal{B}$ be a parallel class, of sizes $s_i \geq 1$. The singular support of the hinge module of a class of $s \geq 2$ marks lies in the conormals of P, of the hyperbolas H_a of its sign values, of the axes X, X' and of the origin O (Proposition 42.29); for a mark it is the conormal of H_1. Every singular value of $\mathcal{D}_{\mathcal{B}}[1]$ is the value of $\Phi_{\mathcal{H}}$ at a critical point of its restriction to a product $W = \prod_i W_i$ of these, or a limit at infinity of the hinge space of such values along points with the differential of the restriction tending to 0. The class C_i is* occupied *with the weight a when $W_i = H_a$,* empty *when $W_i = P$,* silent *when $W_i = X$ or X', and* balanced *when $W_i = O$.*

Theorem 42.32 (The source count bounds the vanishing ranks)**.** *Let every cell of $\mathcal{B}$ be a parallel class, let Γ be the group generated by the Cremona and the exchanges of equal classes, acting on the hinge space, and let $t_0 \in \mathbb{C}^\times$ be a value at which the direct image N of $\boxtimes_i \mathcal{H}_{C_i}$ under $\Phi_{\mathcal{H}}$, modulo the scale, has no cohomology outside the degree 0 near t_0 and no vanishing cycles at t_0 coming from infinity of the hinge space. For a product W as in Theorem 42.31 put $m(W) = \prod_i m_{s_i}(W_i)$, and let $I_{t_0}(W)$ be the intersection number over t_0 of T^*_W with the graph of $d\Phi_{\mathcal{H}}$, the sum of the Milnor numbers of $\Phi_{\mathcal{H}}|_W$ at its critical points of the value t_0. Then the vanishing cycles of N at t_0 have the dimension $\sum_W m(W)\, I_{t_0}(W)$, and*

$$r_{t_0}(\mathcal{D}_{\mathcal{B}}[1]) \leq N_{t_0},$$

the dimension of the part of these vanishing cycles on which Γ acts by the character of [1].

Proposition 42.33 (Local contributions)**.** *In Theorem 42.32:*

(a) a weighted point*, a nondegenerate critical point of $\Phi_{\mathcal{H}}|_W$ with every class on a hyperbola, the image of an orbit of nondegenerate native gauges of $\mathcal{B}$ with no asymptotic native gauge of its value, contributes at most 1 to N_{t_0} for its orbit;*

(b) points exchanged by Γ, each a nondegenerate critical point of multiplicity $m(W)$, contribute $m(W)$ together to N_{t_0};

(c) at a nondegenerate critical point of $\Phi_{\mathcal{H}}|_W$ the local contribution to the vanishing cycles is $m(W)$; in particular an odd corner*, an odd class C_i silent with the other classes on hyperbolas, at a nondegenerate critical point of $\Phi_{\mathcal{H}}|_W$, $W_i = X$, at which the covector of $\Phi_{\mathcal{H}}$ lies on no other component of the characteristic cycle, contributes $\frac{s_i-1}{2}$ there, and the two corners on X and X', exchanged by the Cremona, contribute $\frac{s_i-1}{2}$ to N_{t_0} together;*

(d) an empty point*, the classes C_i, $i \in I$, on P and the others on hyperbolas, at a nondegenerate critical point of $\Phi_{\mathcal{H}}|_W$, contributes $\prod_{i\in I}(s_i - 1)$ to the vanishing cycles;*

(e) a clean critical curve Z of $\Phi_{\mathcal{H}}|_W$ along which the characteristic cycle has the constant multiplicity $m(W)$ and which meets no other component contributes $-m(W)\chi(Z)$, the ends of Z at infinity of the hinge space excepted.

The kinds of native gauges of Theorem 42.24, the corners of Proposition 38.26 at the classes (Corollary 38.28), and the curves of balanced classes are all critical points of the two-sided core on the strata of the hinge space. The exercises work the triangles of classes, with a mark of another norm among them (Section 55.4).

Chapter 43

Arithmetic along a ray

A free share closed along a ray brings at every lattice point a rational number of tier one in the point times Trailmoments of the counting input at cuts that move with the point; summed, these are Trailmoments of live inputs, and along the ray the same finitely many live inputs carry every value, the step from one point of the ray to the next entering as rational words. The terms are rational in the lattice point, up to a sign, exactly when the lower Gammas of the word whose slope is at least two in modulus pair off; the word is then a product of sines times a rational function, and its closings are combinations of Trailmoments of lattice inputs with coefficients polynomial in $(\mathsf{T}_{2;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$. The frame of a law of the values bounds every clearing of their rows from below, by the product of the roots of the symbol, and the merit of the rows, the decay at the native gauge of the direction against the growth of the clearing, decides the gap along the ray. On a ray from the origin the law of [1] vanishes to the order $n-1$ at its low end, which gives one linear relation among the first values; at order two every value is then a row in the one coordinate $\langle 1\rangle_1$, and when the law is reflexive the coefficient of that coordinate is a closing of the ray, the constant term of a power of the reciprocal stride, read with no lattice sum. A hinge closing is a row over finitely many periods of the room as soon as the room's periods along the lattice of the closing satisfy a recurrence of finite order. The critical primes of a native gauge, the primes at which its native value is not integral, are primes at which the letters degenerate, and when every root of the symbol of a law is such a native value they are the primes of its leading coefficient.

43.1 Closing a free share along a ray

Theorem 43.1 (Closing one free share along a ray)**.** *Let A and B be finite sets with integers b_γ and u_γ for $\gamma \in A \sqcup B$,* slopes *$\epsilon_\alpha \in \{1,-1\}$ for $\alpha \in A$ and $\epsilon_\beta \in \mathbb{Z}\setminus\{0\}$ for $\beta \in B$, balanced in the slopes, $\sum_{\alpha\in A}\epsilon_\alpha = \sum_{\beta\in B}\epsilon_\beta$. In this statement write, for $k \in \mathbb{N}$ and a share a,*

$$W_k(a) = \frac{\prod_{\alpha\in A}\Gamma(\epsilon_\alpha a + b_\alpha + k u_\alpha)}{\prod_{\beta\in B}\Gamma(\epsilon_\beta a + b_\beta + k u_\beta)},$$

the stacked Gamma (Definition 1.2) of one free share at the k-th point of the ray along the integral direction $(u_\gamma)_\gamma$; write $A_\pm$ for the $\alpha \in A$ with $\epsilon_\alpha = \pm 1$, $B_\pm$ for the $\beta \in B$ with $\pm\epsilon_\beta > 0$, $w = |A_+| - |B_+|$, and

$$r_W = \prod_{\beta\in B_+} \epsilon_\beta^{\epsilon_\beta} \Big/ \prod_{\beta\in B_-} |\epsilon_\beta|^{|\epsilon_\beta|}.$$

(i) The step factor. $W_k = W_0\, g_k$ *with*

$$g_k(a) = \frac{\prod_{\alpha\in A}(\epsilon_\alpha a + b_\alpha)_{k u_\alpha}}{\prod_{\beta\in B}(\epsilon_\beta a + b_\beta)_{k u_\beta}}, \qquad (x)_{-r} = \frac{1}{(x-r)_r} \quad (r\in\mathbb{N}),$$

a rational function of the share with rational coefficients.

(ii) The terms. *The poles of W_k lie at integers. Let n_1 be an integer beyond which, at $a=-n$, the Gammas of A_+ and of B_+ have nonpositive integer arguments and those of A_- and of B_- positive ones, and for $\gamma\in A\sqcup B$ let $N_\gamma(n)$ be minus the argument of its Gamma at $a=-n$ in the first case and that argument less one in the second; $N_\gamma(n)$ is affine in n with the slope $|\epsilon_\gamma|$. For every integer $n>n_1$ and small ε,*

$$W_k(-n+\varepsilon) = C_n\,\varepsilon^{-w}\exp\Big(\sum_{i\ge1}\Lambda_{n,i}\,\varepsilon^i\Big),$$

where C_n is a nonzero rational number, a signed product of the factorials $N_\gamma(n)!$, to the power 1 for $\gamma\in A_-\cup B_+$ and -1 for $\gamma\in A_+\cup B_-$, and of the slopes of B_+; $C_{n+1}=\rho(n)\,C_n$ for a rational function ρ with rational coefficients, so that $(C_n)_n$ has tier at most one (Proposition 38.11), and $|C_n|^{1/n}\to r_W$, so that r_W is the root rate (Definition 1.1(viii)) of the C_n; $\Lambda_{n,1}$ is a rational combination of the heads $(\mathsf{T}_{1;(1)}[x]\,\mathbb{I}_\mathbb{Z})((0,N_\gamma(n)])$; and for $i\ge2$, $\Lambda_{n,i}$ is a rational combination of $(\mathsf{T}_{i;(1)}[x]\,\mathbb{I}_\mathbb{Z})((0,\infty))$ and the heads $(\mathsf{T}_{i;(1)}[x]\,\mathbb{I}_\mathbb{Z})((0,N_\gamma(n)])$. The coefficients of these combinations do not depend on n or k. The residue of W_k at $-n$ is C_n times the coefficient of ε^{w-1} in the exponential, a polynomial with rational coefficients, not depending on n, in the Trailmoments $(\mathsf{T}_{i;(1)}[x]\,\mathbb{I}_\mathbb{Z})((0,\infty))$, $2\le i\le w-1$, and the heads $(\mathsf{T}_{i;(1)}[x]\,\mathbb{I}_\mathbb{Z})((0,N_\gamma(n)])$, $1\le i\le w-1$, each of its monomials of total index $w-1$; it is zero when $w\le0$.

(iii) The closing. *Let W_k close to the left on a line $\operatorname{Re}a=c$ that separates the poles of the Gammas of A_+ from those of A_- (Theorem 4.5). Then $\frac{1}{2\pi i}\int_{(c)}W_k(a)\,da$ is the sum of the residues of W_k at the integers $-n<c$. When $r_W<1$ it is a finite rational combination of products of Trailmoments $(\mathsf{T}_{i;(1)}[x]\,\mathbb{I}_\mathbb{Z})((0,\infty))$, $i\ge2$, with 1 and with the absolutely convergent sums*

$$(\mathsf{T}_{0;(1)}[x]\,\psi\,\mathbb{I}_\mathbb{Z})((n_1,\infty)) = \sum_{n>n_1}\psi(n), \qquad \psi(n) = C_n\prod_{l=1}^{q}(\mathsf{T}_{i_l;(1)}[x]\,\mathbb{I}_\mathbb{Z})((0,N_{\gamma_l}(n)]),$$

over the finitely many products with $\gamma_l\in A\sqcup B$, $i_l\ge1$ and $i_1+\cdots+i_q\le w-1$; each such ψ is a live input, its density read from the serif family at the moving cut, and it satisfies a recurrence of order at most 2^q with polynomial coefficients and nonzero extreme coefficients.

(iv) Along the ray. *For two steps k and k' and every n beyond both bounds n_1, C_n at k is C_n at k' times a rational function of n with rational coefficients, and every $N_\gamma(n)$ at k is $N_\gamma(n)$ at k' plus an integer that does not depend on n. So every input ψ of (iii) at the step k is a combination, with coefficients rational functions of n with rational coefficients, of the inputs ψ of (iii) at the step k': when $r_W<1$ every value along the ray is a finite rational combination of products of Trailmoments $(\mathsf{T}_{i;(1)}[x]\,\mathbb{I}_\mathbb{Z})((0,\infty))$ with 1 and with Trailmoments at index zero of the finitely many live inputs of one step against rational functions of the point with rational coefficients, whose rows Theorem 6.10 reads.*

Closing to the right is the same statement after the share a is replaced by $-a$.

A word of one free share arises from the atom formula (Corollary 18.16) when its other shares are closed or merged, for instance by the four Gammas on a line (Corollary 4.7): integrating $\Gamma(a+z)\Gamma(b+z)\Gamma(c-z)\Gamma(d-z)$ over z leaves four upper Gammas and the lower Gamma $\Gamma(a+b+c+d)$, whose slope in a remaining share is the sum of the slopes of a, b, c and d. A lower Gamma of slope v contributes v^v to the root rate of the terms and one of slope $-v$ contributes v^{-v}, so a lone lower Gamma of slope -2 makes the terms of a left closing fall like 4^{-n}, while lower Gammas that pair off leave terms that do not fall geometrically and are rational in n up to a sign.

Proposition 43.2 (Paired words)**.** *In Theorem 43.1 the following are equivalent.*

(a) The lower Gammas of slope at least two in modulus pair off: for every integer $v \geq 2$ as many $\beta \in B$ have $\epsilon_\beta = v$ as have $\epsilon_\beta = -v$.

(b) For some k, and then for every k, there are $\varsigma \in \{0,1\}$ and a rational function R with $C_n = (-1)^{\varsigma n} R(n)$ for every $n > n_1$.

When they hold, put $p = |A_+| - \#\{\beta \in B : \epsilon_\beta = 1\}$ and let $B^{\geq 2}$ be the set of the β with $\epsilon_\beta \geq 2$, so that $w = p - |B^{\geq 2}|$. Then

$$W_k(a) = \pm\, \pi^w \, \frac{\prod_{\beta \in B^{\geq 2}} \sin(\pi \epsilon_\beta a)}{\sin(\pi a)^p} \, R_k(a),$$

with R_k a rational function with rational coefficients, and for $n > n_1$ the residue of W_k at $-n$ is

$$\pm(-1)^{\varsigma n} \sum_{0 \leq l \leq (w-1)/2} \tau_l \, \pi^{2l} \, \frac{R_k^{(w-1-2l)}(-n)}{(w-1-2l)!},$$

with $\varsigma \equiv p + \sum_{\beta \in B^{\geq 2}} \epsilon_\beta \pmod 2$, rational τ_l that depend only on the slopes, and $\tau_0 = \prod_{\beta \in B^{\geq 2}} \epsilon_\beta$. So a closing of Theorem 43.1(iii) is, up to finitely many terms in $\mathbb{Q}[\pi^2]$, a sum over the lattice of $(-1)^{\varsigma n} r(n)$ with r a rational function of n whose coefficients lie in $\mathbb{Q}[\pi^2]$, and Lemma 38.32 over the field $\mathbb{Q}(\pi^2)$, applied to $m \mapsto r(n_1+1+m)$ when $\varsigma = 0$ and to $m \mapsto r(n_1+1+2m) - r(n_1+2+2m)$ when $\varsigma = 1$, writes it over 1, the Trailmoments of the lattice inputs on the cosets of the poles at their cuts and differences of the index-one values of these inputs, with coefficients in $\mathbb{Q}[\pi^2]$; here $\pi^2 = 6\,(\mathsf{T}_{2;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$ (Theorem 5.17(iv)).

So the pairing of the lower Gammas, not their number, keeps the terms rational. The two-mark word $\Gamma_{\substack{4\\0}}\big[a,\ a,\ 1-a,\ 1-a\big]$ of Lemma 5.16 has no lower Gamma; the word of two merged pairs on four marks, with one lower Gamma of slope 2 and one of slope -2, pairs off, and the poles of its rational factor lie on the coset $\frac{1}{2} + \mathbb{Z}$; the word of one merged pair on three marks, with one lower Gamma of slope -2, does not pair off, and its terms carry a live input of root rate $\frac{1}{4}$. Exercise 54.7 works the word on four marks.

43.2 The clearing along a ray

Theorem 43.3 (The frame bounds the clearing from below)**.** *Let $p_0, \ldots, p_h \in \mathbb{Q}[k]$, $h \geq 1$, with p_0 and p_h without zeros at the integers $k \geq k_0$; let d_0, d_h and c be the degrees of p_0 and p_h and the quotient of their leading coefficients.*

(i) Let rational sequences $x^{(1)}, \ldots, x^{(h)}$ on the integers $k \geq k_0$ satisfy $\sum_{j=0}^{h} p_j(k)\, x^{(i)}_{k+j} = 0$ and be linearly independent, with frame C_k (Proposition 38.11). If a positive integer D_k makes

every $D_k\, x^{(i)}_{k+l}$, $1 \le i \le h$, $0 \le l < h$, an integer, then $D_k^h\, |C_k| \ge 1$, and as $k \to \infty$

$$\frac{\log D_k}{k} \;\ge\; \frac{d_h - d_0}{h}\,(\log k - 1) + \frac{1}{h}\log\frac{1}{|c|} + O\Big(\frac{\log k}{k}\Big).$$

When $d_0 = d_h$ is the largest degree of the p_j, $\liminf_k \frac{1}{k}\log D_k \ge \frac{1}{h}\log\frac{1}{|c|}$, and $|c|$ is the modulus of the product of the roots of the symbol (Proposition 38.12).

(ii) Let $x_k = \sum_{l=1}^m A_{k,l} v_l - B_k$, $k \ge k_0$, with rational $A_{k,l}$ and B_k and real v_l such that $1, v_1, \dots, v_m$ are linearly independent over $\mathbb{Q}$, satisfy $\sum_j p_j(k)\, x_{k+j} = 0$. Then each of the $m+1$ sequences $(A_{k,l})_k$ and $(B_k)_k$ satisfies the same recurrence, and if h of them are linearly independent, every D_k clearing the rows of $x_k, \dots, x_{k+h-1}$ (Definition 36.5) satisfies (i).

The bound reads the clearing on h consecutive rows together, through one determinant: the frame grows like the k-th power of the product of the roots of the symbol, and the clearing raised to the power h must undo it. For the values $\langle 1\rangle_k$ along a ray with $\kappa_{1,S} > 0$ for every nonempty proper S, the roots of the symbol of every law of the values with rational coefficients include the native value $f(\alpha^\star)$ of the native gauge of the direction and its conjugates (Proposition 38.9). The frame does not say how the clearing is shared among the coordinates; on the rays of Section 43.4 the denominator of the ratio of a reflexive law falls on the coefficient of the one coordinate, at its full power up to what the closings absorb.

43.3 The merit of a ray

Definition 43.4 (The merit of rows along a ray)**.** Let a ray of a family have real origin and $\kappa_{1,S} > 0$ for every nonempty proper S, with the native gauge $\alpha^\star$ of its direction on $\mathbb{R}^{\mathcal{E}}_{>0}$ (Theorem 38.14), and let its values have rows $\langle 1\rangle_k = \sum_{l=1}^m A_{k,l} v_l - B_k$, $k \ge k_0$, over fixed real numbers $v_1, \dots, v_m$ (Definition 36.5), cleared by positive integers D_k. The *merit* of these rows is

$$-\log f(\alpha^\star) - \limsup_{k\to\infty} \frac{1}{k}\log D_k \;\in [-\infty, \infty).$$

Theorem 43.5 (The merit decides the gap along a ray)**.** *In Definition 43.4 let $k_1 \ge k_0$ be an integer with $\kappa_{0,S} + k_1\kappa_{1,S} > 0$ for every nonempty proper S.*

(i) For every $k \ge k_1$, $0 < D_k\langle 1\rangle_k \le D_k\, f(\alpha^\star)^{k-k_1}\, \langle 1\rangle_{k_1}$.

(ii) If the merit is positive, then $D_k\langle 1\rangle_k \to 0$ and some v_l is irrational; for $m = 1$, $v_1 \notin \mathbb{Q}$ and $A_{k,1} \ne 0$ for all large k.

(iii) If $D_k \le C\gamma^k\, d^w_{\lfloor ak+b\rfloor}$ for all large k, with constants $C, \gamma > 0$, $a, w \ge 0$ and b, and $\lfloor ak+b\rfloor \ge 0$, the merit is at least $-\log f(\alpha^\star) - \log\gamma - a\,w\,c_{\mathrm{lcm}}$ (Lemma 37.1), and $\gamma\, e^{awc_{\mathrm{lcm}}} f(\alpha^\star) < 1$ gives (ii).

(iv) If each D_k also clears the rows of $\langle 1\rangle_{k+1}, \dots, \langle 1\rangle_{k+h-1}$, $1, v_1, \dots, v_m$ are linearly independent over $\mathbb{Q}$, the values satisfy a law $\sum_{j=0}^h p_j(k)\langle 1\rangle_{k+j} = 0$, $k \ge k_0$, as in Theorem 43.3 with p_0 and p_h of the largest degree, and h of the sequences $(A_{k,l})_k$, $(B_k)_k$ are linearly independent, then the merit is at most $-\log f(\alpha^\star) + \frac{1}{h}\log|c|$, with $|c|$ the modulus of the product of the roots of the symbol.

On the centre ray of a family, $f(\alpha^\star) = \prod_j K_j(\mathbf{1})^{-2\sigma_j}$ (Theorem 38.15), and a clearing $D_k = \gamma^{k-1} d^w_{k-1}$ passes the gap when $\gamma\, e^{wc_{\mathrm{lcm}}} < \prod_j K_j(\mathbf{1})^{2\sigma_j}$, the minimum of the reciprocal stride on the

orthant. Only the upper bound of the values is used: positivity and the largest value of the stride on the orthant, both read before any closing. By (iv), with the native value among the roots of the symbol, a law of order h leaves positive merit only to a ray whose symbol has roots of modulus larger than $f(\alpha^\star)$.

43.4 Laws at the low end and their closings

Proposition 43.6 (The low end of the law)**.** *Let a ray be as in Proposition 39.34, on n marks, with origin 0, every letter of positive exponent in the direction, $\kappa_{1,S} > 0$ for every nonempty proper S, and the volume V_1 of the direction; let the law of $[1]$ (Definition 39.1) be $\sum_{i=0}^{h} p_i(k)\,\mathrm{Sh}^i[1] = 0$ with $p_0, \dots, p_h \in \mathbb{Q}[k]$, and write $x_k = \langle 1\rangle_k$.*

(i) The values satisfy the law at every integer $k \geq 1$. Further k^{n-1} divides p_0, and with ϖ the coefficient of k^{n-1} in p_0 the values satisfy the low-end relation

$$\varpi\, V_1 + \sum_{i=1}^{h} p_i(0)\, x_i = 0;$$

V_1 is rational. For a solution y of the law on the integers $k \geq 1$, $\sum_i p_i(k) y_{k+i} = 0$ for every $k \geq 1$, call $-\sum_{i=1}^{h} p_i(0)\, y_i$ its low-end coefficient*; that of the values is ϖV_1, the value at $k = 0$ of the continuation of $p_0(k)\langle 1\rangle_k$.*

(ii) Let $h = 2$ and $p_2(k) \neq 0$ at every integer $k \geq 0$, and let c and r be the solutions of the law on $k \geq 1$ with $(c_1, c_2) = \big(1, -p_1(0)/p_2(0)\big)$ and $(r_1, r_2) = \big(0, -\varpi V_1/p_2(0)\big)$. They are rational, the low-end coefficient of c vanishes, that of r is ϖV_1, and

$$x_k = x_1\, c_k + r_k \qquad (k \geq 1):$$

every value has a row in the one coordinate x_1, its coefficient the solution whose low-end coefficient vanishes and whose first term is 1.

Definition 43.7 (Reflexive laws)**.** A recurrence $\sum_{i=0}^{h} p_i(k)\, x_{k+i} = 0$ with $p_i \in \mathbb{Q}[k]$ is *reflexive* with the *ratio* $\lambda \in \mathbb{Q}^\times$ when there is a constant $\gamma \neq 0$ with

$$p_{h-i}(-k-h+1) = \gamma\, \lambda^i\, p_i(k) \qquad (0 \leq i \leq h)$$

as polynomials in k. When p_0 and p_h have the largest degree d of the p_i, the roots of the symbol of a reflexive recurrence are exchanged by $\varrho \mapsto \lambda/\varrho$, and at $h = 2$ their product is $\pm\lambda$.

Theorem 43.8 (The closings read the coordinate of a reflexive law)**.** *Let a ray be as in Proposition 43.6, with the law of $[1]$ reflexive with the ratio λ, and let $\mathsf{C}_j(1) = \mathrm{CT}(f^{-j})$ be the closings of 1 (Definition 39.30).*

(i) $y_k = \lambda^{k-1}\, \mathsf{C}_{k-1}(1)$, $k \geq 1$, is a solution of the law on $k \geq 1$, and its low-end coefficient vanishes.

(ii) If $h = 2$ and $p_2(k) \neq 0$ at every integer $k \geq 0$, then y is the solution c of Proposition 43.6(ii):

$$\langle 1\rangle_k = \lambda^{k-1}\, \mathsf{C}_{k-1}(1)\, \langle 1\rangle_1 + r_k \qquad (k \geq 1),$$

the coefficient of the coordinate read from the closings of the ray, with no lattice sum. If moreover $\langle 1\rangle_1 = A_1 v - B_1$ is a row in one coordinate v, the coefficient of v in $\langle 1\rangle_k$ is $A_1 \lambda^{k-1} \mathsf{C}_{k-1}(1)$.

(iii) If moreover the weights are integers, $\mathsf{C}_j(1) \in \mathbb{Z}$, and with $\lambda = a/b$ in lowest terms, $b > 0$, the coefficient of $\langle 1\rangle_1$ in $\langle 1\rangle_k$ has the denominator $b^{k-1}/\gcd\big(b^{k-1}, \mathsf{C}_{k-1}(1)\big)$.

Corollary 43.9 (The merit of a reflexive ray of order two)**.** *In Theorem 43.8(iii), every clearing D_k of the rows $\langle 1\rangle_k = \lambda^{k-1}\mathsf{C}_{k-1}(1)\,\langle 1\rangle_1 + r_k$ in the coordinate $\langle 1\rangle_1$ has merit (Definition 43.4) at most*

$$-\log f(\alpha^\star) - \log b + \liminf_{k\to\infty} \frac{1}{k} \log\gcd\big(b^{k-1}, \mathsf{C}_{k-1}(1)\big).$$

The closings are the constant terms of the powers of the reciprocal stride, finite sums of products of weights; on a reflexive ray of order two they are the coefficient of the coordinate at every step, up to the power λ^{k-1}, and the clearing pays the full power b^{k-1} of the denominator of the ratio except for what the closings absorb. The ray is then judged by the divisibility of its closings. The centre rays of the lists $\binom{[3]}{1}$ and $\binom{[4]}{1}$ have reflexive laws of order two with the ratios $\frac{1}{9}$ and $\frac{1}{64}$; the exercises derive both laws (Exercises 54.2 and 54.8), and on four marks the rows, the coefficient of the coordinate and the clearing (Exercises 54.9, 54.10 and 54.11).

43.5 The hinge closing as a row over the room

Proposition 43.10 (The hinge closing as a row over the room)**.** *For one table in Theorem 19.13 let $\sup_{\Delta_B} \varrho_B < \inf_{\Delta_R} \varrho_R$, so that the even share closes on the lattices of the level d (Corollary 19.21(i)). Group the residues by the index n of their points and write the closed value as $P_F(\mathbf{m}; s, t) = \sum_{n\ge 0}\langle \Phi_n, \mathcal{X}_n\rangle$, where $\mathcal{X}_n$ lists the data of the room family that the residues at the n-th points contain, its periods at the level shares of those points and, where the two lattices meet, their derivatives in the even share (Corollary 19.21(ii)), and Φ_n lists the coefficients that Corollary 19.21(ii) puts in front of them.*

(i) Let there be numbers $\chi_1, \dots, \chi_h$ and lists $\mathbf{c}_1(n), \dots, \mathbf{c}_h(n)$ with $\mathcal{X}_n = \sum_{i=1}^h \chi_i\, \mathbf{c}_i(n)$ for every n and $\sum_n |\langle \Phi_n, \mathbf{c}_i(n)\rangle| < \infty$ for every i. Then

$$P_F(\mathbf{m}; s, t) = \sum_{i=1}^{h} \chi_i\, \Xi_i, \qquad \Xi_i = \sum_{n\ge 0} \langle \Phi_n, \mathbf{c}_i(n)\rangle :$$

a row over h data of the room, with coefficients that are sums along the lattice of the bunch's data against the sequences $\mathbf{c}_i$.

(ii) When $2\delta^d \notin \mathbb{Z}$ every pole is simple and $\mathcal{X}_n$ lists the two room periods $x_n^\pm$ at the points $\sigma^d = \pm\delta^d - n$. If each sequence $x^\pm$ satisfies a recurrence $\sum_{i=0}^{h_\pm} p_i^\pm(n)\, x_{n+i}^\pm = 0$, $n \ge 0$, with $p_{h_\pm}^\pm(n) \ne 0$ for $n \ge 0$, let $c_i^\pm$, $0 \le i < h_\pm$, be its solutions with the initial values $c_i^\pm(l) = \delta_{il}$, $0 \le l < h_\pm$, rational when the $p_i^\pm$ have rational coefficients. Then $x_n^\pm = \sum_i x_i^\pm\, c_i^\pm(n)$ for every n, and whenever the sums $\sum_n \Phi_n^\pm\, c_i^\pm(n)$ converge absolutely, (i) holds with the $h_+ + h_-$ initial periods $x_0^\pm, \dots, x_{h_\pm - 1}^\pm$.

(iii) When $2\delta^d \in \mathbb{Z}$ the poles lie on the one lattice $\sigma^d = |\delta^d| - n$, $n \in \mathbb{N}$. Let the room period at $\sigma^d = \sigma - n$, a function $x_n(\sigma)$ of σ near $\sigma_0 = |\delta^d|$, satisfy a recurrence $\sum_{i=0}^h p_i(n, \sigma)\, x_{n+i}(\sigma) = 0$ whose coefficients are polynomials in n and σ, with $p_h(n, \sigma_0) \ne 0$ for $n \ge 0$. Then the values $x_n(\sigma_0)$ and the derivatives $x_n'(\sigma_0)$ satisfy the block-triangular recurrence of Proposition 37.17, they are combinations of the $2h$ initial data $x_i(\sigma_0)$, $x_i'(\sigma_0)$, $i < h$, with coefficients that do not depend on the room's periods, and whenever the resulting sums converge absolutely (i) holds with these $2h$ data.

The same holds with the bunch and the room exchanged when $\inf_{\Delta_B} \varrho_B > \sup_{\Delta_R} \varrho_R$*, the share closing on the level* r*.*

Read down a tree of bunches, a hinge closing writes a period as a row over finitely many periods of its room, the coefficients being sums along the lattice of the hinge of the bunch's data against the fundamental solutions of the room's recurrence. The room's periods along the lattice are the moments of one ratio against one form (Corollary 19.21(ii)); when they have tier one, each lattice contributes one room period times one sum along the lattice. Proposition 45.13 gives a condition on the roots of the symbols under which the sums converge.

43.6 Critical primes

Definition 43.11 (Critical primes)**.** Let a ray of a family have an integral direction with the stride $f = \alpha^{\mathbf{m}_1} \prod_L L^{-w_L}$, the product over the distinct letters L of positive exponent w_L, and let its weights lie in a number field $\Bbbk$ that contains the coordinates of a native gauge α_c (Definition 38.4) on the chart $\alpha_{e_0} = 1$. A prime $\mathfrak{p}$ of $\Bbbk$ at which the weights are integral and the coordinates of α_c are units is a *critical prime* of α_c when the native value is not integral there, $v_{\mathfrak{p}}\big(f(\alpha_c)\big) < 0$.

Theorem 43.12 (The letters degenerate at a critical prime)**.** *Let* $\mathfrak{p}$ *be a critical prime of a native gauge* α_c*, with the residue field* κ *and the reduction* $\bar{\alpha}_c \in (\kappa^\times)^{\mathcal{E}}$*, and let* S *be the set of the letters of positive exponent whose valuation* $v_{\mathfrak{p}}(L(\alpha_c))$ *is the largest, a positive number.*

(i) Every letter of S *vanishes at* $\bar{\alpha}_c$ *after reduction, and there are units* u_L *of the local ring at* $\mathfrak{p}$ *with*

$$\sum_{L \in S} \overline{w_L u_L}\, \nabla \bar{L}(\bar{\alpha}_c) = 0,$$

∇ *the gradient in the coordinates* α_e*,* $e \in \mathcal{E}$*, and the bar the reduction.*

(ii) If the characteristic of κ *divides none of the exponents* w_L*,* $L \in S$*, the zero sets of the reduced letters of* S *are not smooth hypersurfaces meeting transversally at* $\bar{\alpha}_c$*: when* S *has one letter, that letter is singular at* $\bar{\alpha}_c$*, and when it has several, their gradients there are linearly dependent.*

Proposition 43.13 (Critical primes and the symbol)**.** *Let* $\sigma(\lambda) = \sum_{j=0}^{h} c_j \lambda^j \in \mathbb{Z}[\lambda]$*,* $c_h \neq 0$*,* $h \geq 1$*, be a symbol (Corollary 38.7) with coprime coefficients, and* K *a number field containing its roots.*

(i) For every root λ *of* σ*,* $c_h\lambda$ *is an algebraic integer.*

(ii) A prime p *divides* c_h *exactly when some root of* σ *has negative valuation at some prime of* K *above* p*; and then at every prime of* K *above* p *some root has negative valuation.*

(iii) Let every root of σ *be the native value of a native gauge whose coordinates lie in* K*, at which the weights are integral and the coordinates are units at the primes above* p*. Then* p *divides* c_h *exactly when some prime of* K *above* p *is a critical prime of one of these native gauges. When* σ *is the symbol of a recurrence whose* p_0 *and* p_h *have the largest degree,* c_0/c_h *is the quotient of their leading coefficients, whose* k*-th power enters the frame (Proposition 38.11).*

At a critical prime the native gauge reduces to a point at which the letters of largest valuation meet badly, so the critical primes of a ray are read from the stride and its critical points before any value is computed, and under (iii) they are the primes of the leading coefficient of the symbol, which the frame carries. The value span of a ray can see fewer primes: on the centre ray of $\binom{[4]}{1}$ the

critical prime 2 sits in the frame and in the denominators of the coefficients, and the coordinate is the Trailmoment $(\mathsf{T}_{3;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$ of the counting input. On the centre ray of $\binom{[3]}{1}$ the native value $\frac{1}{9}$ reduces modulo 3 to a tangency of the letters, and on that of $\binom{[4]}{1}$ the native value $\frac{1}{16}$ reduces modulo 2 to the collapse of three intersection points of the letters onto the native gauge.

Part VIII

Relations and the content

Chapter 44

Relations and separation

A value is the evaluation of a word, and two words of equal value either are related by the proved relations of the theory or are not, a problem that relation blocks make finite. The admitted words form an algebra with an evaluation, the proved relations generate an ideal inside its kernel, and completeness asks for equality. Relation blocks reduce a finite space of words to representatives, each word with a certificate; when the representatives have values independent over the rationals, the block is complete. Words of polynomials on a box are complete outright, a finite census of insertions separates numerators, and the critical-line words of order k of polynomials form a block whose values are the rational combinations of 1 and $(\mathsf{T}_{2k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$; its two representatives have values independent over the rationals exactly when $(\mathsf{T}_{2k+1;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty)) \notin \mathbb{Q}$, and the block is then complete. Independence of values is proved by separators: families of rational matrices whose rows are small on the vector of values. Along a ray the words are complete as functions of the strength: an element of the module of the ray has the values 0 exactly when its closings vanish, and finitely many rational closings decide it. A block is separated at once by a separator, or value by value by separating generators, each a sequence of linear forms small on one value against the values already separated, whose independence measures combine.

44.1 Words and relations

Definition 44.1 (Words, evaluation, relations, completeness)**.** An *admitted word* is a word (Definition 1.1(vi)) given by finite rational data (tables and weights, coefficients, masses, exponents, inputs with a finite presentation, cuts) together with the rule that assigns its value: a convergent integral, a finite part or a continuation, as proved for it. The admitted words span a rational algebra $\mathfrak{W}$, whose product tensors the data, with independent integration variables and separate regulators, and *evaluation* is the map $\mathrm{ev} : \mathfrak{W} \to \mathbb{C}$. The *relation ideal* $\mathfrak{I} \subseteq \mathfrak{W}$ is generated by the proved relations, each on its stated domain: linearity; changes of variables and of order; scale and shape; split, port and gluing; the Gramma relations; the letter relations and the mark relations (Theorems 8.9 and 35.10); the subtraction of a common boundary term from the two sides of a relation; the cut relation of the Trailmoment (Proposition 5.3); the closings. A set of words is *complete* when each of its rational combinations of value zero lies in $\mathfrak{I}$.

Proposition 44.2 (Products keep separate regulators)**.** *If $A(\varepsilon)$ and $A'(\varepsilon')$ have Laurent expansions in disjoint sets of regulators, then* $\mathrm{CT}_{\varepsilon}\,\mathrm{CT}_{\varepsilon'}\big(A(\varepsilon)A'(\varepsilon')\big) = \big(\mathrm{CT}_{\varepsilon}\,A\big)\big(\mathrm{CT}_{\varepsilon'}\,A'\big)$*, and evaluation is multiplicative on $\mathfrak{W}$. Identifying regulators is a further operation:* $\mathrm{CT}(\varepsilon^{-1}) = \mathrm{CT}(\varepsilon) = 0$*, while* $\mathrm{CT}(\varepsilon^{-1}\varepsilon) = 1$*.*

Proposition 44.3 (Soundness)**.** $\mathfrak{I} \subseteq \ker(\mathrm{ev})$.

Proposition 44.4 (A finite matrix of mark relations)**.** *On $[0,1]^d$ let $a_l, b_l > 0$, let $D_1, \dots, D_h$ be rational polynomials positive on the closed box with exponents $p_1, \dots, p_h \in \mathbb{Q}$, and in this statement write $D = \prod_k D_k = \sum_\gamma D_\gamma x^\gamma$ and $x_i \sum_k p_k\, \partial_i D_k \prod_{k' \neq k} D_{k'} = \sum_\gamma D_\gamma^{(i)} x^\gamma$. For every polynomial A and every coordinate i,*

$$\mathrm{mr}_i(A) = D\big[x_i(1-x_i)\,\partial_i A + \big(a_i - (a_i+b_i)x_i\big)A\big] - x_i(1-x_i)\,A \sum_k p_k\, \partial_i D_k \prod_{k' \neq k} D_{k'}$$

has $\int_{[0,1]^d} \mathrm{mr}_i(A) \prod_l x_l^{a_l - 1}(1-x_l)^{b_l - 1} \prod_k D_k^{-p_k - 1}\, dx = 0$ (Theorem 35.10(a) with the letters D_k at the exponents $p_k + 1$ and the polynomial AD), and

$$\mathrm{mr}_i(x^\beta) = \sum_\gamma \Big[\big((\beta_i + a_i)D_\gamma - D_\gamma^{(i)}\big)x^{\beta+\gamma} - \big((\beta_i + a_i + b_i)D_\gamma - D_\gamma^{(i)}\big)x^{\beta+\gamma+\mathbf{e}_i}\Big].$$

For a degree bound these vectors form a finite rational relation matrix; a rational solution of its column equation for a numerator writes the numerator as a sum of polynomials $\mathrm{mr}_i(A_i)$, so that its word vanishes.

Theorem 44.5 (Words of polynomials on a box are complete)**.** *For $P \in \mathbb{Q}[x]$ and rational $a_i, b_i > 0$ the words $\int_{[0,1]^d} P(x) \prod_i x_i^{a_i - 1}(1-x_i)^{b_i - 1}\, dx$ have the mark relations $x^{\beta + \mathbf{e}_i} \equiv \frac{\beta_i + a_i}{\beta_i + a_i + b_i}\, x^\beta$, and every P reduces to*

$$\sum_\beta \big([x^\beta]P\big) \prod_i \frac{(a_i)_{\beta_i}}{(a_i + b_i)_{\beta_i}},$$

the expectation of P under the Dirichlet laws $\mathrm{Dir}_{(a_i,b_i)}$ of the pairs $(x_i, 1-x_i)$, times the base word, of value $\prod_i \Gamma_2^1\left[\begin{matrix} a_i,\ b_i \\ a_i + b_i \end{matrix}\right] > 0$. A word vanishes exactly when its reduction is zero. The same holds for every finite tensor product of such words.

Theorem 44.6 (A finite insertion census separates numerators)**.** *Let ϕ be a measure on $[0,1]^d$ with an integrable density positive on the interior, and D a rational polynomial positive on the closed box. For $|\beta|, |\gamma| \le h$ the matrix $\mathbf{G}_{\beta\gamma} = \int x^{\beta+\gamma} D^{-1}\, d\phi$ is positive definite. For $A = \sum_\beta a_\beta x^\beta$ of degree at most h the insertion values $v_\beta = \int x^\beta A D^{-1}\, d\phi$ satisfy $\mathbf{v} = \mathbf{G}\mathbf{a}$ and $\mathrm{adj}(\mathbf{G})\,\mathbf{v} = \det(\mathbf{G})\,\mathbf{a}$: these $\binom{d+h}{d}$ values determine A. Equivalently, the Laplace transform $t \mapsto \int AD^{-1} e^{-\langle t, x\rangle}\, d\phi$ has all its Taylor coefficients of degree at most h zero at $t = 0$ only for $A = 0$.*

Evaluation is multiplicative because a product of words keeps the regulators of its factors apart; identifying two regulators is a new operation, not a relation. Every relation the theory proves lies in the kernel of evaluation, and completeness asks whether the kernel holds anything more. On a box against positive letters the mark relations form a finite rational matrix, so that vanishing is certified by linear algebra; for polynomials on a box without a letter the relations reduce every insertion to one rational multiple of the base word, and with a letter the values of finitely many monomial insertions, through the positive definite matrix $\mathbf{G}$ of Theorem 44.6, recover the insertion itself.

44.2 Relation blocks

Definition 44.7 (Relation block)**.** A *relation block* is a finite-dimensional rational space V of admitted words with a matrix C whose columns are proved relations in V, each with its derivation.

Rational row reduction gives representatives $\mathfrak{w}_0, \dots, \mathfrak{w}_s$ of $V/\operatorname{im} C$ and for every $\mathfrak{w} \in V$ a certificate $\mathfrak{w} = C\mathbf{v} + \sum_j c_j \mathfrak{w}_j$.

Proposition 44.8 (Separation completes a block)**.** *If* $\operatorname{ev}(\mathfrak{w}_0), \dots, \operatorname{ev}(\mathfrak{w}_s)$ *are linearly independent over* $\mathbb{Q}$*, then* $\ker(\operatorname{ev}|_V) = \operatorname{im} C$*.*

Theorem 44.9 (Completeness from separated blocks)**.** *If every finite set of words of a subalgebra* $\mathfrak{W}' \subseteq \mathfrak{W}$ *lies in a relation block whose representatives have values linearly independent over* $\mathbb{Q}$*, then* $\mathfrak{W}'$ *is complete, and each of its words of value zero has a finite derivation, its certificate.*

Proposition 44.10 (Tensoring relation blocks)**.** *For blocks* (V_1, C_1) *and* (V_2, C_2) *the induced relations on* $V_1 \otimes V_2$ *have the matrix* $\left[\, C_1 \otimes I \;\middle|\; I \otimes C_2 \,\right]$*, with quotient* $(V_1/\operatorname{im} C_1) \otimes (V_2/\operatorname{im} C_2)$*, and the values of the representatives are the products of the values (Proposition 44.2).*

Proposition 44.11 (The critical polynomial block)**.** *For an integer* $k \geq 1$ *and* $P \in \mathbb{Q}[x]$ *put* $Q_P(u) = \frac{P(2u)-P(1)}{1-2u}$ *and* $h(P) = \frac{2}{(2k)!}\, \mathbb{E}_{Y \sim \mathbb{P}_{\mathrm{crit}}}\big[Q_P^{(2k-1)}(\frac{1}{2} + iY)\big]$*. Then* $h(P) \in \mathbb{Q}$ *and*

$$\operatorname{crit}_k[P(2u)] = h(P) + (2^{2k+1} - 1)\, P(1)\, (\mathsf{T}_{2k+1;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((0,\infty)).$$

So the values of the rational constants and of the critical-line words of order k *of polynomials factor through the surjective coordinate map* $(c, P) \mapsto \big(c + h(P), (2^{2k+1} - 1)P(1)\big) \in \mathbb{Q}^2$ *followed by* $(a, b) \mapsto a + b\, (\mathsf{T}_{2k+1;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((0,\infty))$*, which is injective exactly when* $(\mathsf{T}_{2k+1;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((0,\infty)) \notin \mathbb{Q}$*; moving the cut of the Trailmoment subtracts a rational head.*

A relation block is the finite form of completeness: inside a finite space of words, rational row reduction by the proved relations leaves representatives and certificates, and independence of the values of the representatives over the rationals makes the block complete (Proposition 44.8). Blocks tensor, their quotients tensoring and the values of their representatives multiplying, so a product of blocks is complete as soon as the products of those values are independent over the rationals. The critical-line words of order k of polynomials have a block whose quotient has dimension at most two: every such word is a rational number plus a rational multiple of $(\mathsf{T}_{2k+1;(1)}[x]\, \mathbb{I}_{\mathbb{Z}})((0,\infty))$, read off two coordinates of the polynomial, and the values of the two representatives are independent over the rationals exactly when that Trailmoment is irrational, the block being then complete.

44.3 Separators

Theorem 44.12 (A primitive exterior separator)**.** *Let* $v = (v_1, \dots, v_s, 1) \in \mathbb{R}^{s+1}$*. For a rational* $s \times (s+1)$ *matrix* A *of rank* s *with rows* r_i*, let* $w \in \mathbb{Q}^{s+1}$ *be its cofactor vector,* $\det[x; A] = \langle x, w \rangle$ *for all* x*, and* $z = Mw$ *its primitive integral multiple,* $M > 0$*. If* D_i *clears* r_i*, then* $M = \prod_i D_i / c$ *with* c *the greatest common divisor of the maximal minors of* $\operatorname{diag}(D_i)A$*. Put* $y_i = \langle r_i, v \rangle$*, let* $\hat{A}_i$ *be the other rows restricted to the first* s *columns, and*

$$\beta(A) = M \sum_i |y_i| \sum_{J \subseteq \{1,\dots,s\},\ |J| = s-1} \big|\det \hat{A}_i[:, J]\big|.$$

If for all large n *finitely many such matrices* $A_1^{(n)}, \dots, A_{k_n}^{(n)}$ *have primitive cofactor vectors spanning* $\mathbb{Q}^{s+1}$ *and* $\max_l \beta(A_l^{(n)}) \to 0$*, then* $1, v_1, \dots, v_s$ *are linearly independent over* $\mathbb{Q}$*.*

Corollary 44.13 (Separation with bounded integer entries)**.** *If integer matrices $A_l^{(n)}$ with spanning cofactor vectors have entries at most $H_n \geq 1$ and $|\langle r_i, v\rangle| \leq \epsilon_n$ for every row, with $H_n^{s-1}\epsilon_n \to 0$, then $1, v_1, \ldots, v_s$ are linearly independent over $\mathbb{Q}$. In rates: if rational matrices with spanning cofactor vectors have entries at most $e^{an+o(n)}$, a common clearing integer at most $e^{bn+o(n)}$ and row values at most $e^{-cn+o(n)}$, with $c > sb + (s-1)a$, the same conclusion holds.*

Corollary 44.14 (Consecutive rows)**.** *Let rows $r_k \in \mathbb{Q}^{s+1}$ be such that the square matrix of the rows $r_k, \ldots, r_{k+s}$ is invertible for large k. Then for each such k the $s+1$ matrices omitting one of these rows have spanning primitive cofactor vectors, and Theorem 44.12 applies with these matrices. If the coordinate sequences of the rows satisfy one recurrence of order $s+1$ whose extreme coefficients have no integer zeros from k_0 on, invertibility of that matrix at k_0 gives it for every $k \geq k_0$.*

Theorem 44.15 (Function level: pole pinning)**.** *Let f and g be meromorphic on a connected open subset of $\mathbb{C}$. If f has infinitely many poles at which g is holomorphic, and the values of g at those poles include infinitely many distinct numbers, then no nonzero polynomial $Q \in \mathbb{C}[X, Y]$ has $Q(f, g) \equiv 0$.*

A separator is a family of rational matrices whose rows are nearly orthogonal to the vector of values: a primitive integral multiple of the cofactor vector of each matrix pairs with any integer relation to an integer, and if the rows are small enough against the clearing and the bounds on the entries, no rational relation among the values survives. Consecutive rows of a recurrence give such matrices as soon as one square matrix of $s+1$ consecutive rows is invertible. At the level of functions, a function with infinitely many poles at which a second function takes infinitely many values satisfies no polynomial relation with it.

44.4 Completeness along a ray

A ray carries its words as functions of the strength. Their relations are read in the module of the ray, and the closings are a solution that sees every one of them.

Theorem 44.16 (Completeness along a ray)**.** *Let a ray have an integral origin and an integral direction in which every letter has a positive exponent, with $\kappa_{1,S} > 0$ for every nonempty proper S, and let $\mathfrak{M}$ be its module (Definition 39.1).*

(i) An element $m \in \mathfrak{M}$ has the values $\langle m\rangle_k = 0$ for all large integers k exactly when its closings vanish, $V_{\mathsf{C}}(m) = 0$, and then the continuation of $\langle m\rangle_k$ in k vanishes identically. So every relation among the values of the words of the ray, as functions of the strength, is certified by the closings, a proved relation (Definition 44.1); the elements of $\mathfrak{M}$ with the values 0 form the submodule $\mathrm{Ann}(V_{\mathsf{C}})$, which is 0 exactly when the closings vanish on no nonzero submodule, as they do on every irreducible submodule on which they are not zero.

(ii) Let $m \in \mathfrak{M}$ be the class of a rational combination of insertions, let d be the dimension of the submodule generated by m, and let $\sum_{i=0}^{d} q_i(k)\,\mathrm{Sh}^i m = 0$ with $q_i \in \mathbb{Q}[k]$, $q_0 q_d \neq 0$. Then the closings of m, which are rational numbers, satisfy

$$\sum_{i=0}^{d} q_i(k)\, V_{\mathsf{C}}(m)(k+i) = 0$$

at every integer $k \leq -j(m) - d$, and m has the values 0 along the ray exactly when $V_{\mathsf{C}}(m)$ vanishes at d consecutive integers below every integer zero of q_0 and of q_d. In particular

whether two words of the ray have equal values along it is decided by finitely many rational numbers.

So along a ray completeness holds outright, and the decision is exact. The values are moreover positive (Theorem 38.14(i)), so a linear form that is a value does not vanish, and consecutive rows of a recurrence are nondegenerate as soon as one square matrix of them is (Corollary 44.14); these are the inputs that the separation of numbers below takes from the ray.

44.5 Separating generators

A block is complete when the values of its representatives are independent over $\mathbb{Q}$ (Proposition 44.8). A separator proves the independence of all of them at once (Corollary 44.13). A separating generator proves it for one more value against values already separated, with an explicit measure, and the measures combine.

Lemma 44.17 (A separating generator)**.** *Let $1, v_1, \dots, v_j \in \mathbb{R}$ be linearly independent over $\mathbb{Q}$ with the independence measure $\mu \geq 0$: there is H_0 such that $|c_0 + \sum_i c_i v_i| \geq H^{-\mu}$ for every integer vector $c \neq 0$ of height $H = \max_i |c_i| \geq H_0$. A* separating generator *of a number v against them is a sequence of linear forms*

$$L_n = A_n v - \sum_{i=1}^{j} B_{n,i} v_i - B_{n,0}, \qquad n \geq n_0,$$

with rational coefficients and integers $D_n \geq 1$ such that $D_n A_n$ and $D_n B_{n,i}$ are integers, for which $0 < |L_n| \leq e^{-Fn+o(n)}$, $\max(|A_n|, |B_{n,i}|) \leq e^{hn+o(n)}$ and $D_n \leq e^{dn+o(n)}$, and whose consecutive coefficient rows $(A_n, B_{n,0}, \dots, B_{n,j})$ are not proportional. If

$$F > d + \mu\,(h + d),$$

then $1, v_1, \dots, v_j, v$ are linearly independent over $\mathbb{Q}$, with the independence measure

$$\mu' = \mu + \frac{(1+\mu)^2 (h+d)}{F - d - \mu(h+d)} + \varepsilon \qquad \text{for every } \varepsilon > 0.$$

Theorem 44.18 (Separating generators in turn)**.** *Let a relation block (Definition 44.7) have the representatives $w_0, \dots, w_s$ with $\mathrm{ev}(w_0) = 1$, and let them be ordered so that each $\mathrm{ev}(w_j)$, $j \geq 1$, has a separating generator against $1, \mathrm{ev}(w_1), \dots, \mathrm{ev}(w_{j-1})$ with the rates (F_j, h_j, d_j) of Lemma 44.17. Put $\mu_0 = 0$ and let μ_j be the measure that Lemma 44.17 gives at step j from μ_{j-1}. If $F_j > d_j + \mu_{j-1}(h_j + d_j)$ for every j, the block is complete, its values have the independence measure μ_s, and every word of value zero in it has a finite derivation from the proved relations.*

The inputs of a separating generator are read on rays that carry the value: the rate F from the native value of the direction (Proposition 38.9), the height h from the frame of the law (Proposition 38.12), the clearing d from the orders of the poles of the closing (Lemma 38.32), and the nonvanishing and the nondegeneracy from the ray itself (Theorem 44.16 and the paragraph after it).

Chapter 45

The content and its coaction

The content is the algebra of the trails of lattice inputs at rational frequencies, on rational cosets and at rational cuts, read modulo the proved relations. At the level M it is spanned by the roots of unity of order M times the trails of the counting lattice at the cut 0 whose frequencies have the denominator M; it is closed under products, it holds every trail with rational data at the level that its denominators fix, and it holds the differences of the index-one values of lattice inputs on rational cosets, so the sums along the lattices of paired words lie in it. Its values are the chains of level M: the iterated integrals from 0 to 1 whose letters are 0 and the roots of unity of order M, each a trail whose frequencies are the ratios of its consecutive nonzero letters; read between 0 and a root of unity in either order a chain is again a value of the content. The cutting rule keeps a subsequence of the letters of a chain and reads every run of the letters it drops between the two letters that bound it; on the symbols of chains it is a coassociative coaction, graded by the weight and compatible with the rotations and the reversal of chains. A live input has a letter too, its generating function, which satisfies a linear differential equation singular at the reciprocals of the roots of the symbol of its recurrence; the letter of a product of two live inputs continues across every point that is not a product of singular points of the letters of the factors, and the row of a hinge closing is the room's periods against the letters of the live inputs built on the room's fundamental solutions. Beyond the content a period is read through chains over the factors of its equation, whatever their monodromy, and along a ray those factors are generated down the hinge tree. What a period needs is read on its word along the canonical hinge tree: the prime nodes carry its content, the series and parallel nodes contribute stacked Gammas and powers of one mark's input, and a repetition adds nothing to the group of an input that the word reads on a scale, a class of any size needing no more than one mark's group; the word that reads every value of a ray through its stride's law needs the group of that input, a quotient of the group of the pencil, which on the class grows with the number of marks. Along the tree a period pays for each series or parallel node either in work, through the fibre of the node, or on one scale, through the transforms of the cells below it: paid in work it never reads more than one mark's input, and paid on scales its work does not grow with the multiplicities and its group is a quotient of the group of one mark's input, its dilations and the transforms of the distinct cells directly below a series or parallel node, born at the prime nodes and where the tree changes its kind.

45.1 The content

Definition 45.1 (The content)**.** Let $M \geq 1$ be an integer and μ_M the group of the roots of unity of order dividing M. A *trail of level M* is the trail (Definition 5.23) at the cut 0 of a lattice input

on $\mathbb{Z}^d$ at frequencies in $\frac{1}{M}\mathbb{Z}$, with positive integer indices and no constant columns,

$$T = \big(\mathsf{T}_{\boldsymbol{\nu};I_d}[y]\; e^{2\pi i\langle \mathbf{a},y\rangle}\,\mathbb{I}_{\mathbb{Z}^d}\big)\big(\{0<y_1<\cdots<y_d\}\big), \qquad d\geq 1,\ \boldsymbol{\nu}\in\{1,2,\dots\}^d,\ \mathbf{a}\in\big(\tfrac{1}{M}\mathbb{Z}\big)^d,$$

with $e^{2\pi i a_d}\neq 1$ when $\nu_d=1$, read as the limit of its heads over $\{0<y_1<\cdots<y_d\leq N\}$ as $N\to\infty$, which exists and is the Trailmoment itself when $\nu_d\geq 2$ (Theorem 5.27); $|\boldsymbol{\nu}|$ is its *weight* and d its *depth*. The *content of level* M, $\mathcal{C}^{(M)}$, is the $\mathbb{Q}$-span in $\mathfrak{W}/\mathfrak{I}$ (Definition 44.1) of the classes of the words ζ and ζT, for $\zeta\in\mu_M$, read as $e^{2\pi i r/M}$, and T a trail of level M; $\mathcal{C}^{(M)}_w$ is the span of those with T of weight at most w, and the *content* is $\mathcal{C}=\bigcup_M \mathcal{C}^{(M)}$.

The content is not the content $\mathcal{C}_M$ of a childcule M in Definition 20.58, a $\mathcal{Z}$-module of values of periods; the level is written as an upper index to keep the two apart. The algebra $\mathcal{Z}$ of Definition 20.58 maps onto the subalgebra of $\mathcal{C}^{(1)}$ generated by its trails of depth one, the Trailmoments $(\mathsf{T}_{k;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$, $k\geq 2$ (Proposition 45.2(i)).

Proposition 45.2 (The content is an algebra)**.** *(i) $\mathcal{C}^{(M)}$ contains the classes of* 1 *and of every product of Trailmoments $(\mathsf{T}_{k;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$, $k\geq 2$, so it contains the image of $\mathcal{Z}$ (Definition 20.58); and $\mathcal{C}^{(M)}\subseteq\mathcal{C}^{(M')}$ when $M\mid M'$.*

(ii) Let T and T' be trails of level M with the data $(\nu_i,a_i)_{i\leq d}$ and $(\nu'_j,a'_j)_{j\leq d'}$. For a surjection ϕ from the disjoint union $\{1,\dots,d\}\sqcup\{1',\dots,d'\}$ onto $\{1,\dots,e\}$, strictly increasing on each of the two parts, let T_ϕ be the trail of level M of depth e whose r-th point has the index $\sum_{\phi(x)=r}\nu_x$ and the frequency $\sum_{\phi(x)=r}a_x$. Then

$$TT'=\sum_\phi T_\phi,$$

the sum over these surjections, of depths between $\max(d,d')$ and $d+d'$, every T_ϕ of the weight $|\boldsymbol{\nu}|+|\boldsymbol{\nu}'|$.

(iii) So $\mathcal{C}^{(M)}$ is a $\mathbb{Q}$-algebra with $\mathcal{C}^{(M)}_w\,\mathcal{C}^{(M)}_{w'}\subseteq\mathcal{C}^{(M)}_{w+w'}$, and $\mathcal{C}$ is a $\mathbb{Q}$-algebra.

Proposition 45.3 (Cosets, cuts and index one)**.** *Let $M,M'\geq 1$ be integers.*

(i) Let a trail have a lattice input on $\prod_{i=1}^d(b_i+\mathbb{Z})$ with $b_i\in\frac{1}{M}\mathbb{Z}$, at frequencies $a_i\in\frac{1}{M'}\mathbb{Z}$, with positive integer indices, no constant columns and a cut $N\in\frac{1}{M}\mathbb{Z}$, $N\geq 0$, and with $e^{2\pi i a_d}\neq 1$ when $\nu_d=1$, read as the limit of its heads. Then its class lies in $\mathcal{C}^{(MM')}$, and the class of every head of it lies in the span of the classes of $\mu_{MM'}$; its value is a combination, with coefficients in $\mathbb{Q}(\mu_{MM'})$, of 1 *and the trails of level MM' of depths at most d.*

(ii) For $b,b'\in\frac{1}{M}\mathbb{Z}$ and cuts $N,N'\in\frac{1}{M}\mathbb{Z}$, $N,N'\geq 0$, the difference $(\mathsf{T}_{1;(1)}[x]\,\mathbb{I}_{b+\mathbb{Z}})((N,\infty))-(\mathsf{T}_{1;(1)}[x]\,\mathbb{I}_{b'+\mathbb{Z}})((N',\infty))$ of index-one values (Definition 5.2) has its class in $\mathcal{C}^{(M)}$.

So the sum along a lattice of a paired word at integer data (Proposition 43.2), a combination of Trailmoments of lattice inputs on rational cosets at their cuts and differences of their index-one values with coefficients in $\mathbb{Q}[(\mathsf{T}_{2;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))]$, lies in the content. The values met on the centre rays of the lists of three and four marks are trails of depth one: at the frequency $\frac{1}{3}$ and the index 2, and on the coset $\frac{1}{2}$ at the index 3, which the coset relation returns to the counting input; Exercise 56.1 reads them.

45.2 Chains

Definition 45.4 (Chains)**.** For distinct points $a_0, a_{w+1} \in \mathbb{C}$ and points $a_1, \dots, a_w$, $w \geq 0$, none on the open segment from a_0 to a_{w+1}, the *chain* is the iterated integral along that segment, $\gamma(t) = a_0 + t(a_{w+1} - a_0)$,

$$\mathrm{I}(a_0; a_1, \dots, a_w; a_{w+1}) = \int_{0<t_1<\cdots<t_w<1} \prod_{i=1}^{w} \frac{\gamma'(t_i)\,dt_i}{\gamma(t_i) - a_i},$$

with $\mathrm{I}(a_0; \varnothing; a_{w+1}) = 1$, wherever it converges. The $a_1, \dots, a_w$ are its *letters*, a_0 and a_{w+1} its *ends* and w its *weight*. It converges when its first letter differs from its first end and its last letter from its last end (Proposition 45.6(i), below). A chain is *of level M* when its ends and letters lie in $\{0\} \cup \mu_M$.

Proposition 45.5 (The content as chains)**.** *(i) A trail T of level M with the data $(\nu_i, a_i)_{i \leq d}$ is*

$$T = (-1)^d \,\mathrm{I}\big(0;\ c_1^{-1}, 0^{\nu_1 - 1},\ \dots,\ c_d^{-1}, 0^{\nu_d - 1};\ 1\big), \qquad c_i = e^{2\pi i(a_i + \cdots + a_d)} \in \mu_M,$$

a chain of level M from 0 to 1 whose first letter is not 0 and whose last letter is not 1 (Theorem 5.27).

(ii) Conversely, let $\mathrm{I}(0; a_1, \dots, a_w; 1)$ be a chain of level M with $a_1 \neq 0$ and $a_w \neq 1$, let $j_1 < \cdots < j_d$ be the positions of its nonzero letters, $j_{d+1} = w+1$, and put $c_i = a_{j_i}^{-1}$, $\nu_i = j_{i+1} - j_i$, $c_{d+1} = 1$. With frequencies $a'_i \in \frac{1}{M}\mathbb{Z}$ such that $e^{2\pi i a'_i} = c_i / c_{i+1}$, the chain is $(-1)^d$ times the trail of level M with the data $(\nu_i, a'_i)_{i \leq d}$.

(iii) So the values of $\mathcal{C}^{(M)}$ form the $\mathbb{Q}(\mu_M)$-span of 1 and of the chains of level M from 0 to 1 with first letter not 0 and last letter not 1, and those of $\mathcal{C}_w^{(M)}$ the span of 1 and of such chains of weight at most w.

Proposition 45.6 (Chains with an end at zero)**.** *(i) A chain whose first letter differs from its first end and whose last letter differs from its last end converges absolutely.*

(ii) For $\lambda \in \mathbb{C}^\times$ and $\eta \in \mathbb{C}$, $\mathrm{I}(\lambda a_0 + \eta; \lambda a_1 + \eta, \dots, \lambda a_w + \eta; \lambda a_{w+1} + \eta) = \mathrm{I}(a_0; a_1, \dots, a_w; a_{w+1})$.

(iii) $\mathrm{I}(a_{w+1}; a_w, \dots, a_1; a_0) = (-1)^w \,\mathrm{I}(a_0; a_1, \dots, a_w; a_{w+1})$.

(iv) Every chain of level M with one end 0 and the other in μ_M, whose first letter differs from its first end and whose last letter differs from its last end, is ± 1 times a chain of level M from 0 to 1 with first letter not 0 and last letter not 1, so its value lies in the values of $\mathcal{C}^{(M)}$.

A chain between two singular points, two points of $\{0\} \cup \mu_M$, is the verb that the cutting rule uses on its right factors; with one end at 0 it is a value of the content, and on the symbols below it is read as it stands.

45.3 The cutting rule

Definition 45.7 (Symbols of chains)**.** For an integer $M \geq 1$ the *symbols of level M* form the commutative $\mathbb{Q}(\mu_M)$-algebra $\mathfrak{S}_M$ of polynomials in the *formal chains* $\mathrm{I}^{\mathfrak{s}}(a_0; a_1, \dots, a_w; a_{w+1})$, $w \geq 1$, with $a_0, \dots, a_{w+1} \in \{0\} \cup \mu_M$ and $a_0 \neq a_{w+1}$, as independent variables. In $\mathfrak{S}_M$ one writes $\mathrm{I}^{\mathfrak{s}}(a; \varnothing; b) = 1$ for all a, b, and $\mathrm{I}^{\mathfrak{s}}(a; a_1, \dots, a_w; a) = 0$ for $w \geq 1$. The *weight* of $\mathrm{I}^{\mathfrak{s}}(a_0; a_1, \dots, a_w; a_{w+1})$ is w, and $\mathfrak{S}_M$ is graded by the weight, the weight of a product being

the sum. The *symbol* of a trail of level M is $(-1)^d\,\mathrm{I}^{\mathfrak{s}}\big(0;c_1^{-1},0^{\nu_1-1},\dots,c_d^{-1},0^{\nu_d-1};1\big)$ (Proposition 45.5(i)), and the *realization* of a formal chain with one end 0, the other in μ_M, first letter not its first end and last letter not its last end, is the chain with the same entries (Proposition 45.6(i)).

Definition 45.8 (The cutting rule)**.** The *cutting rule* is the homomorphism of $\mathbb{Q}(\mu_M)$-algebras $\Delta:\mathfrak{S}_M\to\mathfrak{S}_M\otimes_{\mathbb{Q}(\mu_M)}\mathfrak{S}_M$ given on the formal chains by

$$\Delta\,\mathrm{I}^{\mathfrak{s}}(a_0;a_1,\dots,a_w;a_{w+1})=\sum_{S\subseteq\{1,\dots,w\}}\mathrm{I}^{\mathfrak{s}}(a_0;a_S;a_{w+1})\otimes\prod_{p=0}^{|S|}\mathrm{I}^{\mathfrak{s}}\big(a_{s_p};a_{s_p+1},\dots,a_{s_{p+1}-1};a_{s_{p+1}}\big),$$

where $s_1<\dots<s_{|S|}$ lists S, $s_0=0$, $s_{|S|+1}=w+1$ and $a_S=(a_{s_1},\dots,a_{s_{|S|}})$: the left factor keeps the letters of S between the same ends, and each right factor is a run of dropped letters read between the two kept letters, or ends, that bound it. The *counit* $\varepsilon:\mathfrak{S}_M\to\mathbb{Q}(\mu_M)$ is the homomorphism that vanishes on the formal chains. For $\lambda\in\mu_M$ the *rotation* ρ_λ multiplies every entry of every formal chain by λ, and the *reversal* ϱ maps $\mathrm{I}^{\mathfrak{s}}(a_0;a_1,\dots,a_w;a_{w+1})$ to $(-1)^w\,\mathrm{I}^{\mathfrak{s}}(a_{w+1};a_w,\dots,a_1;a_0)$; both extend to automorphisms of the algebra.

Theorem 45.9 (The cutting rule is a coaction)**.** *(i)* Δ *is coassociative and counital:* $(\Delta\otimes\mathrm{id})\circ\Delta=(\mathrm{id}\otimes\Delta)\circ\Delta$ *and* $(\varepsilon\otimes\mathrm{id})\circ\Delta=\mathrm{id}=(\mathrm{id}\otimes\varepsilon)\circ\Delta$.

(ii) Δ *preserves the weight: it maps a symbol of weight* w *to a sum of tensors of weights* w' *and* w'' *with* $w'+w''=w$*; and for every formal chain* x*,* $\Delta x-x\otimes1-1\otimes x$ *is a sum of tensors whose two factors have positive weights.*

(iii) $\Delta\circ\rho_\lambda=(\rho_\lambda\otimes\rho_\lambda)\circ\Delta$ *for* $\lambda\in\mu_M$*, and* $\Delta\circ\varrho=(\varrho\otimes\varrho)\circ\Delta$.

Proposition 45.10 (The cutting rule on motivic chains)**.** *Let* $M\geq1$*. Every chain of level* M *(Definition 45.4) between distinct points* a_0,a_{w+1} *of* $\{0\}\cup\mu_M$*, read with tangential base points at an end that equals the adjacent letter, is the period of a motivic period* $\mathrm{I}^{\mathfrak{m}}(a_0;a_1,\dots,a_w;a_{w+1})\in\mathcal{P}^{\mathrm{mot}}$ *(Definition 34.5), the* motivic chain*, with* $\mathrm{I}^{\mathfrak{m}}(a;\varnothing;b)=1$*,* $\mathrm{I}^{\mathfrak{m}}(a;a_1,\dots,a_w;a)=0$ *for* $w\geq1$*, and* $\mathrm{I}^{\mathfrak{m}}(0;0;1)=\mathrm{I}^{\mathfrak{m}}(0;1;1)=0$*. Its coaction is the cutting rule (Definition 45.8) with the left factors read as motivic chains and the right factors as their de Rham periods:*

$$\Delta\,\mathrm{I}^{\mathfrak{m}}(a_0;a_1,\dots,a_w;a_{w+1})=\sum_{S\subseteq\{1,\dots,w\}}\mathrm{I}^{\mathfrak{m}}(a_0;a_S;a_{w+1})\otimes\prod_{p=0}^{|S|}\mathrm{I}^{\mathrm{dR}}\big(a_{s_p};a_{s_p+1},\dots,a_{s_{p+1}-1};a_{s_{p+1}}\big).$$

The motivic chains satisfy the shuffle product, the composition of paths and the reversal of Proposition 45.6(iii), which the formal chains of Definition 45.7 do not; so the realization of the formal chains by the motivic chains intertwines the cutting rule with the coaction and is not injective.

On the symbol of a trail of level M the left factors are the symbols of the chains from 0 to 1 of the letters kept, up to sign the symbol of a trail of level M whenever the kept letters begin with a letter other than 0 and end with one other than 1 (Proposition 45.5(ii)), and the right factors are runs of the trail's letters read between singular points, which at tier one are 0 and roots of unity of order M. Exercise 56.2 computes the rule on the symbols of the trails $(\mathsf{T}_{3;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$ and of index 2 at the frequency $\frac{1}{3}$.

45.4 The letter of a live input

Definition 45.11 (The letter of an input)**.** The *letter* of the input with density ψ on the integers $n \geq n_0$ of the counting input, $n_0 \in \mathbb{N}$, is the power series $L_\psi(z) = \sum_{n \geq n_0} \psi(n)\, z^n$. At $z = e^{-u}$ it is the Laplace transform of the input beyond the cut $n_0 - 1$ (Definition 5.4), and where the series converges at $z = 1$ its value there is the Trailmoment at index zero $(\mathsf{T}_{0;(1)}[x]\, \psi\, \mathbb{I}_{\mathbb{Z}})((n_0 - 1, \infty)) = \sum_{n \geq n_0} \psi(n)$. The letter of the lattice input at the frequency a on $\mathbb{Z}$ beyond the cut 0 is $e^{2\pi i a} z/(1 - e^{2\pi i a} z)$, singular at the letter $e^{-2\pi i a}$ of its chains (Proposition 45.5).

Proposition 45.12 (The letter of a live input)**.** *Let ψ satisfy $\sum_{i=0}^{h} p_i(n)\, \psi(n+i) = 0$ for the integers $n \geq n_0$, with $p_i \in \mathbb{C}[n]$, let d be the largest degree of the p_i and $\sigma(\lambda) = \sum_i c_i \lambda^i$ the symbol, c_i the coefficient of n^d in p_i; write $\theta = z\frac{d}{dz}$.*

(i) As formal power series, $\sum_{i=0}^{h} z^{h-i} p_i(\theta - i)\, L_\psi = Q$ for a polynomial Q of degree less than $n_0 + h$: a linear differential equation of order d whose coefficient of $\frac{d^d}{dz^d}$ is $z^d \sum_i c_i z^{h-i} = z^{d+h}\sigma(1/z)$. Its singular points in $\mathbb{C}^\times$ are the reciprocals of the nonzero roots of σ.

(ii) Let $c_h \neq 0$, that is, p_h of the largest degree, and let ϱ be the largest modulus of a root of σ. Then for every $\eta > 0$, $|\psi(n)| \leq C_\eta(\varrho + \eta)^n$ for $n \geq n_0$; L_ψ converges on $|z| < 1/\varrho$ and continues analytically along every path in $\mathbb{C}^\times$ that starts in that disc and avoids the reciprocals of the nonzero roots of σ, and to the plane cut along the rays $\{t/\lambda : t \geq 1\}$, λ a nonzero root of σ.

(iii) The termwise product of two sequences that satisfy, for large n, recurrences of orders h and h' with polynomial coefficients and nonzero extreme coefficients satisfies, for large n, one of order at most hh' with nonzero extreme coefficients.

(iv) Let ψ and ψ' be as in (ii), with symbols σ and σ'. Then the letter of $\psi\psi'$ converges on $|z| < 1/(\varrho\varrho')$ and continues analytically to the plane cut along the rays $\{t/(\lambda\lambda') : t \geq 1\}$, λ and λ' nonzero roots of σ and σ'.

Proposition 45.13 (The row of a hinge closing read by letters)**.** *In Proposition 43.10(ii) let the recurrences of the room have nonzero extreme coefficients and $p^\pm_{h_\pm}$ of the largest degree, with $\varrho^\pm$ the largest modulus of a root of their symbols, and let the coefficients $\Phi^\pm_n$ of the room periods $x^\pm_n$ satisfy, for large n, recurrences of the same kind, with $\varrho^\pm_\Phi$ the largest modulus of a root of their symbols. If $\varrho^\pm_\Phi \varrho^\pm < 1$, then:*

(i) every sum $\Xi^\pm_i = \sum_n \Phi^\pm_n\, c^\pm_i(n)$ converges absolutely, it is the value $L_{\psi^\pm_i}(1)$ of the letter of the live input $\psi^\pm_i(n) = \Phi^\pm_n\, c^\pm_i(n)$, and

$$P_F(\mathbf{m}; s, t) = \sum_{\pm} \sum_{i < h_\pm} x^\pm_i\, L_{\psi^\pm_i}(1) :$$

the room's $h_+ + h_-$ initial periods against the letters of the live inputs built on its fundamental solutions;

(ii) each $L_{\psi^\pm_i}$ satisfies a linear differential equation with polynomial coefficients and continues analytically to the plane cut along the rays $\{t/(\lambda\lambda') : t \geq 1\}$, λ a nonzero root of the symbol of the room's recurrence and λ' one of the symbol of the coefficients' recurrence.

At tier one the room's recurrence has order one, its fundamental solution is a power times a stacked Gamma (Proposition 38.11), and each lattice carries one letter; at higher tier the room's periods open into its h fundamental solutions, and the letters of the row are singular only at products of the reciprocals of the roots of the two symbols.

45.5 Separation of the content

The words of the content carry motivic values, on which the cutting rule acts (Proposition 45.10). At the levels 1 to 4 the separation of motivic values is complete: the cuts of the cutting rule, the parts with one run, separate what they see by induction on the weight; what they do not see is, in each weight, at most one separating generator, a trail of depth one whose value is not zero, and the power of the circle; and the value reads these. So every word of the content of these levels has one normal form. The proved relations reach every motivic relation of a weight as soon as the cuts of their quotient have only the separating generators in their common kernel, and at the number level the content is complete as soon as the values of its polynomial generators are algebraically independent.

Definition 45.14 (The motivic content; cuts; separating generators)**.** Let $M \in \{1,2,3,4\}$.

(i) The *motivic value* $w^{\mathfrak{m}}$ of a rational combination w of trails of level M is the same combination of the motivic chains of their symbols (Definition 45.7, Proposition 45.5(i)), motivic chains from 0 to 1 whose first letter is not 0 and whose last letter is not 1. The *motivic content* $\mathcal{P}^{(M)}$ is the $\mathbb{Q}$-span in $\mathcal{P}^{\mathrm{mot}}$ of 1 and of these motivic values, an algebra graded by the weight, the number of letters; $\mathcal{P}^{(M)}[N]$ is its part of weight N.

(ii) $\mathbb{L}$ is the motivic period of the circle, with the period $2\pi i$. At the levels $3,4$ it is $\mathbb{L} = \big(\frac{1}{2} - \frac{1}{M}\big)^{-1}\big((\mathsf{T}_{1;(1)}[x]\,2i\sin(\frac{2\pi x}{M})\,\mathbb{I}_{\mathbb{Z}})((0,\infty))\big)^{\mathfrak{m}}$, and at the levels $1,2$ its square is $\mathbb{L}^2 = -24\,\big((\mathsf{T}_{2;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))\big)^{\mathfrak{m}}$, with the trails of depth one of (iv). Put $e = 1$ at the levels $3,4$ and $e = 2$ at the levels $1,2$, so that $\mathbb{L}^e \in \mathcal{P}^{(M)}$, and

$$\mathfrak{n}^{(M)}[r] = \mathcal{P}^{(M)}[r]\Big/\Big(\mathbb{L}^e\,\mathcal{P}^{(M)}[r-e] + \sum_{0<i<r} \mathcal{P}^{(M)}[i]\,\mathcal{P}^{(M)}[r-i]\Big),$$

the classes of weight r modulo the circle and modulo products of elements of positive weight.

(iii) For $1 \le r < N$ the *cut* $\mathsf{D}_r : \mathcal{P}^{(M)}[N] \to \mathfrak{n}^{(M)}[r] \otimes \mathcal{P}^{(M)}[N-r]$ is the part of the coaction with exactly one run, of r letters. The run is read in $\mathfrak{n}^{(M)}[r]$ through its motivic chain, written by the composition of paths, the reversal, the rotations of $\{0\} \cup \mu_M$ and the regularization as a polynomial in $\mathbb{L}$ and in motivic values of trails, and read modulo $\mathbb{L}$; the kept letters form a motivic chain from 0 to 1, regularized at its ends:

$$\begin{aligned}&\mathsf{D}_r\,\mathrm{I}^{\mathfrak{m}}(a_0;a_1,\dots,a_N;a_{N+1})\\ &\qquad = \sum_{p=0}^{N-r} \big[\mathrm{I}^{\mathfrak{m}}(a_p;a_{p+1},\dots,a_{p+r};a_{p+r+1})\big] \otimes \mathrm{I}^{\mathfrak{m}}(a_0;a_1,\dots,a_p,a_{p+r+1},\dots,a_N;a_{N+1}).\end{aligned}$$

(iv) For $N \ge 1$ and $a \in \frac{1}{M}\mathbb{Z}$ the trail of level M of depth one at the frequency a is $(\mathsf{T}_{N;(1)}[x]\,e^{2\pi i a x}\mathbb{I}_{\mathbb{Z}})((0,\infty)) = \sum_{y\ge1} e^{2\pi i a y} y^{-N}$, read as the limit of its heads at $N = 1$. The *separating generator* of weight N is the trail

$$\mathsf{w}_N = \begin{cases} (\mathsf{T}_{N;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty)), & N \ge 3 \text{ odd, every } M;\\ -(\mathsf{T}_{1;(1)}[x]\,e^{\pi i x}\mathbb{I}_{\mathbb{Z}})((0,\infty)) = \log 2, & N = 1,\ M = 2,4;\\ -(\mathsf{T}_{1;(1)}[x]\,2\cos(\frac{2\pi x}{3})\,\mathbb{I}_{\mathbb{Z}})((0,\infty)) = \log 3, & N = 1,\ M = 3;\\ (\mathsf{T}_{N;(1)}[x]\,2i\sin(\frac{2\pi x}{M})\,\mathbb{I}_{\mathbb{Z}})((0,\infty)), & N \ge 2 \text{ even},\ M = 3,4;\end{cases}$$

there is none in even weight at the levels $1,2$, and none in weight one at level 1.

Theorem 45.15 (The content is separated by its cuts and its value)**.** *Let $M \in \{1,2,3,4\}$ and $N \geq 1$. Let $\mathcal{S}^{(M)}$ be the shuffle algebra over $\mathbb{Q}$ on one letter x_N for each separating generator w_N, with the coproduct that cuts a word into its two ends, tensored with $\mathbb{Q}[\mathbb{L}^e]$.*

(i) What the cuts see. *An element $\xi \in \mathcal{P}^{(M)}[N]$ whose cuts $\mathsf{D}_r\xi$, $1 \leq r < N$, all vanish is*

$$\xi = c\,\mathsf{w}_N^{\mathfrak{m}} + b\,\mathbb{L}^N, \qquad c, b \in \mathbb{Q},$$

the first term absent in a weight without a separating generator and the second when $e \nmid N$; the pair (c, b) is the readout *of ξ. The cuts of an element of weight N have their second factors in the weights below N.*

(ii) The separating generators. *Every cut of $\mathsf{w}_N^{\mathfrak{m}}$ vanishes. For N odd its value is positive: $(\mathsf{T}_{N;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$, $\log 2$ or $\log 3$. For N even it is*

$$\begin{aligned} i\sqrt{3}\,\big((\mathsf{T}_{N;(1)}[x]\,\mathbb{I}_{1+3\mathbb{Z}})((0,\infty)) - (\mathsf{T}_{N;(1)}[x]\,\mathbb{I}_{2+3\mathbb{Z}})((0,\infty))\big) \qquad (M=3),\\ 2i\,\big((\mathsf{T}_{N;(1)}[x]\,\mathbb{I}_{1+4\mathbb{Z}})((0,\infty)) - (\mathsf{T}_{N;(1)}[x]\,\mathbb{I}_{3+4\mathbb{Z}})((0,\infty))\big) \qquad (M=4), \end{aligned}$$

i times a positive number. The value of $\mathbb{L}^N$ is $(2\pi i)^N$, imaginary for N odd and real for N even. So the period is injective on the span of $\mathsf{w}_N^{\mathfrak{m}}$ and $\mathbb{L}^N$, and the readout of ξ is read off the real and the imaginary part of its value.

(iii) Combined. *An element of $\mathcal{P}^{(M)}[N]$ is 0 exactly when its cuts and its value vanish. With $\mathsf{w}_N^{\mathfrak{m}}$ for the letter x_N, the cuts, applied recursively, and the readouts give an injective homomorphism of algebras and comodules $\mathcal{P}^{(M)} \to \mathcal{S}^{(M)}$. The image of the motivic value of a content word is its* normal form*, and two content words have equal motivic values exactly when their normal forms are equal.*

(iv) The content is free. *This homomorphism is onto, and $\mathcal{P}^{(M)}$ is the polynomial algebra over $\mathbb{Q}$ on $\mathbb{L}^e$ and on one element for each Lyndon word in the letters x_N, a word that is smaller than each of its proper rotations in the order of the weights.*

Corollary 45.16 (The values of the content and its generators)**.** *Let $M \in \{1,2,3,4\}$ and let $g_1, g_2, \ldots$ be content words of level M whose motivic values, with $\mathbb{L}^e$, are polynomial generators of $\mathcal{P}^{(M)}$ (Theorem 45.15(iv)). If the values of the g_i and $(2\pi i)^e$ are algebraically independent over $\mathbb{Q}$, every relation among the values of the content words of level M holds among their motivic values, and so is decided by their cuts and readouts (Theorem 45.15(iii)). A polynomial relation over $\mathbb{Q}$ among the values of the g_i and $(2\pi i)^e$ is a relation among values that does not hold among motivic values.*

Definition 45.17 (The separation procedure)**.** Data: a level $M \in \{1,2,3,4\}$, a weight $N \geq 2$, for each $k \leq N$ a set R_k of proved relations among the trails of level M of weight k that hold for their motivic values, and a set $\mathcal{R} \subseteq \{1, \ldots, N-1\}$ of lengths of runs.

(1) For $k \leq N$ let V_k be the rational combinations of the trails of level M of weight k modulo R_k, and $\mathfrak{v}_k \subseteq V_k$ the span of the classes of the products of trails of positive weights (Proposition 45.2(ii)) and of the trails whose values are rational multiples of $(2\pi i)^e$ when $k = e$. Reduce by exact row reduction.

(2) For each trail of weight N and each $r \in \mathcal{R}$ compute D_r on its chain (Proposition 45.5(i)) by Definition 45.14(iii): write each run of r letters, modulo $\mathbb{L}$, and each chain of the kept letters as a combination of chains of trails, and read the run in $V_r/\mathfrak{v}_r$ and the kept chain in V_{N-r}.

(3) Check that the cuts of step (2) vanish on R_N, so that they are linear maps on V_N.

(4) Compute the joint kernel of these cuts on V_N, and check that it is spanned by classes of trails whose values are linearly independent over $\mathbb{Q}$.

Theorem 45.18 (Completeness by proved relations, weight by weight)**.** *In Definition 45.17, if $V_k \to \mathcal{P}^{(M)}[k]$ is injective for every $k < N$ and the checks of steps (3) and (4) succeed, then $V_N \to \mathcal{P}^{(M)}[N]$ is injective: every relation among the motivic values of the trails of level M of weight N is a consequence of R_N.*

At level 1, with the stuffle product, the shuffle product of chains and the relation of index one, and with $\mathcal{R}$ the odd lengths from 3 to $N-2$, the procedure succeeds in every weight from 2 to 14, the joint kernel being the line of $(\mathsf{T}_{N;(1)}[x]\,\mathbb{I}_{\mathbb{Z}})((0,\infty))$; Part XI works it, with the polynomial generators it finds.

45.6 The closing in any number of shares

The closing of a period finds a law on the integers in any number of shares: the period is the total mass of a live input whose density is rational and nonnegative, whose letter satisfies a linear differential equation over $\mathbb{Q}(z)$, at a tail rate read off the walls; the share closing of the word in all its free shares at once is the expansion of a deformation of the period at a regular singular point, with frames times polynomials in cumulants as its terms; and whatever the monodromy of that letter, the period is read through chains over its equation, whose kernels come from the factors of the equation; when the monodromy is unipotent every factor is trivial and the chains are those of Definition 45.4. Along a ray the equation is that of the pencil, whose factors the hinge tree generates, every period at rational data is a moment of the pencil of one integral ray, and the equation of the letter is generated down the same tree, each vertex carrying the load sum of its marks.

The letters of this section satisfy linear differential equations, and a solution of such an equation is read along a path through the factors of the equation, one variation of the constants for each step of a composition series.

Definition 45.19 (Chains over an equation)**.** Let $\Bbbk \subseteq \mathbb{C}$ be a field, $K = \Bbbk(z)$, and L a linear differential operator of order h with coefficients in K, whose singular points in $\mathbb{P}^1$ are regular singular; S is the set of them together with ∞. The *factors* of L are the composition factors over K of the module $K\langle\partial_z\rangle/K\langle\partial_z\rangle L$, each the module of an operator irreducible over K, and the dual of a factor is the module of the adjoint of that operator. On a simply connected domain avoiding S, a *kernel* of L is a form $\phi\,\psi\,dz$, with ψ a combination with coefficients in K of a solution of one factor and of its derivatives, and ϕ the same for the dual of a factor. A *chain over L* along a path $\gamma : [0,1] \to \mathbb{C} \setminus S$ is

$$\mathrm{I}_\gamma(\omega_1,\dots,\omega_w) = \int_{0<t_1<\cdots<t_w<1} \prod_{i=1}^{w} \omega_i\big(\gamma(t_i)\big),$$

with the kernels ω_i continued along γ and $\mathrm{I}_\gamma(\varnothing) = 1$; its *weight* is w, and $\mathrm{I}_\gamma(\cdot)(z)$ is the chain along the part of γ from $\gamma(0)$ to $z = \gamma(\tau)$.

When every factor has rank one and trivial monodromy, its solutions are rational functions, being single-valued with moderate growth at the points of S, those of its dual are their reciprocals, and the kernels are rational forms; the chains of Definition 45.4 are the chains over such an equation along a segment whose kernels are $dz/(z-s)$, s a finite point of S.

Proposition 45.20 (Every solution is read through chains over its equation)**.** *In Definition 45.19 let y be a solution of L near a point $a \notin S$, continued along a path γ from a to b that avoids S except possibly at b. There are finitely many c_i, each a combination with coefficients in K of a solution of a factor and of its derivatives, and chains I_i over L along γ, such that for every z on γ before b*

$$y(z) = \sum_i c_i(z)\, \mathrm{I}_i(z)\, \beta_i,$$

with each β_i a combination of $y(a), y'(a), \dots, y^{(h-1)}(a)$ whose coefficients are the values at a of elements of K regular off S. Every $c_i\mathrm{I}_i$ has at b an expansion in the powers $(z-b)^\rho$, $\rho \in \mathbb{C}$, and in the powers of $\log(z-b)$, times convergent power series, for one branch of $\log(z-b)$ on the end of γ, the same for every i. If $b \in S$, γ ends with a segment, and $y(z)$ has a limit at b along it, that limit is $\sum_i [c_i\mathrm{I}_i]_b\, \beta_i$, with $[\cdot]_b$ the constant term of the expansion at b.

Theorem 45.21 (The closing in any number of shares)**.** *Let a family F on $\mathcal{E}$, $|\mathcal{E}| = n$, have rational weights, rational masses $\mathbf{m}$ and rational exponents $s_j, t_j \geq 0$, on the balance wall with every proper wall positive. Write its active letters as L_i, with the exponents $w_i > 0$ and the degrees g_i, take rational references $M_i \geq \max_{\Delta_\mathcal{E}} L_i$, such as $M_i = \max_T \theta_{j,T}/g_i!$ for the table j of L_i (Theorem 15.13), and put $P_0 = \Gamma_1^n \begin{bmatrix} \mathbf{m} \\ m_\mathcal{E} \end{bmatrix} \prod_i M_i^{-w_i}$.*

(i) The law the closing finds. *$P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) = P_0 \sum_{N \geq 0} \psi(N)$, where*

$$\psi(N) = \sum_{|\mathbf{n}| = N} \prod_i \frac{(w_i)_{n_i}}{n_i!\, M_i^{n_i}}\ \mathbb{E}_{U \sim \mathrm{Dir}_\mathbf{m}}\Big[\prod_i \big(M_i - L_i(U)\big)^{n_i} \Big]\ \in \mathbb{Q}_{\geq 0}.$$

The letter $L_\psi(z) = \sum_N \psi(N) z^N$ (Definition 45.11) converges on $|z| < 1$, where

$$P_0\, L_\psi(z) = \int_{\Delta_\mathcal{E}} u^{\mathbf{m}-\mathbf{1}} \prod_i \big((1-z)M_i + z\, L_i(u)\big)^{-w_i}\, d\omega_\mathcal{E}(u),$$

and it satisfies a nonzero linear differential equation with coefficients in $\mathbb{Q}[z]$. So ψ satisfies a recurrence $\sum_{l=0}^h p_l(N)\psi(N+l) = 0$ with $p_l \in \mathbb{Q}[N]$ and $p_0 p_h \neq 0$, $\psi\, \mathbb{I}_\mathbb{Z}$ is a live input, and the period is P_0 times its read at index zero, its total mass. The tail is $\sum_{N' > N} \psi(N') = \Theta\big(N^{-\varpi}(\log N)^{k-1}\big)$, with the rate $\varpi > 0$ and the order k of Theorem 15.13(ii).

(ii) The share closing. *Open every active letter with one share per basis, on the fibre of Corollary 18.16, of a dimension D, and deform the weights to $\theta_{j,T} z^{c_{j,T}}$ in K_j and $\theta_{j,T} z^{c'_{j,T}}$ in Ψ_j, with integers (c, c') off finitely many hyperplanes. The deformed period $P_c(z)$ is real analytic on $(0, \infty)$, satisfies a nonzero linear differential equation with coefficients in $\mathbb{Q}[z]$ with at most a regular singular point at 0, and $P_c(1) = P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$. There is $z_0 > 0$ such that for $0 < z < z_0$ the D successive closings of the word converge absolutely and give*

$$P_c(z) = \sum_\sigma \sum_{\mathbf{j} \in \mathbb{N}^D} z^{e_\sigma(\mathbf{j})} \sum_{i \geq 0} (\log z)^i\, F_{\sigma,i}(\mathbf{j}),$$

a finite sum over the sequences σ of the Gamma families crossed, each e_σ affine with positive slopes, and each $F_{\sigma,i}(\mathbf{j})$ a frame*, a product of Gamma values and reciprocal factorials at points affine in $\mathbf{j}$, times a polynomial in the cumulants $(l-1)!\, (\mathsf{T}_{l;(1)}[x]\, \mathbb{I}_{b+\mathbb{Z}})((b, \infty))$ of Proposition 5.13 at rational b. The period is the continuation of this expansion along $(0, 1]$. The exponents lie in finitely many classes $\rho + \mathbb{N}$, and in each class the coefficients of $z^{\rho+m}(\log z)^i$ are live inputs in m. If $\sum_\mathbf{j} |F_{\sigma,i}(\mathbf{j})| < \infty$ for every σ and i, the period is $\sum_\sigma \sum_\mathbf{j} F_{\sigma,0}(\mathbf{j})$.*

(iii) Chains over the letter. *Let L be the equation over $\mathbb{Q}(z)$ of the letter L_ψ of (i), or of P_c of (ii), with S as in Definition 45.19, and let $a \in (0,1)$, not in S, be joined to 1 by a path γ that avoids S except possibly at 1 and ends with a segment, in the disc $|z| < 1$ for L_ψ and near $(0,1]$ for P_c. Then $L_\psi(1)$, and $P_c(1)$, read by Proposition 45.20, are finite sums of terms $[c_i\,\mathrm{I}_i]_1\,\beta_i$, with c_i combinations over $\mathbb{Q}(z)$ of a solution of a factor of L and of its derivatives, I_i chains over L along γ, $[\cdot]_1$ the value at 1 or, when $1 \in S$, the constant term of the expansion there, and β_i combinations, with the values at a of rational functions regular off S as coefficients, of the values at a of the letter, or of P_c, and of its derivatives of order below that of L. For L_ψ these values are the series $\sum_N \psi(N)\frac{N!}{(N-i)!}a^{N-i}$, of rational terms when a is rational; for P_c and $a < z_0$ they are absolutely convergent sums of frames times cumulants, times powers of a and of $\log a$, the expansion of (ii) and its derivatives at a. The period is $P_0 L_\psi(1) = P_c(1)$. If the monodromy of the solutions of L is unipotent, every factor of L is $\mathbb{Q}(z)$ with the derivation d/dz; if moreover S meets the open segment from 0 to 1 nowhere, $L_\psi(1)$ is a combination with algebraic coefficients of 1 and of chains (Definition 45.4) from 0 to 1 whose letters lie in $\{0\} \cup (S \setminus \{\infty\})$, regularized at the ends, and $P_c(1)$ is such a combination whose coefficients are combinations, with algebraic coefficients, of finitely many of the $F_{\sigma,i}(\mathbf{j})$. When $S \subseteq \{0,\infty\} \cup \mu_M$ these chains are of level M, and for the equation of L_ψ the period is P_0 times an element of the span of $\mathcal{C}^{(M)}$ over the algebraic numbers.*

So the closing of every period, in any number of shares, finds a law on the integers: the period is the total mass of a live input with a rational nonnegative density, at a known rate, and the share closing in all the free shares at once is the expansion of one holonomic deformation at a corner, whose terms are frames times cumulants. The letter of the closing in (i) is singular at the points $M_i/(M_i - L_i^*)$ of the critical values L_i^* of the letters on the strata of the simplex; for one free share the closing is Theorem 43.1. Whatever the monodromy of the letter, (iii) reads the period through the factors of its equation, with the values at an inner point as its data, power series with rational coefficients for the letter and sums of frames and cumulants for the deformation: the chains of the content are the case in which every factor is trivial. With a common hinge tree of the tables the factors of the equation of the letter are generated down the tree (Corollary 45.23), and the same period is a moment of the pencil of one integral ray, whose factors the tree generates as well (Corollary 45.22).

Corollary 45.22 (The values of a ray are read through chains over its tree)**.** *Let a ray of a family whose tables have a common hinge tree have an integral origin and $\kappa_{1,S} > 0$ for every nonempty proper S, and let L_1 be the equation of 1 over $\mathbb{C}(t)$, the monic generator of the annihilator of 1 in $\mathbb{C}(t)\langle\partial_t\rangle$ (Theorem 39.49(i)).*

(i) The factors are generated down the tree. *The factors of L_1 are the composition factors of $\mathcal{D}_F[1]$ that are not supported at points, read over $\mathbb{C}(t)$. Each is a composition factor of $H^0(R_o|_{U_o})_+\big((\boxtimes_c S_c)|_{U_o}\big)$ for composition factors S_c of the modules of the children of the root, and so on down the tree to the marks (Theorem 39.56(iv)).*

(ii) The composition series follow the tree. *For every vertex v, filtrations of the modules $\mathbb{G}_c$ of its children by submodules give $\mathbb{G}_v$ the filtration whose term p is the image of the direct image under N_v of the sum of the external products of terms with indices adding to p, and its graded piece p is a quotient of the direct image $H^0(N_v)_+$ of the sum of the $\boxtimes_c \mathrm{gr}_{p_c}\mathbb{G}_c$ over $\sum_c p_c = p$. At the root this filters $\mathcal{G}_F$, and $\mathcal{D}_F[1]$ by intersection.*

(iii) Chains over the pencil. *Every solution of L_1, continued along a path that avoids its singular points, is read through chains over L_1 along that path (Proposition 45.20); among these*

solutions are the orthant fibre integral P_1 on (A,∞) and the torus fibre integral T near ∞. Every value of the ray is a moment of P_1: $\langle 1\rangle_k = \int_A^\infty t^{-k}P_1(t)\,dt$ wherever the value converges.

(iv) Every period at rational data is a moment of a ray. *For rational data $(\mathbf{m};\mathbf{s},\mathbf{t})$ of the family on the balance wall, with nonnegative exponents and every proper wall positive, and an integer $N\geq 1$ with $N(\mathbf{m};\mathbf{s},\mathbf{t})$ integral, the ray with the origin 0 and the direction $N(\mathbf{m};\mathbf{s},\mathbf{t})$ is such a ray, and*

$$P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \int_A^\infty t^{-1/N}P_1(t)\,dt$$

for its orthant fibre integral P_1.

The letter of the closing reads one quantity that the pencil does not: the total load, through the reference term $M_i|u|^{g_i}$ of its deformation. A vertex carries it as the load sum of its marks, which adds along the tree, and a rational mass is a module of rank one at its mark.

Corollary 45.23 (The letter of the closing along the tree)**.** *In Theorem 45.21 let the tables of F have a common hinge tree, and let L be the equation of L_ψ over $\mathbb{Q}(z)$, the monic generator of its annihilator. Give every vertex $v\neq o$ the data $\tilde\lambda_v=(\lambda_v,\sigma_v)$: its data in Definition 39.55, with the last coordinate of the data of a mark e taken to be α_e, so that the last coordinate μ_v is the product of the loads of the marks B_v below v, and their sum $\sigma_v=\sum_{e\in B_v}\alpha_e$, the node maps $\tilde N_v$ extended by $\sigma_v=\sum_c\sigma_c$. Put $\mathbb{L}_e=H^0(\tilde\lambda_e)_+\mathcal{O}_{\mathbb{C}^\times}\alpha_e^{m_e}$ at a mark, the direct image of the module of rank one of $\alpha_e^{m_e}$, and $\mathbb{L}_v=H^0(\tilde N_v)_+\big(\boxtimes_c\mathbb{L}_c\big)$ at a vertex $v\neq o$. On the data of the children of o read $K_j=\mathcal{H}^{\hom}_{o,j}(\mathbf{c},\mathbf{d})$, $\Psi_j=\prod_c\mu_c\,\mathcal{H}^{\hom}_{o,j,\Psi}(\mathbf{c}',\mathbf{d}')$ and $\sigma_o=\sum_c\sigma_c$, and let $\mathcal{K}$ be the module of rank one of $\prod_i\big((1-z)M_i\sigma_o^{g_i}+zL_i\big)^{-w_i}$ on the open set W of the product of their data with the z-line on which every deformed letter is nonzero.*

(i) The letter is an iterated direct image. $\mathbb{L}_v=H^0(\tilde\lambda_v)_+\big(\boxtimes_{e\in B_v}\mathcal{O}_{\mathbb{C}^\times}\alpha_e^{m_e}\big)$, *and P_0L_ψ is a period of $H^0(\mathrm{pr}_z)_+\big(\mathcal{K}\otimes(\boxtimes_c\mathbb{L}_c\boxtimes\mathcal{O}_{\mathbb{C}})|_W\big)$, the scale of the torus contributing one factor in the top degree.*

(ii) Its factors are generated down the tree. *Every factor of L, read over $\mathbb{C}(z)$, has its composition factors among the generic fibres of the composition factors of $H^0(\mathrm{pr}_z)_+\big(\mathcal{K}\otimes(\boxtimes_cS_c\boxtimes\mathcal{O}_{\mathbb{C}})|_W\big)$, for composition factors S_c of the $\mathbb{L}_c$ of the children of the root; every composition factor of $\mathbb{L}_v$ is one of $H^0(\tilde N_v)_+\big(\boxtimes_c S_c\big)$ for composition factors S_c of the modules of its children; the $\mathbb{L}_e$ are simple; and the filtrations of Corollary 45.22(ii) hold for the $\mathbb{L}_v$, with $H^0(\mathrm{pr}_z)_+(\mathcal{K}\otimes\cdot\,)$ at the root.*

So every period of a family whose tables have a common hinge tree, at rational data on the balance wall with nonnegative exponents and positive walls, is read down the tree in two ways: as the moment $\int_A^\infty t^{-1/N}P_1(t)\,dt$ of a solution of the pencil of one integral ray, with $N=1$ at integral data, and as P_0 times the value at 1 of the letter of the closing. In both, the solution is read through chains over an equation whose factors are generated from the marks along the hinge tree and whose composition series follow the tree, as the nesting of the chains does.

45.7 The group of a period

A period is a closed serif word (Proposition 18.20), and what it needs is read on its word. Down the canonical hinge tree the word of a table is, at its full leans, a product of stacked Gammas, monomials in the weights and the periods of its prime nodes, and on its centre ray, at every strength,

the word of its core with the word of each cell set at the load of its marker (Corollary 26.11, Proposition 42.26): the content of a period sits in its prime nodes, and its series and parallel nodes and its repetitions add stacked Gammas, powers and the binary lengths of multiplicities (Chapter 33). Where the word reads an input on a scale it needs what that input generates, and the group of the input counts it: its dimension is the transcendence degree of the functions the input generates, a power of a function adds nothing to it, and functions whose groups have simple derived algebras, pairwise not isomorphic, add those algebras. Every ray also has one word for all of its values: one Trailmoment of one input, the reciprocal image of its stride's law, read at the index of the strength (Proposition 40.2(i)). In that word the Gamma stacks of the tree are divided out of the input and a product of Trailmoments becomes a multiplicative convolution of inputs (Theorem 5.31(ii)), and the group of the stride's law, a quotient of the group of the pencil, is what that word needs. On the class of s marks the tree's word reads one mark's input raised to the s-th power, whose group is the image of one mark's, of dimension three for every s; the stride's law, weighted by t, is that input with one mark's input divided out, and from $s = 5$ on its module is not a power and its group has dimension at least $(s-1)(s-2)/2$.

Definition 45.24 (The group of a module, of a function and of an input)**.** Let N be a differential module of finite dimension over $\mathbb{C}(y)$, and $\operatorname{Sol}_x N$ the space of its solutions near a point x off its singular points. The *group* $G_N \subseteq \mathrm{GL}(\operatorname{Sol}_x N)$ of N is the group of the automorphisms of the field generated over $\mathbb{C}(y)$ by these solutions and their derivatives that fix $\mathbb{C}(y)$ and commute with d/dy, acting on $\operatorname{Sol}_x N$; when the singular points of N in $\mathbb{P}^1$ are regular singular, it is the Zariski closure of the monodromy of the solutions. Its Lie algebra is $\mathfrak{g}_N$, the Lie algebra of its unipotent radical is the *unipotent part* $\mathfrak{u}_N$, and $\mathfrak{r}_N = \mathfrak{g}_N/\mathfrak{u}_N$ is the *reductive part*; another point x conjugates all three. The group of a function W that satisfies a nonzero linear differential equation over $\mathbb{C}(y)$ is the group of the module $\mathbb{C}(y)\langle\partial_y\rangle W$ that it generates, and the group of an input $W\,\mathbb{I}_D$ on an interval $D \subseteq (0,\infty)$, W such a function, is the group of W.

Proposition 45.25 (The group counts the functions)**.** *Let N be as in Definition 45.24, with a composition series of length r and the factors $S_1, \dots, S_r$.*

(i) The solutions of N near x and their derivatives generate over $\mathbb{C}(y)$ a field of transcendence degree $\dim \mathfrak{g}_N$.

(ii) If N is simple, G_N is reductive and acts irreducibly, and $\mathfrak{u}_N = 0$.

(iii) The unipotent radical of G_N is the subgroup that acts trivially on the graded pieces of the flag of solutions that the series gives, and G_N modulo it is the group of $S_1 \oplus \cdots \oplus S_r$. So $\mathfrak{r}_N$ is the Lie algebra of the group of $S_1 \oplus \cdots \oplus S_r$, and $\mathfrak{u}_N$ is nilpotent of class at most $r-1$.

(iv) When the singular points of N are regular singular, the chains of Proposition 45.20 have weight at most $r-1$, r the length of the series used there.

(v) For rational a and W as in Definition 45.24, the group of $y^a W$ has the identity component of the group of W, the solutions of the two modules identified by the multiplication by y^a; so the two have the same Lie algebra.

So the group of a function counts what the function generates, nested at most one less than the length of a composition series, and a rational power of the variable, as in the moment $\int_A^\infty t^{-1/N} P_1(t)\,dt$ of Corollary 45.22(iv), changes nothing in its Lie algebra.

Proposition 45.26 (Powers add nothing, distinct factors add)**.** *Let N, N_1, N_2 be as in Definition 45.24.*

(i) Every module obtained from N by sums, tensor products, duals and subquotients, such as $\mathrm{Sym}^k N$, $N^{\otimes k}$, $\wedge^k N$ and $N^\vee$, has as its group a quotient of G_N, and as its Lie algebra a quotient of $\mathfrak{g}_N$.

(ii) The Lie algebra of the group of $N_1 \oplus N_2$ is a subalgebra of $\mathfrak{g}_{N_1} \oplus \mathfrak{g}_{N_2}$ that projects onto each, so its dimension lies between $\max_i \dim \mathfrak{g}_{N_i}$ and $\dim \mathfrak{g}_{N_1} + \dim \mathfrak{g}_{N_2}$.

(iii) If $S_1, \dots, S_k$ are simple and the derived algebras $\mathfrak{s}_j = [\mathfrak{g}_{S_j}, \mathfrak{g}_{S_j}]$ are simple and pairwise not isomorphic, the derived algebra of the Lie algebra of the group of $S_1 \oplus \cdots \oplus S_k$ is $\mathfrak{s}_1 \oplus \cdots \oplus \mathfrak{s}_k$.

So the rank of a module, the order of its law, does not measure what it needs: $\mathrm{Sym}^k N$ of a module N of rank two whose group lies in SL_2 has rank $k+1$ and a group of dimension at most three for every $k \geq 1$. A power of a function adds nothing to its group, as a repeated subtree adds only the binary length of its multiplicity to the price (Chapter 33), and functions whose groups have simple derived algebras, pairwise not isomorphic, add those algebras.

Theorem 45.27 (A full Jordan block)**.** *Let S be a simple module as in Definition 45.24 whose singular points are regular singular, of rank $r \geq 2$, with a local monodromy that is unipotent with a single Jordan block. Then the derived group of the identity component of G_S, on the solutions of S, is one of:*

(a) the image of SL_2 in the symmetric power Sym^{r-1} of its standard representation;

(b) Sp_r for even r, SO_r for odd r, or G_2 in its representation of dimension 7 for $r = 7$;

(c) SL_r.

In case (a) $S \cong \mathrm{Sym}^{r-1} S_2 \otimes \chi$ for a simple module S_2 of rank two and a module χ of rank one, both with regular singular points: S is a power, and the derived algebra of $\mathfrak{g}_S$ is $\mathfrak{sl}_2$. In case (b) the derived group keeps a form, alternating for Sp_r and symmetric for SO_r and G_2, and for Sp_r and SO_r it is the identity component of the whole stabilizer of that form; for $r \geq 3$ the group SL_r of case (c) keeps no form.

Theorem 45.28 (The class read by the tree and by its stride's law)**.** *Let $s \geq 2$, let $\mathsf{g}(y) = \mathsf{G}_{0;(1,-1)}(1, y)$ (Section 42.6), let μ_s be the stride's law and P_1 the orthant fibre integral of the centre ray of $\binom{[s]}{1}$ at the strength one (Definitions 40.1 and 39.47), and $\iota(t) = t^{-1}$.*

(i) One sequence, two words. *For every integer $k \geq 1$, with $P(k) = P_{\binom{[s]}{1}}(k\mathbf{1}; k, k)$,*

$$\Gamma(k)^2 P(k) = (\mathsf{T}_{1-k;(1)}[x]\, \mathsf{g}^s\, \mathbb{I}_{(0,\infty)})((0,\infty)), \qquad \Gamma(k)^2 = (\mathsf{T}_{1-k;(1)}[x]\, \mathsf{g}\, \mathbb{I}_{(0,\infty)})((0,\infty)),$$
$$P(k) = (\mathsf{T}_{k;(1)}[x]\, \iota_* \mu_s)((0,\infty)) = (\mathsf{T}_{1-k;(1)}[x]\, t\, \mu_s)((0,\infty)),$$

and the inputs are tied by

$$\mathsf{g}^s\, \mathbb{I}_{(0,\infty)} = \big(\mathsf{g}\, \mathbb{I}_{(0,\infty)}\big) \boxtimes (t\, \mu_s);$$

the density of $\iota_* \mu_s$ is P_1 on (s^2, ∞).

(ii) The input of the tree's word. *$\vartheta^2 \mathsf{g} = y\, \mathsf{g}$, $\vartheta = y\, d/dy$, and g satisfies no equation of order one over $\mathbb{C}(y)$. The group of the input $\mathsf{g}\, \mathbb{I}_{(0,\infty)}$ is SL_2. The module of g^s is Sym^s of the module of g, of rank $s+1$, and the group of $\mathsf{g}^s\, \mathbb{I}_{(0,\infty)}$ is the image of SL_2 on Sym^s of its standard representation, SL_2 for odd s and PGL_2 for even s: for every s its dimension is three.*

(iii) The input of the stride's law. *The inputs $\iota_* \mu_s$ and $t\, \mu_s$ have the group of the solutions V_s of the class (Theorem 42.28). For $s \geq 5$, V_s is not Sym^{s-2} of the solutions of a module of rank two up to a twist of rank one, and the derived group of the identity component of that group is Sp_{s-1} for odd s, SO_{s-1} for even s, or SL_{s-1}, of dimension at least $(s-1)(s-2)/2$.*

The tree reads the class as one mark's input raised to the s-th power, and the law of its values is the s-th symmetric power of one mark's relation read in the index (Theorem 42.12): the rank of that law, its order $\lceil s/2 \rceil$, grows with s, and the group does not. The stride's law weighted by t is the same input with one mark's input divided out by the multiplicative convolution of (i), the input whose Trailmoment is the Gamma stack $\Gamma(k)^2$ of the word; from $s = 5$ on, the word through the stride's law pays for that division with a group of dimension at least $(s-1)(s-2)/2$, where the tree's word needs one of dimension three. That measures the reading through the pencil and not the class, in the same way that the continuations of the solutions V_s of the class say what functions with unipotent continuations cannot reach and nothing about the class (Theorem 42.28, Corollary 42.30, Definition 18.19).

Corollary 45.29 (The word along the canonical tree)**.** *Let $(\mathcal{B}, \theta)$ be a connected table whose weights factor across each bunch of width one at which its canonical hinge tree decomposes it (Theorem 23.16), as those of a list do.*

(i) At each of its full leans its period is a product of stacked Gammas, monomials in the weights and the periods of the prime nodes of the tree at their full leans; the period of a prime node $\mathcal{H}_v$ on n_v marks with $|\mathcal{H}_v|$ bases is a fibre integral of dimension $|\mathcal{H}_v| - n_v$ on its share side, and prime nodes that are equal, with equal data, contribute one period raised to their number.

(ii) When it is built by substitution with plain cells, with the norms 1 on the marks of the cells of at least two marks and norms on the marks left in place, its value at every strength is the word of its core with the word of each cell set at the load ℓ of its marker: a mark of the norm m left in place enters as $\mathsf{m}^{-\ell}$, a parallel class of $s \geq 2$ marks as $\Gamma(\ell)^{-2}\,(\mathsf{T}_{1-\ell;(1)}[x]\,\mathsf{G}_{0;(1,-1)}(1,x)^s\,\mathbb{I}_{(0,\infty)})((0,\infty))$, a Trailmoment of one input whose group is the image of one mark's, of dimension three (Theorem 45.28(ii)), and any other cell through the period of the family of its two hinge minors.

So the content of a period is carried by the prime nodes of its canonical hinge tree, each with the work of its share side, which a node of few marks keeps small whatever the number of bases of the whole table (Corollary 26.8); the series and parallel nodes contribute stacked Gammas at the full leans and powers of one mark's input on the centre ray, and a repeated subtree is written once with its multiplicity (Definition 33.2). When a cell is itself built by substitution, the family of its two hinge minors is read against its own cells in the same way (Proposition 42.26(v)), so the word recurses down the tree, a prime node below the root entering through the family of the two minors of its table at its hinge. The pencil is built down the same tree by direct images, one at every vertex, a parallel node among them (Theorem 39.56): it is the tree read through the stride's law, and on a parallel node of s marks it gives the solutions V_s of the class (Theorem 42.28) where the tree's word has the s-th power of one mark's input.

The stride's law has its own structure, read at the far end of the pencil.

Corollary 45.30 (The far end of the pencil)**.** *Let a ray on $n \geq 3$ marks satisfy the hypotheses of Proposition 39.54, and let W be the module of its orthant fibre integral P_1, the density of the input $\iota_* \mu_f$ of Proposition 40.2(i), $\iota(t) = t^{-1}$, of rank r_P. Then $r_P \geq n-1$, and if $r_P = n-1$:*

(i) the monodromy T_∞ is unipotent with a single Jordan block on the solutions of W; the submodules of W form a chain, so its composition series is unique; and T_∞ has a single Jordan block on the solutions of every factor, the sizes adding to $n-1$;

(ii) every factor of rank $b \geq 2$ is of one of the kinds of Theorem 45.27, and every factor of rank one has a group in $\mathbb{G}_m$;

(iii) the reductive part of the group of W is a subalgebra of the sum of the Lie algebras of the groups of its factors that projects onto each, and its unipotent part is nilpotent of class at most the number of factors less one.

Proposition 45.31 (The group is computable)**.** *The group of the module of an operator with coefficients in $\overline{\mathbb{Q}}(y)$, whatever its singular points, and with it its Lie algebra, its dimension and its reductive and unipotent parts, are computable from the operator. The relation $\vartheta^2 u = y\,u$ of one mark, which $\mathsf{G}_{0;(1,-1)}(1,y)$ satisfies, has coefficients in $\mathbb{Q}(y)$; when the weights of a family are algebraic, L_1 has coefficients in $\overline{\mathbb{Q}}(t)$, and the Lie algebra of the group of every solution of L_1, the orthant fibre integral among them, is a quotient of that of L_1.*

So the complexity of a period is read on its word along the canonical hinge tree. The prime nodes carry its content, each with the work of its share side; the series and parallel nodes and every repetition add stacked Gammas, powers and the binary lengths of multiplicities; and where the word reads an input on a scale, the group of the input counts the functions it needs, a power of one mark's input needing no more than one mark's group. The values of a ray are also one Trailmoment of the reciprocal image of its stride's law, and the group of that input, a quotient of the group of the pencil, is what that word needs: the input from which the Gamma stacks of the tree's word have been divided out, larger than the tree's from the class of five marks on, and of a kind that its rank, the form it keeps and whether it is a power decide wherever the far end gives a full Jordan block.

45.8 The group of a word along the tree

A word reads an input on a scale wherever it holds a Trailmoment, and the group of the input counts what it reads there (Section 45.7). Down the canonical hinge tree the value of a table on its centre ray can pay for each series or parallel node in either of two currencies: through the fibre of the node, in work, or on one scale, through the transforms of the cells directly below it (Proposition 42.26(v)–(vii)). Paid in work, the value reads nothing on a scale but powers of one mark's input, whatever the table, and its group is never more than one mark's. Paid on scales, its work does not grow with the multiplicities, and its group is a quotient of the group of one mark's input, its dilations by the norms at the root and the transforms of the distinct cells, other than marks, directly below a series or parallel node, each read once and each such cell rooted at a prime node or at a node of the other kind. A prime node is read on its shares in both readings: at the root through the fibre of its own table, below it through the fibre of the family of the two minors of its table at its hinge.

Definition 45.32 (The inputs and the group of a word)**.** The *inputs* of a word (Definition 1.1(vi)) are the inputs of its Trailmoments, an integral $\int_0^\infty y^{-\nu} W(y)\,dy$ in it being read as the Trailmoment $(\mathsf{T}_{\nu;(1)}[x]\,W(x)\,\mathbb{I}_{(0,\infty)})((0,\infty))$ (Definitions 5.2 and 5.4); inputs with one density on one interval are one input, at whatever indices and cuts they are read. A product or a power of Trailmoments is read as written: its inputs are those of its factors. When the density of every input satisfies a nonzero linear differential equation over $\mathbb{C}(y)$, the *group of the word* is the group of the sum of the modules that the densities of its distinct inputs generate (Definition 45.24); a word without inputs has the trivial group.

So the group, like the price and the work (Definition 33.2), belongs to the word as it is written: the multiplicative convolution that collects a product of Trailmoments at one index into one

Trailmoment (Theorem 5.31(ii)) changes the input and can change the group, as it does for the class (Theorem 45.28).

Lemma 45.33 (The transforms satisfy linear equations)**.** *At the exponents (k,k) with the masses k, the transform and the dual transform of a connected plain cell (Definition 23.1) satisfy nonzero linear differential equations over $\mathbb{C}(y)$.*

Theorem 45.34 (What the word along the canonical tree reads)**.** *Let $(\mathcal{B},\theta)$, its norms and k be as in Proposition 42.26(iii), built down its canonical hinge tree (Theorem 23.16) with the weights* 1 *at its series and parallel nodes, every cell decomposed at its own node. In this statement $\mathsf{g}(y)=\mathsf{G}_{0;(1,-1)}(1,y)$, a* class *is a series or parallel node all of whose cells are marks, and a node or a cell is counted once for each distinct subtree. Let S be a set of series and parallel nodes, and read the root by Proposition 42.26(vii) if it lies in S and by (iii) if not, every class below the root on one scale by (iii) and (vi), every other node of S by (vi), and every other node by (v).*

(i) Inputs. *The value is a closed serif word whose inputs are the $\mathsf{g}(x)^s\,\mathbb{I}_{(0,\infty)}$, s running over the sizes of the classes below the root, and, at every node of S, the product of the dual transforms of the cells directly below it if it is a parallel node and of their transforms if it is a series node, a repeated cell entering as one function to a power, a mark as g, and a mark at the root as $\mathsf{g}(\mathsf{m}_e x)$ or $\mathsf{m}_e^{-k}\mathsf{g}(x/\mathsf{m}_e)$.*

(ii) Group. *Its group is a quotient of the group of the sum of the modules of g, of those dilations and of the transforms that the nodes of S read of the distinct cells, other than marks, directly below them, each counted once, whatever the multiplicities (Lemma 45.33); every such cell is rooted at a prime node or at a node of the other kind. With S empty the group is the image of SL_2 on the sum of the symmetric powers Sym^s of its standard representation over the sizes of the classes: SL_2 when some size is odd, PGL_2 when every size is even, and trivial when there is no class below the root; for every table its dimension is at most three.*

(iii) Work. *Its work is the sum of the dimensions of the fibres of its distinct nodes outside S that are not classes below the root, $2N_v-n_v-1$ at the root and $2N_v-n_v-2$ below it for a node of N_v bases on n_v marks, one for each distinct size of class below the root, one for each distinct node of S that is not a class below the root, and one for each distinct transform that a node of S reads of a cell other than a mark, a cell directly below nodes of S of both kinds bringing both of its transforms. Below the root a series or parallel node outside S that is not a class has a fibre of dimension one less than the number of the cells directly below it, counted with their multiplicities; with every series and parallel node in S the work is at most twice the number of distinct subtrees other than marks plus the dimensions of the fibres of the distinct prime nodes, and does not grow with the multiplicities.*

So the value of such a table on its centre ray never needs more than one mark's group: the word that pays in work reads only the powers of one mark's input that close its classes, and what it pays is the work of its fibres, which at a series or parallel node grows with the number of cells below it and at a prime node is fixed by the node. The word that pays on scales keeps every repetition as a power of one transform, so that its work is set by the distinct subtrees, as the price is (Theorem 33.3); what it needs beyond one mark's input and its dilations is the transforms of the distinct cells directly below a series or parallel node, born where the tree meets a prime node or changes its kind. The class pays the same in either reading, one integral of its index whatever its size and no group beyond one mark's: its cells are marks, and a mark's transform is one mark's input whichever kind of node reads it. Reading a whole cell through its law instead, one Trailmoment (Proposition 42.26(iv)), collapses its subtree to one integral and brings its law as

the input: at the strength one the law of a parallel class of s marks is $t\,\mu_s$, its two Trailmoments agreeing on a strip (Theorem 45.28(i)), the input whose group has dimension at least $(s-1)(s-2)/2$ from $s = 5$ on (Theorem 45.28(iii)). The theorem is the reading of one table at width one on the scales of its series and parallel nodes (Corollary 48.16): at every width every full node of every tree of nested bunches reads on its scales the blocks of any partition of its parts that it separates, at one point, a repeated block entering as one transform to a power, and the group of what the word reads there, at any number of scales, is a quotient of the group of its distinct blocks and of the exponentials of their constant parts (Theorem 48.15).

Chapter 46

Finite algebra for scale reads

A bunch read on its scale against linear letters is a Breta of one bunch at the unit configuration (Proposition 15.1), and a Breta of unit columns on one bunch is, up to a stacked Gamma, such a scale integral. Its values at integer shifts of its index and its letter exponents satisfy two relations, the letter split and the scale exchange, and these relations are complete: every linear relation between the shifted values, with coefficients rational in the index and the letter exponents, is a combination of shifted letter splits and scale exchanges, and the values modulo the relations form a space whose dimension is the number of letters. The same holds at every corner, with the coefficients ξ_ℓ of the letters $x+\xi_\ell$ as the variables. For polynomial letters on one scale the same two relations reduce every insertion to one read per distinct root of the product of the letters, counted without finding a root; at a numerical corner three Laurent coefficients per read suffice, every integer ray has a recurrence with a certificate, and the jets in the coefficients of the letters are reads of rational insertions.

46.1 Complete relations for linear letters and unit columns

Definition 46.1 (Shifts, relations between shifts, the relation space)**.** Let $J=\{0,\dots,L\}$ carry distinct coefficients $\xi_\ell \in \mathbb{C}\setminus(-\infty,0]$, with the unit configuration I_J, and let $\mathbb{K}=\mathbb{C}(\kappa,w_0,\dots,w_L)$ be the field of rational functions of an index κ and letter exponents $\mathbf{w}$. Let $\mathcal{M}$ be the vector space over $\mathbb{K}$ with one basis element $[a,\mathbf{b}]$ for each *shift* $(a,\mathbf{b})\in\mathbb{Z}\times\mathbb{Z}^J$. The *value* of $[a,\mathbf{b}]$ is the scale integral at the shifted index and letter exponents,

$$\int_0^\infty x^{\kappa+a-1}\prod_{\ell\in J}(x+\xi_\ell)^{-w_\ell-b_\ell}\,dx \\ = \Gamma_{\,2}^{\,|J|}\begin{bmatrix}\kappa+a,\ |\mathbf{w}|+|\mathbf{b}|-\kappa-a\\ \mathbf{w}+\mathbf{b}\end{bmatrix}\mathsf{B}^{\{J\}}_{\mathbf{w}+\mathbf{b},\,|\mathbf{w}|+|\mathbf{b}|-\kappa-a;\,I_J}(\boldsymbol{\xi})$$

which converges on $0<\operatorname{Re}\kappa+a<\operatorname{Re}|\mathbf{w}|+|\mathbf{b}|$, the second form holding where moreover $\operatorname{Re}(w_\ell+b_\ell)>0$ for every ℓ (Proposition 15.1); finitely many shifts converge together on a nonempty convex open set. An element $\sum_i c_i[a_i,\mathbf{b}_i]$ of $\mathcal{M}$ is a *relation between shifts* when the combination of the values of the $[a_i,\mathbf{b}_i]$ with the coefficients $c_i(\kappa,\mathbf{w})$ vanishes at every point where all its terms converge and every c_i is defined. At the shift $(a,\mathbf{b})$ the letter split of the letter $x+\xi_\ell$ and the scale exchange are

$$\operatorname{split}_\ell(a,\mathbf{b})=[a,\mathbf{b}]-[a+1,\mathbf{b}+\mathbf{e}_\ell]-\xi_\ell\,[a,\mathbf{b}+\mathbf{e}_\ell],$$

$$\operatorname{exch}(a,\mathbf{b}) = (\kappa + a)\,[a,\mathbf{b}] - \sum_{\ell\in J}(w_\ell + b_\ell)\,[a+1,\mathbf{b}+\mathbf{e}_\ell],$$

the letter split and the scale exchange of Proposition 3.6 for the letters $x+\xi_\ell$. The *relation space* $\mathcal{L}_J \subseteq \mathcal{M}$ is the span over $\mathbb{K}$ of all letter splits and scale exchanges, and the *dimension* of the shifts is $\dim_{\mathbb{K}} \mathcal{M}/\mathcal{L}_J$; on one scale these play the part of the relation space and the dimension of a ray (Definition 38.4).

Theorem 46.2 (The relations of a scale integral are complete)**.** *Let the coefficients range over distinct points of* $\mathbb{C}\setminus(-\infty,0]$.

(i) Every element of $\mathcal{L}_J$ *is a relation between shifts.*

(ii) $\mathcal{M} = \mathcal{L}_J + \sum_{\ell\in J}\mathbb{K}\,[0,\mathbf{e}_\ell]$*: the dimension is at most* $|J|$.

(iii) The values of the $|J|$ *shifts* $[0,\mathbf{e}_\ell]$,

$$\Gamma_{\,2}{}_{|J|}\begin{bmatrix}\kappa,\ |\mathbf{w}|+1-\kappa\\ \mathbf{w}+\mathbf{e}_\ell\end{bmatrix}\,\mathsf{B}^{\{J\}}_{\mathbf{w}+\mathbf{e}_\ell,\,|\mathbf{w}|+1-\kappa;\,I_J}(\boldsymbol{\xi}),\qquad \ell\in J,$$

are linearly independent over $\mathbb{K}$*: a combination of them with coefficients in* $\mathbb{K}$ *that vanishes on a nonempty open subset of* $\{0<\operatorname{Re}\kappa<\operatorname{Re}|\mathbf{w}|+1\}$ *has every coefficient* 0.

(iv) The dimension is $|J|$*, and every relation between shifts lies in* $\mathcal{L}_J$*: it is a combination over* $\mathbb{K}$ *of shifted letter splits and scale exchanges.*

(v) Coefficients as variables. *Let the coefficients be rational functions of parameters* $\mathbf{u}=(u_1,\dots,u_d)$*, distinct and not* 0 *as rational functions, defined with distinct values in* $\mathbb{C}\setminus(-\infty,0]$ *on a nonempty open subset of* $\mathbb{R}^d$ *or of* $\mathbb{C}^d$*. Then (i), (ii) and (iv) hold with the field* $\mathbb{C}(\mathbf{u},\kappa,\mathbf{w})$ *in the place of* $\mathbb{K}$*, a relation between shifts being an element whose combination of values vanishes at every* $\mathbf{u}$ *of that set and every* $(\kappa,\mathbf{w})$ *where all its terms converge and every coefficient is defined.*

The letter splits are the partial fractions of the integrand, and the scale exchange is one integration by parts along the scale. Part (ii) reduces every shift to the $|J|$ values with one letter exponent raised by one, by these two relations alone, and part (iii) says that those values are linearly independent over $\mathbb{K}$. So a relation between shifts that is not a combination of shifted letter splits and scale exchanges does not exist, and the number of independent values is the number of letters; for one letter the dimension is one: every shift of the Beta corner of a linear letter is a rational multiple of one value. By Theorem 15.3 the scale integral of a family at a bunch is such an integral, with the points of the joint spectrum as its coefficients, so its relations in its index and its letter exponents are complete; relations between scale integrals of a family at shifted masses and exponents, where the letter exponents are tied to the exponents of the family, are a further problem.

What decides the relations at a corner, where the index and the letter exponents are numbers and the coefficients are the variables, is the behaviour of the values as one coefficient tends to 0: its letter becomes a power of the scale and joins the index.

Lemma 46.3 (A coefficient tends to 0)**.** *Let* $L\geq 1$*, let the coefficients be positive, and let the index and the letter exponents be numbers with* $\operatorname{Re} w_\ell > 0$ *for every* ℓ *and* $0\leq\operatorname{Re}\kappa'<1$*, where* $\kappa' = \kappa - w_0$*. In this statement* $J' = J\setminus\{0\}$*,* $\mathbf{w}' = \mathbf{w}|_{J'}$*,* $\boldsymbol{\xi}' = \boldsymbol{\xi}|_{J'}$*,* f_ℓ *is the value of* $[0,\mathbf{e}_\ell]$ *(Definition 46.1), and for letter exponents* $\mathbf{v}$ *on* J' *with* $\operatorname{Re}|\mathbf{v}|>0$ *and* $h_{\mathbf{v}}(x) = \prod_{j\in J'}(x+\xi_j)^{-v_j}$*,*

$$S'(z;\mathbf{v}) = \frac{h_{\mathbf{v}}(0)}{z} + \int_0^1 x^{z-1}\big(h_{\mathbf{v}}(x) - h_{\mathbf{v}}(0)\big)\,dx + \int_1^\infty x^{z-1}h_{\mathbf{v}}(x)\,dx$$

for $-1 < \operatorname{Re} z < \operatorname{Re}|\mathbf{v}|$, $z \neq 0$. *For* $\operatorname{Re} z > 0$ *and* $\operatorname{Re} v_j > 0$ *for every* j, $S'(z;\mathbf{v}) = \Gamma_{\substack{2\\|J'|}}\begin{bmatrix} z,\ |\mathbf{v}|-z \\ \mathbf{v}\end{bmatrix} \mathsf{B}^{\{J'\}}_{\mathbf{v},\,|\mathbf{v}|-z;\,I_{J'}}(\boldsymbol{\xi}')$, *the scale integral with the coefficients* $\boldsymbol{\xi}'$, *so* S' *continues it in its index across the wall* $\operatorname{Re} z = 0$, *with a simple pole at* $z = 0$ *of residue* $h_{\mathbf{v}}(0)$*; its constant term* $\operatorname{CT}_{z=0} S'(z;\mathbf{v})$ *is the sum of the two integrals at* $z = 0$, *and its values off the pole, at complex* z *and complex letter exponents, are the finite parts* $\operatorname{Reg}\int_0^\infty x^{z-1}h_{\mathbf{v}}\,dx$, *its constant term at* $z = 0$ *being* $\operatorname{Reg}\int_0^\infty x^{-1}h_{\mathbf{v}}\,dx$ *(Theorem 1.7). Fix* $\boldsymbol{\xi}'$ *and let* $\xi_0 \to 0^+$. *Then, with* $j \in J'$ *in (ii)–(v):*

(i) $\xi_0^{1-\kappa'} f_0 \to \Gamma_{\substack{2\\1}}\begin{bmatrix}\kappa,\ 1-\kappa' \\ w_0+1\end{bmatrix} h_{\mathbf{w}'}(0)$, *which is not* 0.

(ii) If $\operatorname{Re}\kappa' > 0$, *then* $f_j \to S'(\kappa';\mathbf{w}'+\mathbf{e}_j)$.

(iii) If $\operatorname{Re}\kappa' = 0$ *and* $\kappa' \neq 0$, *then*

$$f_j = \Gamma_{\substack{2\\1}}\begin{bmatrix}\kappa,\ -\kappa' \\ w_0\end{bmatrix} \frac{h_{\mathbf{w}'}(0)}{\xi_j}\,\xi_0^{\kappa'} + S'(\kappa';\mathbf{w}'+\mathbf{e}_j) + o(1).$$

(iv) If $\kappa' = 0$, *then*

$$f_j = \frac{h_{\mathbf{w}'}(0)}{\xi_j}\Big(\log\frac{1}{\xi_0} + (\log\Gamma)'(1) - (\log\Gamma)'(\kappa)\Big) + \operatorname*{CT}_{z=0} S'(z;\mathbf{w}'+\mathbf{e}_j) + o(1).$$

(v) The relations across the wall. *For* $-1 < \operatorname{Re} z \le 0$, $z \neq 0$,

$$S'(z;\mathbf{v}) = S'(z+1;\mathbf{v}+\mathbf{e}_j) + \xi_j\, S'(z;\mathbf{v}+\mathbf{e}_j), \qquad z\,S'(z;\mathbf{v}) = \sum_{i\in J'} v_i\, S'(z+1;\mathbf{v}+\mathbf{e}_i),$$

and $\operatorname{CT}_{z=0} S'(z;\mathbf{v}) = S'(1;\mathbf{v}+\mathbf{e}_j) + \xi_j\ \operatorname{CT}_{z=0} S'(z;\mathbf{v}+\mathbf{e}_j)$.

As the coefficient ξ_0 tends to 0 its letter $x+\xi_0$ becomes the power x. The value with the exponent of that letter raised grows like $\xi_0^{\kappa'-1}$, and when $\operatorname{Re}\kappa' > 0$ the others tend to the scale integrals of the remaining coefficients at the index $\kappa' = \kappa - w_0$, the index left when the letter exponent w_0 has joined it. When $\operatorname{Re}\kappa' = 0$ that index lies on the wall of the remaining integral, and a second term of the same size stands next to the integral continued across its wall: the oscillating power $\xi_0^{\kappa'}$, and at $\kappa' = 0$ a logarithm, which grows. The letter split and the scale exchange hold across the wall, and at the pole $z = 0$ the scale exchange keeps only its residue, the first identity of Theorem 46.4(ii) for the remaining coefficients. These are the first terms of the closing between two separated groups (Corollary 19.19), the letter of ξ_0 being the lower group: one lattice carries the powers $\xi_0^{\kappa'+n}$, with the wall residues of the other letters as coefficients, and the other carries the integer powers ξ_0^n, with the scale integral of the other coefficients continued in its index; at $\kappa' = 0$ the two lattices meet, and what their poles leave is the logarithm of (iv).

Theorem 46.4 (The relations at a corner)**.** *Let the index* κ *and the letter exponents* $\mathbf{w}$ *be numbers with* $0 < \operatorname{Re}\kappa < \operatorname{Re}|\mathbf{w}|+1$, *so that the values of the* $|J|$ *shifts* $[0,\mathbf{e}_\ell]$ *converge, and let the coefficients be distinct points of* $\mathbb{C}\setminus(-\infty,0]$. *A shift* $[a,\mathbf{b}]$ converges at the corner *when* $0 < \operatorname{Re}\kappa + a < \operatorname{Re}|\mathbf{w}| + |\mathbf{b}|$, *and a letter split or a scale exchange at the shift* $(a,\mathbf{b})$, *with the index and the letter exponents at their numbers, converges at the corner when* $[a,\mathbf{b}]$ *does; all its terms then converge. A* linear relation *between shifts that converge at the corner is a combination* $\sum_i r_i[a_i,\mathbf{b}_i]$ *of such shifts, with coefficients* r_i *rational in* $\boldsymbol{\xi}$, *whose value vanishes for* $\boldsymbol{\xi}$ *in a nonempty open set; it is a combination of letter splits and scale exchanges when it is one as a formal combination of shifts. The values are holomorphic in* $\boldsymbol{\xi}$ *on* $(\mathbb{C}\setminus(-\infty,0])^J$, *coincident coefficients included, and functions of* $\boldsymbol{\xi}$ *are* independent over $\boldsymbol{\xi}$ *when no combination of them with coefficients polynomial in* $\boldsymbol{\xi}$, *not all* 0, *vanishes at all* $\boldsymbol{\xi} > 0$, *equivalently for* $\boldsymbol{\xi}$ *in a nonempty open set.*

(i) Reduction. *If no letter exponent lies in* $\{-1,-2,\dots\}$*, the value of every shift that converges at the corner is a combination of the values of the* $[0,\mathbf{e}_\ell]$ *with coefficients rational in* $\boldsymbol{\xi}$*; the combination follows from letter splits and scale exchanges that converge at the corner, taken at shifts* $(a',\mathbf{b}')$ *with* $b'_\ell \geq \min(b_\ell,0)$ *for every* ℓ*.*

(ii) The two walls. *If* $\operatorname{Re}|\mathbf{w}|>0$*, the values of the* $[0,\mathbf{e}_\ell]$ *at the index* 1 *and at the index* $|\mathbf{w}|$ *satisfy*

$$\sum_{\ell\in J} w_\ell \int_0^\infty \prod_{\ell'\in J} (x+\xi_{\ell'})^{-w_{\ell'}-\mathbf{1}[\ell'=\ell]}\,dx = \prod_{\ell\in J}\xi_\ell^{-w_\ell},$$
$$\sum_{\ell\in J} w_\ell\,\xi_\ell \int_0^\infty x^{|\mathbf{w}|-1}\prod_{\ell'\in J} (x+\xi_{\ell'})^{-w_{\ell'}-\mathbf{1}[\ell'=\ell]}\,dx = 1,$$

the integrals being, where every $\operatorname{Re} w_\ell>0$*, the stacked Gammas times the Bretas of Definition 46.1.*

(iii) Independence. *The values of the* $|J|$ *shifts* $[0,\mathbf{e}_\ell]$ *are independent over* $\boldsymbol{\xi}$ *if and only if no letter exponent lies in* $\{-1,-2,\dots\}$*.*

(iv) Completeness. *Whatever the letter exponents, every linear relation between shifts that converge at the corner is a combination, with coefficients rational in* $\boldsymbol{\xi}$*, of letter splits and scale exchanges that converge at the corner, and over the rational functions of* $\boldsymbol{\xi}$ *the values of these shifts span a space of dimension* $|J|$*: at every corner the dimension is* $|J|$*.*

(v) A coefficient equal to 1. *Parts (i), (iii) and (iv) hold as well when one coefficient is the constant* 1 *and the others are the variables.*

At a corner the relations are the same, and when no letter exponent lies in $\{-1,-2,\dots\}$ they reduce every shift that converges to the $|J|$ values with one letter exponent raised without leaving the corner: every relation of the reduction has all its terms convergent, and the leading coefficients $\kappa-r$, $r\geq 1$, and $\kappa+j-|\mathbf{w}|$, $j\geq 0$, by which the descents at the origin and at infinity divide vanish only at shifts that have left the domain. The two identities of (ii) are the relations at the two walls of the domain: the first is the scale exchange at the shift $(-1,\mathbf{0})$ at the index 1, whose member on the wall is replaced by its limit $\prod_\ell \xi_\ell^{-w_\ell}$, and the second is the scale exchange less the letter splits multiplied by their letter exponents at the shift $(0,\mathbf{0})$, at the index $|\mathbf{w}|$, where $|\mathbf{w}|-\kappa$ times the value of $[0,\mathbf{0}]$ tends to 1; at a wall one combination of the $|J|$ values is a monomial in $\boldsymbol{\xi}$. A letter exponent in $\{-1,-2,\dots\}$ is not on a wall: its letter has become a polynomial factor of the integrand, the $|J|$ values with one letter exponent raised are dependent and no longer span the shifts that converge; the corner with that letter exponent moved up to 0 has the same shifts, and its $|J|$ values with one letter exponent raised span them. Independence is read from the coefficients one at a time: as ξ_0 tends to 0 the value with the letter exponent w_0 raised grows faster than the others (Lemma 46.3), so in a relation the polynomial multiplying it vanishes at $\xi_0=0$, and what is left is a relation between scale integrals of the remaining coefficients, at the index $\kappa-w_0$, or on their wall, where the relations across the wall carry it to the next index.

Corollary 46.5 (Unit columns on one bunch)**.** *Let* B *be a bunch with the unit configuration* I_B *and distinct coefficients* $\xi_e>0$*. By Proposition 15.1 with* $J=B$*,* $\mathbf{w}=\mathbf{m}$ *and* $\kappa=m_B-\nu$*, the value* $\mathsf{B}^{\{B\}}_{\mathbf{m}+\mathbf{a},\,\nu+n;\,I_B}(\boldsymbol{\xi})$*,* $\mathbf{a}\in\mathbb{Z}^B$*,* $n\in\mathbb{Z}$*, is the value of the shift* $[|\mathbf{a}|-n,\mathbf{a}]$ *of Definition 46.1 divided by* $\Gamma_{\substack{2\\|B|}}\begin{bmatrix} m_B-\nu+|\mathbf{a}|-n,\ \nu+n\\ \mathbf{m}+\mathbf{a}\end{bmatrix}$*, wherever that proposition applies; this stacked Gamma is the*

one at $(\mathbf{m},\nu)$ *times a rational function of* $(\mathbf{m},\nu)$*. Each relation below is read where all its Bretas converge.*

(i) The mark relation. *For each* $e\in B$*,*

$$m_e\,\mathsf{B}^{\{B\}}_{\mathbf{m},\,\nu;\,I_B}(\boldsymbol{\xi}) = (m_B-\nu)\,\mathsf{B}^{\{B\}}_{\mathbf{m}+\mathbf{e}_e,\,\nu;\,I_B}(\boldsymbol{\xi}) + \nu\,\xi_e\,\mathsf{B}^{\{B\}}_{\mathbf{m}+\mathbf{e}_e,\,\nu+1;\,I_B}(\boldsymbol{\xi}):$$

the sum over $f\in B$ *of the shape exchanges of Theorem 3.5(iv) for the pairs* (e,f)*, reduced by the shape split and the scale exchange; it is the letter split of the letter* $x+\xi_e$*.*

(ii) The shape split, the scale exchange and the shape exchanges of Theorem 3.5, at all integer shifts of $(\mathbf{m},\nu)$*, span over* $\mathbb{C}(\mathbf{m},\nu)$ *every linear relation with coefficients in* $\mathbb{C}(\mathbf{m},\nu)$ *between the values* $\mathsf{B}^{\{B\}}_{\mathbf{m}+\mathbf{a},\,\nu+n;\,I_B}(\boldsymbol{\xi})$*, and the quotient of the space of shifts by these relations has dimension* $|B|$*. The same holds over* $\mathbb{C}(\boldsymbol{\xi},\mathbf{m},\nu)$ *for relations whose coefficients are rational in* $\boldsymbol{\xi}$ *as well and which hold at all distinct* $\boldsymbol{\xi}>0$ *at which their coefficients are defined.*

(iii) At a corner. *Let* $\mathbf{m}$ *and* ν *be numbers with* $\operatorname{Re} m_e>0$ *for every* e *and* $\operatorname{Re}\nu>0$*, and call a value* $\mathsf{B}^{\{B\}}_{\mathbf{m}+\mathbf{a},\,\nu+n;\,I_B}(\boldsymbol{\xi})$ interior *when* $\operatorname{Re}(m_e+a_e)>0$ *for every* e *and* $\operatorname{Re}\nu+n>0$*; the Breta converges there. Over the rational functions of* $\boldsymbol{\xi}$ *the interior values span a space of dimension* $|B|$*, and every linear relation between interior values with coefficients rational in* $\boldsymbol{\xi}$ *is a combination, with such coefficients, of shape splits, scale exchanges and shape exchanges all of whose terms are interior. If* $\operatorname{Re}\nu<\operatorname{Re} m_B$*, the* $|B|$ *values* $\mathsf{B}^{\{B\}}_{\mathbf{m}+\mathbf{e}_e,\,\nu+1;\,I_B}(\boldsymbol{\xi})$*,* $e\in B$*, are a basis of that space.*

Completeness holds for the scale integral of one bunch against linear letters and for unit columns on one bunch, which are the same integrals: the coefficients are the same, the shape index is the letter exponents, and the index of the scale integral is the amount $m_B-\nu$ by which the scale index falls short of the mass m_B. It holds at a free index and free letter exponents, and at every corner with the coefficients as the variables, one of them possibly the constant 1. For a Breta with a kernel, with letters of more than two patterns or of levels other than 0 and 1, or with several bunches, the relations of Theorem 3.5 hold, and their completeness is a further problem.

46.2 Polynomial letters on one scale

A word on one scale with polynomial letters, such as the scale integral of a bunch at fixed shapes (Theorems 15.3 and 19.28), has the same two relations, the letter splits becoming partial fractions over the distinct factors of the letters, and the same finiteness: the retained data are one read per distinct root of the product of the letters, counted without finding a root, and at a numerical corner three Laurent coefficients per read. Every rational insertion, every integer shift of the index and the letter exponents, every derivative in the coefficients of the letters and every integer ray is then finite algebra, with a certificate.

Definition 46.6 (Insertions and reads on one scale)**.** Let $\mathbb{F}\subseteq\mathbb{C}$ be a field, the field of the letters, and let $P_1,\dots,P_N\in\mathbb{F}[x]$ be nonconstant letters without roots on $[0,\infty)$, a constant letter being moved into a scalar; put $\mathbf{P}=(P_1,\dots,P_N)$. For an index κ and letter exponents $w_1,\dots,w_N$ in a field $\mathbb{F}'\supseteq\mathbb{F}(\kappa,\mathbf{w})$ embedded in $\mathbb{C}$, the insertions, the regular functions of the letter complement as in Definition 38.1, are the elements of the ring $\mathfrak{A}=\mathbb{F}'[x,x^{-1},P_1^{-1},\dots,P_N^{-1}]$, and the *read* of an insertion R is

$$\langle R\rangle_{\kappa,\mathbf{w};\mathbf{P}} = \int_0^\infty x^{\kappa-1}\prod_j P_j(x)^{-w_j}\,R(x)\,dx$$

where it converges absolutely, each power $P_j^{-w_j}$ being taken on $[0,\infty)$ by continuity from its principal value at 0, and continued in the index and the letter exponents elsewhere. The shift of the index by a and of the letter exponents by b_j, integers, is the insertion $x^a\prod_j P_j^{-b_j}$, and a derivative in the coefficients of a letter is an insertion. A squarefree decomposition with gcd splitting gives pairwise coprime squarefree $q_1,\dots,q_M\in\mathbb{F}[x]$, none vanishing at 0, with $P_j=c_j\prod_k q_k^{m_{jk}}$, without roots and without a field extension; $Q=q_1\cdots q_M$ is the monic radical of $P_1\cdots P_N$, of degree $D>0$. The *scale exchange* on insertions is

$$\eth g = xg' + \Big(\kappa - \sum_j w_j \frac{xP_j'}{P_j}\Big)g, \qquad \text{so that} \qquad \Big(x^\kappa \prod_j P_j^{-w_j}\, g\Big)' = x^{\kappa-1}\prod_j P_j^{-w_j}\,\eth g.$$

For the linear letters $x+\xi_\ell$ with distinct $\xi_\ell\in\mathbb{C}\setminus(-\infty,0]$, the reads of the shifts are the values of Definition 46.1, $D=|J|$, and $\eth$ applied to $x^a\prod_\ell(x+\xi_\ell)^{-b_\ell}$ is the scale exchange $\mathrm{exch}(a,\mathbf{b})$ read under the integral.

Theorem 46.7 (Reduction by the scale exchange)**.** *Let the numbers*

$$\kappa - r \quad (r\ge 1), \qquad \kappa + a - \sum_j w_j \deg P_j \quad (a\ge 0), \qquad \sum_j m_{jk}w_j + h \quad (h\ge 1,\ 1\le k\le M)$$

be nonzero in $\mathbb{F}'$. Every $R\in\mathfrak{A}$ has a unique decomposition

$$R = \eth g + \sum_{i=0}^{D-1} c_i \frac{x^i}{Q}, \qquad g\in\mathfrak{A},\quad c_i\in\mathbb{F}',$$

obtained by polynomial arithmetic, partial fractions and the extended Euclidean algorithm; so $\dim_{\mathbb{F}'}\mathfrak{A}/\eth\mathfrak{A}=D$, and on the domain where the reads converge $\langle R\rangle_{\kappa,\mathbf{w};\mathbf{P}}=\sum_i c_i\,\langle x^i/Q\rangle_{\kappa,\mathbf{w};\mathbf{P}}$. For the linear letters $x+\xi_\ell$ with distinct $\xi_\ell\in\mathbb{C}\setminus(-\infty,0]$, $D=|J|$ and this is Theorem 46.2(ii) over $\mathbb{K}$, the x^i/Q spanning the same space as the $(x+\xi_\ell)^{-1}$.

The dimension is that of the quotient by the scale exchange, the dimension of the ray on one scale (Theorem 38.31); it does not assert that the reads of the D insertions x^i/Q are independent once parameters are tied, and symmetries of the letters can relate them further. For linear letters Theorem 46.2(iii) gives the independence. The three conditions are the leading coefficients of the reduction at the origin, at infinity and at a repeated factor. Exact computation needs exact arithmetic with a zero test in $\mathbb{F}'$, numerical exponents being taken in an effective extension; the analytic statements hold at all complex exponents.

Definition 46.8 (Deformation; masters)**.** At numerical exponents $(\kappa,\mathbf{w})$ fix a direction $(\lambda_0;\boldsymbol{\lambda})\in\mathbb{R}\times\mathbb{R}^N$ of the index and the letter exponents that is *admissible*: $\lambda_0>0$, $\sum_j\lambda_j\deg P_j>\lambda_0$ and $\sum_j m_{jk}\lambda_j\neq 0$ for every k. The *deformation* moves the data along it, to $(\kappa+\lambda_0\varepsilon,\ \mathbf{w}+\varepsilon\boldsymbol{\lambda})$; the three conditions of Theorem 46.7 hold over $\mathbb{F}'(\varepsilon)$, and for an insertion R the coefficients $c_i(\varepsilon)$ are those of its decomposition there. The *masters* are the deformed reads

$$H_i(\varepsilon) = \big\langle x^i/Q\big\rangle_{\kappa+\lambda_0\varepsilon,\ \mathbf{w}+\varepsilon\boldsymbol{\lambda};\ \mathbf{P}}, \qquad 0\le i<D.$$

For large real ε every finite set of deformed reads converges, the exponent at the origin growing with the slope λ_0 and the decay at infinity with the slope $\sum_j\lambda_j\deg P_j-\lambda_0>0$, so the reductions hold there and then as identities of meromorphic functions. The masters are finite combinations of reads of shifts of the original letters: $1/Q=\big(P_1\cdots P_N/Q\big)\prod_j P_j^{-1}$ with $P_1\cdots P_N/Q$ a polynomial, so each term of $x^iP_1\cdots P_N/Q$ shifts the index by an integer and raises every letter exponent by one. The admissible directions form a nonempty open cone; the direction $(\frac12;\mathbf{1})$ is admissible.

Lemma 46.9 (Simple poles at a corner)**.** *For every insertion R independent of ε, or holomorphic in ε, the coefficients $c_i(\varepsilon)$ have at most a simple pole at $\varepsilon = 0$, and every master $H_i(\varepsilon)$ is meromorphic near 0 with at most a simple pole.*

Theorem 46.10 (Finitely many numbers at every corner)**.** *Along an admissible direction (Definition 46.8), for an insertion R write $H_i(\varepsilon) = h_{i,-1}\varepsilon^{-1} + h_{i,0} + h_{i,1}\varepsilon + O(\varepsilon^2)$ and $c_i(\varepsilon) = c_{i,-1}\varepsilon^{-1} + c_{i,0} + c_{i,1}\varepsilon + O(\varepsilon^2)$. The $3D$* corner numbers *$(h_{i,-1}, h_{i,0}, h_{i,1})_{i<D}$ determine every absolutely convergent read:*

$$\langle R\rangle_{\kappa,\mathbf{w};\mathbf{P}} = \sum_{i=0}^{D-1} \big(c_{i,-1}h_{i,1} + c_{i,0}h_{i,0} + c_{i,1}h_{i,-1}\big).$$

They depend on the letters, the exponents and the direction only, not on the insertion or the size of the shift. The reads of $R\left(\lambda_0 \log x - \sum_j \lambda_j \log P_j\right)^b$, the derivatives ∂_ε^b at $\varepsilon = 0$ of the deformed reads $\langle R\rangle_{\kappa+\lambda_0\varepsilon,\,\mathbf{w}+\varepsilon\boldsymbol{\lambda};\,\mathbf{P}}$, need the masters through the order $b+1$: $(b+3)D$ numbers. When $\langle R\rangle_{\kappa,\mathbf{w};\mathbf{P}}$ converges absolutely, a read of $R\,(\log x)^{k_0}\prod_j(\log P_j)^{k_j}$, $b = k_0 + \sum_j k_j$, is a rational combination of the reads of $R\left(\lambda_0 \log x - \sum_j \lambda_j \log P_j\right)^b$ along finitely many admissible directions, each with its own corner numbers.

The residues are finite extractions of endpoint coefficients, the other numbers finite parts and derivatives in the deformation. The D values of the masters suffice when every pivot of the reduction is regular and the masters are holomorphic at the corner, as for linear letters at a corner with no letter exponent in $\{-1, -2, \dots\}$ and convergent masters (Theorem 46.4(i)); regular pivots alone do not suffice, and at an arbitrary corner the corner numbers are what is retained.

Theorem 46.11 (Integer rays have certified recurrences)**.** *Fix integers $a, b_1, \dots, b_N$, and let $\eth_n$ be the scale exchange at the deformed data $\left(\kappa + an + \frac{\varepsilon}{2},\ \mathbf{w} + n\mathbf{b} + \varepsilon\mathbf{1}\right)$. A finite algorithm gives polynomials $p_0(n,\varepsilon), \dots, p_D(n,\varepsilon)$ and a certificate g, rational in x, n and ε, with*

$$\eth_n g = \sum_{k=0}^{D} p_k(n,\varepsilon)\, x^{ak} \prod_j P_j^{-b_j k},$$

the polynomials $p_k(n) = p_k(n,0)$ not all zero; then

$$\sum_{k=0}^{D} p_k(n)\, \langle 1\rangle_{\kappa+a(n+k),\ \mathbf{w}+(n+k)\mathbf{b};\ \mathbf{P}} = 0$$

at every integer n at which the displayed reads converge.

The recurrence need not have the least order, and its leading coefficient may vanish at finitely many integers, read off that polynomial; there further values are given or another dependence is formed. On one scale this supplies, for every ray, the certificate that a recurrence asks for: an insertion g whose scale exchange is the recurrence.

Theorem 46.12 (Coefficient jets on one scale)**.** *Let $P_j(x;u) = P_j(x) + \sum_{a=1}^{p} u_a P_{ja}(x)$ with $\deg P_{ja} \le \deg P_j$, choose bounds $M_{ja} \ge \sup_{x>0} |P_{ja}/P_j|$, finite since the quotient is continuous on $[0,\infty]$, and let $\langle 1\rangle_{\kappa,\mathbf{w};\mathbf{P}}$ converge absolutely. On the polydisc where $\sum_a |u_a| M_{ja} < 1$ for every*

j the read $\langle 1\rangle_{\kappa,\mathbf{w};\mathbf{P}(\,\cdot\,;u)}$, the powers of the changed letters being continued in u from $u=0$, is holomorphic and

$$\langle 1\rangle_{\kappa,\mathbf{w};\mathbf{P}(\,\cdot\,;u)} = \sum_{(n_{ja})\geq 0} \prod_{j} \frac{(-1)^{|n_j|}(w_j)_{|n_j|}}{\prod_a n_{ja}!} \prod_a u_a^{\sum_j n_{ja}} \Big\langle \prod_{j,a} \Big(\frac{P_{ja}}{P_j}\Big)^{n_{ja}} \Big\rangle_{\kappa,\mathbf{w};\mathbf{P}},$$

$|n_j| = \sum_a n_{ja}$, absolutely; every coefficient is the read of a rational insertion, given by the corner numbers of Theorem 46.10.

Splitting of repeated roots under the change costs nothing, the expansion being made against the original letters; a change that raises a degree is outside the statement. For coefficients that are symbolic parameters with fixed gcds and multiplicities, differentiating the masters gives rational insertions, so Theorem 46.7 gives matrices $\partial_{u_a} H = \mathbf{A}_a H$, with certificates, for the vector H of the masters, whose mixed derivatives agree because they agree before the reduction; at a corner where a leading coefficient of the reduction vanishes the corner numbers replace them. The structural data reused are the squarefree base, Q and the inverses of xq_k' modulo q_k; the analytic data are the D masters or the $3D$ corner numbers. A rational insertion with polynomial part of degree A_+, a pole of order A_- at the origin and of order h_k at q_k takes at most $(A_+ + 1) + A_- + \sum_k \max(h_k - 1, 0)$ elimination rounds, counted in operations, the growth of exact coefficients charged separately; a repeated letter adds m_{jk} times its letter exponent to the exponent of each squarefree factor q_k and leaves Q and D unchanged. A recurrence in a count of repetitions needs the integer shifts of Theorem 46.11, and a multiplicity written in binary, which is what the price of Chapter 33 counts, does not by itself make the evaluation logarithmic in it.

Chapter 47

The module of a family

A family is a function of all its data at once. Every insertion has a value at every point of the balance wall, integration by parts in each mark holds there with coefficients linear in the data, and a monomial in the marks and the letters moves the data by a lattice vector. Modulo the integrations by parts the insertions form one vector space over the rational functions of the data, of finite dimension, on which the lattice of integral data acts by shifts: the module of the family. Its masters and their shift matrices carry the values from a point to every lattice translate of it and reduce every insertion to the masters; they are found by one elimination in a box over the rational functions of the data, with a certificate for every relation used, the matrices of the box presenting the module once they are invertible. The values separate the module: the masses act on the values as the Euler derivatives act on the integrand, so an element whose value vanishes as a function of all the data is zero in the module, every relation among the values is a relation of the module, read off the reductions on masters, and the closings along the rays from one integral point tell it as well, finitely many of them along finitely many parallel rays deciding. On a subspace of the data with a native direction the value zero is told by the expansion of the values at the native gauge of that direction, which asks for no positive direction and no closing; on a subspace cut out by conditions on the exponents alone that meets the tube the values still separate the module. Below its top degree the twisted de Rham complex of the letter complement has no cohomology at generic data, so the number of masters is the signed Euler characteristic of the letter complement, one master for each native point of generic data. Chapter 46 did this on one scale, and the module of a ray (Definition 39.1) is the module of the family restricted to one line of its data space (Proposition 47.5).

47.1 The data of a family

Definition 47.1 (The data space, the lattice and the master form)**.** Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^{N}$ be a family on $\mathcal{E}$, $n = |\mathcal{E}| \geq 2$, and $\Bbbk \subseteq \mathbb{C}$ a field that contains the weights.

(i) The *data space* of F is its balance wall $\mathbb{D}_F = \{\mathbf{d} = (\mathbf{m}; \mathbf{s}, \mathbf{t}) \in \mathbb{C}^{\mathcal{E}} \times \mathbb{C}^N \times \mathbb{C}^N : \ \kappa_{\mathcal{E}}(\mathbf{d}) = 0\}$, a complex vector space of dimension $n + 2N - 1$ on which the walls κ_U of Definition 8.1 are linear forms, none of them zero for U nonempty and proper. Its *lattice* is the set of its integral points $\mathbb{D}_F(\mathbb{Z}) = \mathbb{D}_F \cap (\mathbb{Z}^{\mathcal{E}} \times \mathbb{Z}^N \times \mathbb{Z}^N)$, the integral data, and $\mathbb{D}_F(\mathbb{R})$ is the set of its real points, and its fields of rational functions are $\Bbbk(\mathbb{D}_F)$ and $\mathbb{K}_F = \mathbb{C}(\mathbb{D}_F)$. A *positive direction* is a $\mathbf{d}_1 = (\mathbf{m}_1; \mathbf{s}_1, \mathbf{t}_1) \in \mathbb{D}_F(\mathbb{Z})$ with $s_{1j}, t_{1j} \geq 1$ for every j and $\kappa_U(\mathbf{d}_1) > 0$ for every nonempty proper U.

(ii) For $\lambda = (v; \mathbf{a}, \mathbf{b}) \in \mathbb{D}_F(\mathbb{Z})$ the *stride* of λ is $f_\lambda = \alpha^v \prod_j K_j^{-a_j} \Psi_j^{-b_j}$, a unit of the insertions $\mathbb{C}[X_F]$ (Definition 38.1) with coefficients in $\Bbbk$; $f_\lambda f_\mu = f_{\lambda+\mu}$ and $f_0 = 1$.

(iii) On the chart $y_{e_0} = 0$, with $dy = \prod_{e \neq e_0} d\alpha_e/\alpha_e$, the *master form* at $\mathbf{d}$ is $\omega_{\mathbf{d}} = \alpha^{\mathbf{m}} \prod_j K_j^{-s_j} \Psi_j^{-t_j}\, dy$, the powers principal on the positive orthant, so that $f_\lambda\, \omega_{\mathbf{d}} = \omega_{\mathbf{d}+\lambda}$. Its *defects* are $c_e(\mathbf{d}) = m_e - \sum_j \big(s_j R_{j,e} + t_j R^*_{j,e}\big)$, with the occupations of Definition 38.1: they are linear in $\mathbf{d}$, $\sum_e c_e(\mathbf{d}) = \kappa_{\mathcal{E}}(\mathbf{d}) = 0$ on $\mathbb{D}_F$, $c_e(\mathbf{d}) = \partial_{y_e} \log(\omega_{\mathbf{d}}/dy)$ on the orthant, and $c_e(\lambda) = \partial_{y_e} \log f_\lambda$.

(iv) The *value* of an insertion g at $\mathbf{d}$ is $\langle g \rangle(\mathbf{d}) = \int_{y_{e_0}=0} g\, \omega_{\mathbf{d}}$, where it converges; $\langle 1 \rangle(\mathbf{d})$ is the period $P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$ (Theorem 8.7). An insertion $g = \alpha^u \prod_j K_j^{-a_j} \Psi_j^{-b_j}$, $\mathbf{a}, \mathbf{b} \in \mathbb{N}^N$, has the walls $\kappa_U(g) = u_U - \sum_j \big(a_j d_j(U) + b_j d^*_j(U)\big)$ of its data (Proposition 38.5), and its *tube* is

$$\mathcal{T}_g = \{\mathbf{d} \in \mathbb{D}_F :\ \operatorname{Re} \kappa_U(\mathbf{d}) + \kappa_U(g) > 0 \text{ for every nonempty proper } U\}.$$

When the marks of F form one molecule (Definition 7.4) its tube $\mathcal{T}_1$ is not empty and it has a positive direction. The centre data $\mathbf{d}_\circ = (N\mathbf{1}; \mathbf{1}, \mathbf{1})$ lie on the balance wall, since $\sum_j (r_j + r^*_j) = Nn$, and every proper wall there is $\kappa_U(\mathbf{d}_\circ) = \sum_j c_j(U)$ (Definition 7.12), positive because $c_j(U) = r_j(U) - d_j(U)$ vanishes exactly when every basis of table j meets U in the same number of marks (Theorem 7.13), that is when U is a union of molecules of table j (Lemma 7.10), and no nonempty proper U is that for every table; so $\mathbf{d}_\circ$ is a positive direction and $\mathcal{T}_1$ contains the points $\eta\, \mathbf{d}_\circ$, $\eta > 0$, with neighbourhoods. A compound has, at every point of its balance wall, a wall of real part at most 0 (Proposition 8.16), and it is split into its molecules first. The procedure of Definition 16.14 evaluates a molecule at points of its data space, after the slide (Theorem 16.8).

Theorem 47.2 (The relations in all the data)**.** *Let the marks of F form one molecule.*

(i) For an insertion $g = \alpha^u \prod_j K_j^{-a_j} \Psi_j^{-b_j}$, $\mathbf{a}, \mathbf{b} \in \mathbb{N}^N$, and $\mathbf{d} \in \mathcal{T}_g$ the values $\langle g \rangle(\mathbf{d})$ and $\big\langle \big(c_e(\mathbf{d}) + \partial_{y_e}\big) g \big\rangle(\mathbf{d})$ converge absolutely, and the second is 0 for every mark e. For $\lambda \in \mathbb{D}_F(\mathbb{Z})$ with $\mathbf{d} + \lambda \in \mathcal{T}_g$, $\langle f_\lambda g \rangle(\mathbf{d}) = \langle g \rangle(\mathbf{d} + \lambda)$.

(ii) $\langle g \rangle$ continues to a meromorphic function on $\mathbb{D}_F$, holomorphic on $\mathcal{T}_g$, whose poles lie on the hyperplanes $\kappa_U(\mathbf{d}) + \kappa_U(g) \in \{0, -1, -2, \dots\}$, U nonempty and proper. Extended $\mathbb{K}_F$-linearly to $\mathbb{C}[X_F] \otimes \mathbb{K}_F$, $\big\langle \sum_i g_i \otimes r_i \big\rangle = \sum_i r_i \langle g_i \rangle$, the evaluation vanishes identically on every element of the $\mathbb{K}_F$-span of the $(c_e(\mathbf{d}) + \partial_{y_e}) g$, and $\langle f_\lambda g \rangle(\mathbf{d}) = \langle g \rangle(\mathbf{d} + \lambda)$ identically.

(iii) At every real $\mathbf{d} \in \mathcal{T}_1$, $P_F(\mathbf{m}; \mathbf{s}, \mathbf{t}) > 0$.

On the lattice translates of the period these relations are the letter and mark relations of Theorem 8.9(iii) on the balance wall: $\langle R_{j,e} \rangle(\mathbf{d}) = \sum_{T \ni e} \theta_{j,T} P_F(\mathbf{d} + (\mathbf{1}_T; \mathbf{e}_j, \mathbf{0}))$, so the relation of $g = 1$ at e is the mark relation of P_F at $\mathbf{d}$, and that of f_λ is the mark relation at $\mathbf{d} + \lambda$. The relations of a ray (Theorem 38.3, Proposition 38.5) are these read at the points $\mathbf{d}_0 + k\mathbf{d}_1$.

47.2 The module and its shifts

Definition 47.3 (The module of a family; shifts; masters; shift matrices)**.** Let F and $\Bbbk$ be as in Definition 47.1.

(i) The *relation space* $\mathcal{L}_F \subseteq \mathbb{C}[X_F] \otimes \mathbb{K}_F$ is the $\mathbb{K}_F$-span of the elements $\big(c_e(\mathbf{d}) + \partial_{y_e}\big) g$, $g \in \mathbb{C}[X_F]$, $e \in \mathcal{E}$, and the *module* of F is

$$\mathfrak{M}_F = \big(\mathbb{C}[X_F] \otimes \mathbb{K}_F\big) / \mathcal{L}_F,$$

$[g]$ the class of $g \otimes 1$. Over $\Bbbk$, $\mathcal{L}_{F,\Bbbk}$ is the $\Bbbk(\mathbb{D}_F)$-span of these elements for $g \in \Bbbk[X_F]$, and $\mathfrak{M}_{F,\Bbbk} = \big(\Bbbk[X_F] \otimes \Bbbk(\mathbb{D}_F)\big)/\mathcal{L}_{F,\Bbbk}$.

(ii) For $\lambda \in \mathbb{D}_F(\mathbb{Z})$ put $(\sigma_\lambda r)(\mathbf{d}) = r(\mathbf{d}+\lambda)$ on $\mathbb{K}_F$. The *shift* is $\mathrm{Sh}_\lambda[g \otimes r] = [f_\lambda g \otimes \sigma_\lambda r]$. A *submodule* is a $\mathbb{K}_F$-subspace $\mathfrak{N}$ with $\mathrm{Sh}_\lambda \mathfrak{N} = \mathfrak{N}$ for every $\lambda \in \mathbb{D}_F(\mathbb{Z})$, and $\mathfrak{N} \neq 0$ is *irreducible* when its only submodules are 0 and $\mathfrak{N}$.

(iii) *Masters* of a finite-dimensional submodule $\mathfrak{N}$ are insertions $\mathbf{b} = (b_1, \dots, b_\mathfrak{m})$ whose classes form a basis of $\mathfrak{N}$. Their *shift matrix* at λ is $\mathbf{A}_\lambda \in GL_\mathfrak{m}(\mathbb{K}_F)$ with $\mathrm{Sh}_\lambda[b_i] = \sum_l \mathbf{A}_{\lambda,il}[b_l]$, and the *reduction* of an element of $\mathfrak{N}$ is its vector of coordinates on $[\mathbf{b}]$.

(iv) When the marks of F form one molecule, the *value* of $m \in \mathfrak{M}_F$ is the meromorphic function $\langle m \rangle = \sum_i r_i \langle g_i \rangle$ of any representative $\sum_i g_i \otimes r_i$, and $\mathrm{Ann}\langle\cdot\rangle = \{m \in \mathfrak{M}_F : \ \langle m \rangle = 0\}$.

Theorem 47.4 (The module of a family)**.** *Let the marks of F form one molecule.*

(i) The shifts are well defined, σ_λ-semilinear and bijective, with $\mathrm{Sh}_0 = 1$ and $\mathrm{Sh}_\lambda \mathrm{Sh}_\mu = \mathrm{Sh}_{\lambda+\mu}$: the lattice acts on $\mathfrak{M}_F$. The value of an element is well defined, $\langle \mathrm{Sh}_\lambda m \rangle(\mathbf{d}) = \langle m \rangle(\mathbf{d}+\lambda)$, and $\mathrm{Ann}\langle\cdot\rangle$ is a submodule that does not contain $[1]$.

(ii) $\big[\alpha^u \prod_j K_j^{-a_j} \Psi_j^{-b_j}\big] = \mathrm{Sh}_{(u;\mathbf{a},\mathbf{b})}[1]$. So $\mathfrak{M}_F$ is the $\mathbb{K}_F$-span of the shifts of $[1]$, every submodule that contains $[1]$ is $\mathfrak{M}_F$, and every value is a combination of periods at lattice translates, $\big\langle \sum_\lambda r_\lambda f_\lambda \big\rangle(\mathbf{d}) = \sum_\lambda r_\lambda(\mathbf{d})\, P_F(\mathbf{d}+\lambda)$. The classes of the Laurent insertions span $\mathfrak{M}_F$ as well.

(iii) $\mathfrak{M}_F$ is finite-dimensional over $\mathbb{K}_F$: it is the top cohomology of the twisted algebraic de Rham complex of the letter complement X_F over $\mathbb{K}_F$ for the connection $d + \sum_{e \neq e_0} c_e(\mathbf{d})\, dy_e$.

(iv) $\mathfrak{M}_{F,\Bbbk} \otimes_{\Bbbk(\mathbb{D}_F)} \mathbb{K}_F = \mathfrak{M}_F$. So masters of $\mathfrak{M}_F$ can be taken among the insertions with coefficients in $\Bbbk$, and for such masters every shift matrix has its entries in $\Bbbk(\mathbb{D}_F)$.

(v) For masters $\mathbf{b}$ of a submodule, $\mathbf{A}_0 = 1$ and $\mathbf{A}_{\lambda+\mu} = \sigma_\lambda(\mathbf{A}_\mu)\, \mathbf{A}_\lambda$; so $\sigma_\lambda(\mathbf{A}_\mu)\, \mathbf{A}_\lambda = \sigma_\mu(\mathbf{A}_\lambda)\, \mathbf{A}_\mu$, and $\mathbf{A}_\lambda$ is the product, along any path from 0 to λ in steps of a set of generators of $\mathbb{D}_F(\mathbb{Z})$ and their inverses, of the shifted matrices of the steps. The values of the masters transport,

$$\langle \mathbf{b} \rangle(\mathbf{d}+\lambda) = \mathbf{A}_\lambda(\mathbf{d})\, \langle \mathbf{b} \rangle(\mathbf{d})$$

as an identity of meromorphic functions on $\mathbb{D}_F$, $\langle \mathbf{b} \rangle$ the column of the values of the masters. For masters of $\mathfrak{M}_F$ every insertion g has one reduction $\rho \in \mathbb{K}_F^\mathfrak{m}$, $[g] = \sum_l \rho_l [b_l]$, and $\langle g \rangle = \sum_l \rho_l \langle b_l \rangle$.

So a family carries finitely many functions of its data, the values of its masters, and every value of every insertion at every point of the data space is a combination of them with coefficients rational in the data, read off by the reduction; the integral data carry them from a point to its lattice translates through finitely many matrices with entries in $\Bbbk(\mathbb{D}_F)$. Nothing in this is chosen but the masters, and two choices of masters with coefficients in $\Bbbk$ differ by one matrix in $GL_\mathfrak{m}(\Bbbk(\mathbb{D}_F))$.

Proposition 47.5 (A ray is a line of the data space)**.** *Let $\mathbf{d}_0 \in \mathbb{D}_F$ and $\mathbf{d}_1 \in \mathbb{D}_F(\mathbb{Z})$, $\mathbf{d}_1 \neq 0$, with $s_{1j}, t_{1j} \in \mathbb{N}$ for every j, let $\ell = \{\mathbf{d}_0 + k\mathbf{d}_1 : \ k \in \mathbb{C}\}$, and let $\mathcal{O}_\ell \subseteq \mathbb{K}_F$ be the rational functions regular at the general point of ℓ, restricted by $r|_\ell(k) = r(\mathbf{d}_0 + k\mathbf{d}_1)$. The ray with the origin $\mathbf{d}_0$ and the direction $\mathbf{d}_1$ (Definition 38.1) has the stride $f = f_{\mathbf{d}_1}$, the origin form $\omega_{\mathbf{d}_0}$ and the defects $c_e^{(0)} + k\, c_e^{(1)} = c_e(\mathbf{d}_0 + k\mathbf{d}_1)$. The restriction carries $r\,(c_e(\mathbf{d}) + \partial_{y_e})g$, $r \in \mathcal{O}_\ell$, to $r|_\ell\,(c_e^{(0)} + k\, c_e^{(1)} + \partial_{y_e})g$ in the relation space of the ray (Definition 38.4), and $\mathrm{Sh}_{\mathbf{d}_1}$ to Sh. When the marks of F form one*

molecule it carries the values: for $x = \sum_i g_i \otimes r_i$ with every $r_i \in \mathcal{O}_\ell$, $\langle x\rangle(\mathbf{d}_0 + k\mathbf{d}_1) = \sum_i r_i|_\ell(k)\,\langle g_i\rangle_k$ wherever the integrals converge, and as meromorphic functions of k when $\kappa_U(\mathbf{d}_1) > 0$ for every nonempty proper U (Proposition 38.5(ii)). So the module of a ray (Definition 39.1) is the module of the family restricted to a line of $\mathbb{D}_F$, and its relations are the relations in all the data read on that line.

47.3 Boxes in all the data

Definition 47.6 (Symbols, relations and boxes in all the data)**.** Let the marks of F form one molecule, $\Bbbk$ as in Definition 47.1, and fix a positive direction $\mathbf{d}_1$.

(i) The *symbols* $(u; \mathbf{a}, \mathbf{b})$, their evaluations, levels and walls, and the Laurent symbols, are those of Definition 39.15(i), (ii); a *formal combination* has its coefficients in $\Bbbk(\mathbb{D}_F)$. The *wall degree* of a symbol g is $\deg_\kappa g = \max_U(-\kappa_U(g))/\kappa_U(\mathbf{d}_1)$ over the nonempty proper U.

(ii) The *mark relation* of a symbol $g = (u; \mathbf{a}, \mathbf{b})$ at a mark e is

$$\mathrm{MR}_e(g) = (m_e + u_e)\,g - \sum_j (s_j + a_j) \sum_{T \ni e} \theta_{j,T}\,(u + \mathbf{1}_T; \mathbf{a} + \mathbf{e}_j, \mathbf{b}) \\ - \sum_j (t_j + b_j) \sum_{T \not\ni e} \theta_{j,T}\,(u + \mathbf{1}_{\mathcal{E}\setminus T}; \mathbf{a}, \mathbf{b} + \mathbf{e}_j),$$

with coefficients affine functions on $\mathbb{D}_F$, none identically 0; it evaluates to $(c_e(\mathbf{d}) + \partial_{y_e})$ applied to the evaluation of g. The *letter identities* of g are those of Definition 39.15(iii).

(iii) *Level bounds* are $\bar{\mathbf{a}}, \bar{\mathbf{b}} \in \mathbb{N}^N$ with $\bar{a}_j, \bar{b}_j \geq 1$ for every j. For a real $\mathfrak{t} \geq 0$ the *box* $\mathfrak{B} = \mathfrak{B}_\mathfrak{t}(\bar{\mathbf{a}}, \bar{\mathbf{b}})$ is the set of the symbols of wall degree at most $\mathfrak{t}$ at the levels at most $(\bar{\mathbf{a}}, \bar{\mathbf{b}})$, its *stems* are its symbols at the level $(\bar{\mathbf{a}} - \mathbf{1}, \bar{\mathbf{b}} - \mathbf{1})$, $\mathcal{F}_\mathfrak{B}$ is the space of its formal combinations, and its *relations* $\mathcal{R}_\mathfrak{B} \subseteq \mathcal{F}_\mathfrak{B}$ are the $\Bbbk(\mathbb{D}_F)$-span of the letter identities of its symbols $(u; \mathbf{a}, \mathbf{b})$, for K_j when $a_j < \bar{a}_j$ and for Ψ_j when $b_j < \bar{b}_j$, and of the mark relations of its stems at every mark.

(iv) The *generators* are $\lambda^{\mathrm{m}}_e = (\mathbf{e}_e - \mathbf{e}_{e_0}; \mathbf{0}, \mathbf{0})$ for $e \neq e_0$, $\lambda^K_j = (\mathbf{1}_{T_j}; \mathbf{e}_j, \mathbf{0})$ and $\lambda^\Psi_j = (\mathbf{1}_{\mathcal{E}\setminus T'_j}; \mathbf{0}, \mathbf{e}_j)$, for fixed bases T_j, T'_j of table j. Their *step* is $\mathfrak{c} = \max \max(0, \kappa_U(\mu))/\kappa_U(\mathbf{d}_1)$ over the generators μ and the nonempty proper U.

(v) The *reduction* of a box is that of Definition 39.20 with the trivial group: a ranking in which every symbol at a positive level ranks above every Laurent symbol and, of two Laurent symbols, the one of larger wall degree ranks higher; pivots, free symbols, and the reduction of a formal combination. For $\mathfrak{s} \geq 0$ with $\mathfrak{s} + \mathfrak{c} \leq \mathfrak{t}$ the *spanning set* at $\mathfrak{s}$ is the list $\mathbf{b}$ of the free Laurent symbols of wall degree at most $\mathfrak{s}$, with $b_1 = 1$, and its *targets* are the Laurent polynomials $f_{-\mu} b_i$, μ a generator. The box is *accepted* at $\mathfrak{s}$ when the reduction of every target is a combination of the spanning set, $f_{-\mu} b_i \equiv \sum_l \mathbf{B}_{\mu,il}\, b_l$ modulo $\mathcal{R}_\mathfrak{B}$ with $\mathbf{B}_{\mu,il} \in \Bbbk(\mathbb{D}_F)$; the $\mathbf{B}_\mu$ are the *matrices* of the box.

Proposition 47.7 (Wall degrees and the relations of a box)**.** *In the setting of Definition 47.6:*

(i) For real x, $|g|\, f^x_{\mathbf{d}_1}$ is bounded on the positive orthant exactly when $x \geq \deg_\kappa g$, and $\langle g\rangle(\mathbf{d})$ converges absolutely at every $\mathbf{d}$ with $\mathrm{Re}\,\kappa_U(\mathbf{d}) > \deg_\kappa g\,\kappa_U(\mathbf{d}_1)$ for every nonempty proper U.

(ii) A Laurent symbol α^u has the wall degree $\max_U(-u_U)/\kappa_U(\mathbf{d}_1) \geq 0$, zero exactly for $u = 0$, and every monomial of $f_{-\mu}\alpha^u$, μ a generator, has wall degree at most $\deg_\kappa \alpha^u + \mathfrak{c}$.

(iii) *The terms of the mark relations and of the letter identities of g have wall degree at most $\deg_\kappa g$, and at every level there are finitely many symbols of wall degree at most x.*

(iv) *Every term of every relation of a box lies in the box; every relation evaluates into $\mathcal{L}_{F,\Bbbk}$, and its value vanishes identically on $\mathbb{D}_F$.*

(v) *A formal combination of symbols of a box whose evaluation is 0 is a combination of letter identities of the box.*

(vi) *The mark relation at every mark of every symbol of wall degree at most $\mathfrak{t}$ at a level at most $(\bar{\mathbf{a}}-\mathbf{1},\bar{\mathbf{b}}-\mathbf{1})$ lies in $\mathcal{R}_{\mathfrak{B}}$.*

Theorem 47.8 (The box in all the data)**.** *Let a box $\mathfrak{B}=\mathfrak{B}_{\mathfrak{t}}(\bar{\mathbf{a}},\bar{\mathbf{b}})$ be accepted at $\mathfrak{s}$, with the spanning set $\mathbf{b}$ and the matrices $\mathbf{B}_\mu$.*

(i) *In the module, $\mathrm{Sh}_{-\mu}[b_i]=[f_{-\mu}b_i]=\sum_l \mathbf{B}_{\mu,il}[b_l]$ for every generator μ, and the classes of $\mathbf{b}$ span $\mathfrak{M}_F$. The spanning set is a set of masters exactly when its classes are linearly independent over $\mathbb{K}_F$, and then $\mathbf{B}_\mu=\mathbf{A}_{-\mu}$.*

(ii) The certificate. *There are formal combinations $G_{\mu,i,e}$ of stems such that*

$$f_{-\mu}b_i-\sum_l \mathbf{B}_{\mu,il}\,b_l=\sum_{e\in\mathcal{E}}\big(c_e(\mathbf{d})+\partial_{y_e}\big)G_{\mu,i,e}$$

as functions on X_F with coefficients in $\Bbbk(\mathbb{D}_F)$, the $G_{\mu,i,e}$ evaluated.

(iii) *$\langle\mathbf{b}\rangle(\mathbf{d}-\mu)=\mathbf{B}_\mu(\mathbf{d})\,\langle\mathbf{b}\rangle(\mathbf{d})$ as an identity of meromorphic functions on $\mathbb{D}_F$. At every real $\mathbf{d}$ off the poles of the coefficients with $\kappa_U(\mathbf{d})>\mathfrak{t}\,\kappa_U(\mathbf{d}_1)$ for every nonempty proper U, every value in (ii) converges absolutely and every term $(c_e(\mathbf{d})+\partial_{y_e})s$, s a stem, has the value 0, so the certificate integrates term by term.*

(iv) The search stops. *There are $\mathfrak{s}$, level bounds and $\mathfrak{t}\ge\mathfrak{s}+\mathfrak{c}$ at which the box is accepted. So a search that runs through all the $(\mathfrak{t},\bar{\mathbf{a}},\bar{\mathbf{b}},\mathfrak{s})$ with $\mathfrak{t}$ and $\mathfrak{s}$ in a fixed discrete set, in any order that reaches each, and tests the acceptance by one elimination over $\Bbbk(\mathbb{D}_F)$ at each, stops, with a spanning set of $\mathfrak{M}_F$, its matrices at the generators, and their certificates.*

47.4 Closings and the elements of value zero

Definition 47.9 (Closings in all the data)**.** For $\mathbf{d}\in\mathbb{D}_F(\mathbb{Z})$ and an insertion g such that $g\,\omega_{\mathbf{d}}/dy$ is a Laurent polynomial, as when $g=\alpha^u\prod_j K_j^{-a_j}\Psi_j^{-b_j}$ with $s_j+a_j\le 0$ and $t_j+b_j\le 0$ for every j, the *closing* of g at $\mathbf{d}$ is the constant term

$$\mathsf{C}(g)(\mathbf{d})=\mathrm{CT}\,\big(g\,\omega_{\mathbf{d}}/dy\big)=\frac{1}{(2\pi i)^{n-1}}\oint_{|\alpha_e|=1,\ e\neq e_0} g\,\omega_{\mathbf{d}}$$

on the chart $\alpha_{e_0}=1$. For $x=\sum_i g_i\otimes r_i$, $\mathsf{C}(x)(\mathbf{d})=\sum_i r_i(\mathbf{d})\,\mathsf{C}(g_i)(\mathbf{d})$ at the $\mathbf{d}\in\mathbb{D}_F(\mathbb{Z})$ at which every $\mathsf{C}(g_i)(\mathbf{d})$ is defined and no r_i has a pole.

Proposition 47.10 (The closings are a solution in all the data)**.** *Where both sides are defined, $\mathsf{C}\big((c_e(\mathbf{d})+\partial_{y_e})g\big)(\mathbf{d})=0$ for every mark e and $\mathsf{C}(f_\lambda g)(\mathbf{d})=\mathsf{C}(g)(\mathbf{d}+\lambda)$. When the marks of F form one molecule, $\mathsf{C}(x)=0$ wherever it is defined for $x\in\mathcal{L}_F$. Along a ray with an integral origin $\mathbf{d}_0$ and a positive direction $\mathbf{d}_1$ the closings of Definition 39.30 are $\mathsf{C}_j(g)=\mathsf{C}(g)(\mathbf{d}_0-j\mathbf{d}_1)$, and $V_{\mathsf{C}}(x|_\ell)(k)=\mathsf{C}(x)(\mathbf{d}_0+k\mathbf{d}_1)$ at the integers $k\le-\max_i j(g_i)$, $j(g_i)$ that of Definition 39.30 for this ray, off the poles of the coefficients.*

Theorem 47.11 (The elements of value zero)**.** *Let the marks of F form one molecule, $\mathbf{d}_0 \in \mathbb{D}_F(\mathbb{Z})$, and $m \in \mathfrak{M}_F$ with a representative x. The following are equivalent:*

(a) $\langle m \rangle = 0$ on $\mathbb{D}_F$;

(b) for every positive direction $\mathbf{d}_1$ such that no coefficient of x has a pole along the whole line $\mathbf{d}_0 + \mathbb{C}\mathbf{d}_1$, $\langle m \rangle(\mathbf{d}_0 + k\mathbf{d}_1) = 0$ for all large integers k;

(c) for every such $\mathbf{d}_1$, $\mathsf{C}(x)(\mathbf{d}_0 + k\mathbf{d}_1) = 0$ for all integers k below some bound.

So $\mathrm{Ann}\langle\cdot\rangle$ is the submodule of the elements whose closings vanish along the rays from one integral point, and it is 0 (Proposition 47.15): (a)–(c) hold exactly when $m = 0$. Every relation among the values of insertions, as functions of all the data, is a relation of the module and is certified by these closings, which are proved relations (Definition 44.1); along each ray the vanishing is decided by finitely many closings (Theorem 44.16(ii)), rational numbers when the weights, the insertions of x and its coefficients are rational; and two insertions have the same value as functions of all the data exactly when they have the same reduction on masters.

So the values of a family enter its algebra only through the masters: the reduction, the shift matrices and the certificates are finite computations over $\Bbbk(\mathbb{D}_F)$, the closings are constant terms of Laurent polynomials, and a relation among values as functions of the data is a statement about the module, settled by closings.

The rays of Theorem 47.11 are infinitely many, and the lattice points of one line do not see a function of all the data. The submodule that an element generates carries the vanishing of its value from finitely many parallel rays to every parallel ray through the lattice, and every lattice point lies on one of these.

Proposition 47.12 (Value zero by finitely many closings)**.** *Let the marks of F form one molecule, $\mathfrak{M}$ be $\mathfrak{M}_F$ or its quotient by a submodule of elements of value zero, $m \neq 0$ in $\mathfrak{M}$ with a representative x, $\mathfrak{N}$ the submodule of $\mathfrak{M}$ generated by m, of dimension d, and $\mathcal{G}$ the generators of Definition 47.6(iv) with their negatives.*

(i) $\mathfrak{N}$ is the $\mathbb{K}_F$-span of the $\mathrm{Sh}_\lambda m$ with λ a sum of at most $d-1$ elements of $\mathcal{G}$. So it has a basis $\mathrm{Sh}_{\lambda_1} m, \dots, \mathrm{Sh}_{\lambda_d} m$ among these, $\lambda_1 = \mathbf{0}$, found by eliminations over $\mathbb{K}_F$ on their reductions on masters of $\mathfrak{M}$ (Theorem 47.4(v), Proposition 47.13), and matrices $\mathbf{B}_\mu \in GL_d(\mathbb{K}_F)$, $\mu \in \mathcal{G}$, with $\mathrm{Sh}_\mu \mathrm{Sh}_{\lambda_k} m = \sum_l \mathbf{B}_{\mu,kl} \mathrm{Sh}_{\lambda_l} m$.

(ii) Let $\mathbf{d}_0 \in \mathbb{D}_F(\mathbb{Z})$, and let $\mathbf{d}_1$ be a positive direction at which the top homogeneous part of no reduced denominator of a coefficient of x, or of an entry of a $\mathbf{B}_\mu$, $\mu \in \mathcal{G}$, vanishes. Then $\langle m \rangle = 0$ exactly when, for $k = 1, \dots, d$, the closings $\mathsf{C}(x)(\mathbf{d}_0 + \lambda_k + j\mathbf{d}_1)$ vanish at all integers j below some bound. Along each of these d rays finitely many closings decide (Theorem 44.16(ii)), rational numbers when the weights, the insertions of x and its coefficients are rational. Such directions exist: the excluded ones lie on a proper algebraic subset of $\mathbb{D}_F$, and the positive directions are the lattice points of an open cone.

So whether two elements of $\mathfrak{M}$, two insertions among them, have the same value as functions of all the data is decided by finitely many closings, along finitely many parallel rays.

47.5 Masters from a box

A box gives a spanning set and the matrices of the shifts by the negatives of the generators (Theorem 47.8). When those matrices are invertible they give the shifts by the generators as well, and the spanning set with these maps presents the module: the relations that the box did not see

are generated, as in Theorem 48.18(iv), by the commutators of the maps and by the relations of the family at [1], so that a basis of the presented quotient is a set of masters.

Proposition 47.13 (Masters from a box)**.** *Let the marks of F form one molecule, and let a box be accepted at $\mathfrak{s}$, with the spanning set $\mathbf{b}$, $b_i = f_{\lambda_i}$, $b_1 = 1$, and the matrices $\mathbf{B}_\mu$ at the generators μ of Definition 47.6(iv).*

(i) If some $\mathbf{B}_\mu$ is singular, the classes of $\mathbf{b}$ are not linearly independent.

(ii) Let every $\mathbf{B}_\mu$ be invertible. On $\Bbbk(\mathbb{D}_F)^{\mathbf{b}}$, with the basis (ε_i), let $T_{-\mu}$ be the $\sigma_{-\mu}$-semilinear map with the matrix $\mathbf{B}_\mu$ and T_μ the σ_μ-semilinear map with the matrix $\sigma_\mu(\mathbf{B}_\mu)^{-1}$, as the shifts act on coordinates (Theorem 48.18(iv)); let $\rho(\lambda)$ be the image of ε_1 under the maps of the steps of a path from $\mathbf{0}$ to λ in the generators and their negatives, fixed for each λ; and let $\mathfrak{N}$ be the smallest subspace that these maps carry into itself and that contains the $T_\mu T_\nu \varepsilon_i - T_\nu T_\mu \varepsilon_i$, the $T_{-\mu}T_\mu\varepsilon_i - \varepsilon_i$ and $T_\mu T_{-\mu}\varepsilon_i - \varepsilon_i$, the $\varepsilon_i - \rho(\lambda_i)$, and the images under ρ of the letter identities and of the mark relations of F at [1], $\sum_T \theta_{j,T}\,\rho(\lambda_T^K) - \varepsilon_1$, $\sum_T \theta_{j,T}\,\rho(\lambda_T^\Psi) - \varepsilon_1$ and $m_e\varepsilon_1 - \sum_j s_j \sum_{T\ni e} \theta_{j,T}\,\rho(\lambda_T^K) - \sum_j t_j \sum_{T\not\ni e} \theta_{j,T}\,\rho(\lambda_T^\Psi)$, with $\lambda_T^K = (\mathbf{1}_T; \mathbf{e}_j, \mathbf{0})$ and $\lambda_T^\Psi = (\mathbf{1}_{\mathcal{E}\setminus T}; \mathbf{0}, \mathbf{e}_j)$. Then $\varepsilon_i \mapsto [b_i]$ is an isomorphism of $\Bbbk(\mathbb{D}_F)^{\mathbf{b}}/\mathfrak{N}$ onto $\mathfrak{M}_{F,\Bbbk}$ that carries the maps $T_{\pm\mu}$ to the shifts $\mathrm{Sh}_{\pm\mu}$. So a basis of the quotient among the ε_i, found by finitely many eliminations, is a set of masters, with its shift matrices at the generators and their negatives, and $\mathfrak{N}$ does not depend on the paths.

(iii) Some accepted box has a spanning set whose classes are linearly independent. So a search through the boxes of Theorem 47.8(iv) that also asks every $\mathbf{B}_\mu$ to be invertible stops, and (ii) then gives masters of $\mathfrak{M}_F$ with their shift matrices.

The same holds for a family of positive letters, with the boxes, the generators, the letter identities and the mark relations of Theorem 48.3(iv).

47.6 Value zero on a subspace of the data

A question may be asked on a subspace of the data: on a hyperplane on which a balance holds, or on a slice on which some exponents are fixed. Such a subspace may contain no positive direction, and its integral points may carry no closings. The expansion of the values at the native gauge of one direction asks for neither. Every point of the subspace is the origin of a line in that direction, the expansion of the values along every such line is a formal series whose coefficients are rational functions of the origin, and the values vanish on the subspace exactly when these coefficients do; at a rational native gauge, with rational weights and coefficients, they are rational functions over $\mathbb{Q}$.

Proposition 47.14 (Value zero on a subspace of the data)**.** *Let W be a family of letters of tables (Theorem 48.23), $r = r_W$, $\mathbb{E} \subseteq \mathbb{D}_W$ a linear subspace with the field $\mathbb{C}(\mathbb{E})$ of its rational functions, and $x = \sum_l g_l \otimes r_l$ with strides $g_l = f_{\lambda_l}$, $\lambda_l \in \mathbb{D}_W(\mathbb{Z})$, which span the insertions (Definition 48.1(iii)), and $r_l \in \mathbb{C}(\mathbb{E})$. A* native direction *of $\mathbb{E}$ is a point $\mathbf{d}_1 \in \mathbb{E} \cap \mathbb{D}_W(\mathbb{Z})$ with every wall positive and every exponent $w_{1,i} \geq 0$, the letters with $w_{1,i} > 0$ forming a family W_1 of letters of tables with the active molecules of W. When $\mathbb{E}$ has one it meets the tube $\mathcal{T}_1$, and the* value *of x on $\mathbb{E}$ is the meromorphic function $\langle x \rangle = \sum_l r_l \langle g_l \rangle$ there.*

(i) The native gauge. *For a native direction $\mathbf{d}_1$ the function $\log f$, $f = \omega_{\mathbf{d}_1}/dy$, is strictly concave on V_W and tends to $-\infty$ at infinity, so it has one critical point $y^\star$, a nondegenerate maximum: the* native gauge *$\alpha^\star = e^{y^\star}$ of $\mathbf{d}_1$, with $f^\star = f(\alpha^\star)$ and H the Hessian of $\log f$*

at $y^\star$. Conversely, for a point α° of the positive orthant and exponents $\mathbf{w}_1 \in \mathbb{N}^I$ whose letters with positive exponents form such a family W_1, the point $\big(\sum_i w_{1,i} R_i(\alpha^\circ); \mathbf{w}_1\big)$, R_i the occupations, lies in $\mathbb{D}_W$, has every wall positive and has the native gauge α°. When it lies in $\mathbb{E}$, and α° and the weights are rational, an integral multiple of it is a native direction of $\mathbb{E}$ with the rational native gauge α°. Whatever the weights, the real points of $\mathbb{D}_W$ with the exponents of the letters outside W_1 equal to 0, those of W_1 positive and every wall positive form an open cone in the real points of the subspace on which those exponents vanish; when $\mathbb{E}$ is defined over $\mathbb{Q}$ and meets that cone, its integral points in the cone are native directions of $\mathbb{E}$, and the native gauge of every native direction, an isolated nondegenerate common zero of its defects, which are rational functions over the field of the weights, has coordinates on a chart of V_W algebraic over that field.

(ii) The expansion. *Let $\mathbf{d}_1$ be a native direction of $\mathbb{E}$, $p \in \mathbb{E}$ off a proper algebraic subset, and ν the largest degree in k at $k = \infty$ of the $r_l(p + k\mathbf{d}_1)$. As $k \to \infty$ through the reals,*

$$\langle x\rangle(p + k\mathbf{d}_1) \;\sim\; c_\star \,\frac{\omega_p}{dy}(\alpha^\star)\,(f^\star)^k\, k^{\nu - r/2} \sum_{i\geq 0} Q_i(p)\, k^{-i}, \qquad c_\star = (2\pi)^{r/2}\det(-H)^{-1/2},$$

the determinant taken in a basis of $V_W(\mathbb{Z})$, with $Q_i \in \mathbb{C}(\mathbb{E})$. Each Q_i is a finite sum of products of coefficients of the expansions of the $r_l(p+k\mathbf{d}_1)$ at $k = \infty$, of the values $g_l(\alpha^\star)$, of polynomials in p of degree at most $2i$ formed from the Taylor coefficients at $y^\star$ of the $\log g_l$, the $\log L_i$ and $\log f$, and of Gaussian moments of the covariance $(-H)^{-1}$. So, for $\mathbb{E}$ defined over $\Bbbk'$, the Q_i lie in $\Bbbk'(\mathbb{E})$, $\Bbbk'$ the field generated over $\mathbb{Q}$ by the weights, the coefficients of the r_l and $\alpha^\star$: rational functions over $\mathbb{Q}$ when these are rational and $\mathbb{E}$ is defined over $\mathbb{Q}$.

(iii) Value zero. $\langle x\rangle = 0$ *on $\mathbb{E}$ exactly when every Q_i is* 0.

(iv) Finitely many coefficients. *The $\mathbb{C}(\mathbb{E})$-span $\mathcal{L}_\mathbb{E}$ of the $(c_e(\mathbf{d}) + \partial_{y_e})g$, $g \in \mathbb{C}[X_W]$, $\mathbf{d}$ the point of $\mathbb{E}$, gives the* module of W on $\mathbb{E}$,

$$\mathfrak{M}_{W,\mathbb{E}} = \big(\mathbb{C}[X_W] \otimes \mathbb{C}(\mathbb{E})\big)/\mathcal{L}_\mathbb{E}, \qquad \mathrm{Sh}_{\mathbf{d}_1}[g \otimes r] = [f_{\mathbf{d}_1} g \otimes \sigma_{\mathbf{d}_1} r],$$

of finite dimension over $\mathbb{C}(\mathbb{E})$; the value on $\mathbb{E}$ vanishes on $\mathcal{L}_\mathbb{E}$, and $\langle \mathrm{Sh}_{\mathbf{d}_1} x\rangle = \sigma_{\mathbf{d}_1}\langle x\rangle$. So x has a law along $\mathbf{d}_1$, *$\sum_{j=0}^h q_j \,\mathrm{Sh}_{\mathbf{d}_1}^j x = 0$ in $\mathfrak{M}_{W,\mathbb{E}}$ with $q_j \in \mathbb{C}(\mathbb{E})$ and $q_0 q_h \neq 0$, found by a search through the finite supports of certificates, elements of $\mathcal{L}_\mathbb{E}$, each tested by one elimination over $\mathbb{C}(\mathbb{E})$. Write $q_j(p + k\mathbf{d}_1) = k^{\nu'}\sum_{a\geq 0} q_{j,a}(p)\, k^{-a}$ at $k = \infty$, ν' the largest degree of the $q_j(p + k\mathbf{d}_1)$, $\rho = \nu - r/2$, $\chi_{a,b} = \sum_j q_{j,a}(f^\star)^j j^b$ and*

$$C_s(N) = \sum_{a+b=s} \binom{\rho - N + s}{b} \chi_{a,b},$$

polynomials in N with coefficients in $\mathbb{C}(\mathbb{E})$, not all 0. Let s_0 be the least s with $C_s \neq 0$, and N_0 the largest integer root of C_{s_0} when it has one at least s_0, and s_0 otherwise. Then $Q_i = 0$ for every $i \leq N_0 - s_0$ implies $Q_i = 0$ for every i.

So whether an element has the value zero on a subspace of the data is decided by finitely many identities of rational functions on the subspace, identities over $\mathbb{Q}$ at a rational native gauge, whatever positive directions and closings the subspace carries.

A positive direction is a native direction, and on $\mathbb{E} = \mathbb{D}_W$ the proposition decides what Proposition 47.12 decides by closings. The closings ask for integral origins and for the low end of a ray,

at which every letter is a polynomial. On a subspace cut out by a linear form in the exponents of some letters whose coefficients have one sign, a ray inside it has such a low end only when those exponents vanish at its origin and along it, so that the insertions in which those letters are denominators carry no closings there. The expansion at the native gauge needs no integral origin and no low end: its origin is the point of the subspace itself, and the letters whose exponents the direction leaves at 0 enter only through the Taylor coefficients of the integrand at the native gauge, as polynomials in the origin.

47.7 The values separate the module

The masses act on the values as the Euler derivatives act on the integrand. Multiplying an insertion by the mass of a mark is, by the mark relation of that mark, taking minus its derivative in that mark and adding its products with the occupations of the mark, weighted by the exponents; so, modulo the relations and after one denominator is cleared, every element is the class of one combination of insertions whose coefficients are polynomials in the exponents alone. At fixed exponents its value, as a function of the masses, is the Mellin transform, over the positive points of the letter complement, of that combination times the word of the letters at those exponents, the masses ranging over the space of directions, and a Mellin transform determines the function it transforms. So an element whose value vanishes as a function of all the data is zero in the module: every linear relation among the values of a family, with coefficients rational in its data, is a relation of its module, and the closings that tell the elements of value zero (Theorem 47.11, Proposition 47.12) separate the module. The same holds on a subspace of the data cut out by conditions on the exponents alone that meets the tube, such a subspace leaving every mass free. A subspace that ties the masses can carry nonzero elements of value zero: along a ray kept by symmetries the values vanish on the elements that the symmetries move (Theorem 39.12(ii)), and on every subspace with a native direction Proposition 47.14 tells them.

Proposition 47.15 (The values separate the module)**.** *Let W be a family of positive letters (Definition 48.1), $\pi(\mathbf{m};\mathbf{w}) = \mathbf{w}$ the projection of $\mathbb{D}_W$ onto the exponents, $\mathbb{E}_{\mathbf{w}} \subseteq \mathbb{C}^I$ a linear subspace, and $\mathbb{E} = \pi^{-1}(\mathbb{E}_{\mathbf{w}})$, the data whose exponents lie in $\mathbb{E}_{\mathbf{w}}$, with every mass that $\mathbb{D}_W$ allows at them; $\mathbb{E} = \mathbb{D}_W$ for $\mathbb{E}_{\mathbf{w}} = \mathbb{C}^I$. Let $\mathbb{E}$ meet the tube $\mathcal{T}_1$. The* module of W on $\mathbb{E}$ *is $\mathfrak{M}_{W,\mathbb{E}} = \big(\mathbb{C}[X_W] \otimes \mathbb{C}(\mathbb{E})\big)/\mathcal{L}_{\mathbb{E}}$, $\mathcal{L}_{\mathbb{E}}$ the $\mathbb{C}(\mathbb{E})$-span of the $(c_e(\mathbf{d}) + \partial_{y_e})g$, $g \in \mathbb{C}[X_W]$, $e \in B$, $\mathbf{d}$ the point of $\mathbb{E}$, as in Proposition 47.14(iv); it is $\mathfrak{M}_W$ for $\mathbb{E} = \mathbb{D}_W$. The* value *on $\mathbb{E}$ of $x = \sum_l g_l \otimes r_l$ is $\langle x\rangle = \sum_l r_l \langle g_l\rangle$ there.*

(i) The masses act through the mark relations. *For $g \in \mathbb{C}[X_W]$, $r \in \mathbb{C}(\mathbb{E})$ and $e \in B$, in $\mathfrak{M}_{W,\mathbb{E}}$,*

$$[g \otimes m_e\, r] = \Big[\sum_i R_{i,e}\, g \otimes w_i\, r - \partial_{y_e} g \otimes r\Big],$$

$R_{i,e}$ the occupations. So every element, times a nonzero polynomial on $\mathbb{E}$, is the class of an element $\sum_k G_k \otimes p_k$, $G_k \in \mathbb{C}[X_W]$, whose coefficients p_k are polynomials in the exponents alone.

(ii) Separation. *The value on $\mathbb{E}$ is well defined on $\mathfrak{M}_{W,\mathbb{E}}$, and an element whose value vanishes on $\mathbb{E}$ is 0. So a combination of insertions with coefficients in $\mathbb{C}(\mathbb{E})$ has the value zero on $\mathbb{E}$ exactly when it lies in $\mathcal{L}_{\mathbb{E}}$; two insertions have the same value on $\mathbb{E}$ exactly when they have the same class; and insertions whose classes are linearly independent have values that are linearly independent over $\mathbb{C}(\mathbb{E})$.*

(iii) In all the data. $\mathrm{Ann}\langle\cdot\rangle = 0$ *in* $\mathfrak{M}_W$*, and the quotient of* $\mathfrak{M}_W$ *by a submodule of elements of value zero is* $\mathfrak{M}_W$*. So two insertions have the same value as functions of all the data exactly when they have the same reduction on masters, and the values of masters are linearly independent over* $\mathbb{K}_W$*. For a family of letters of tables an element of* $\mathfrak{M}_W$ *is* 0 *exactly when its closings vanish along the rays of Theorem 47.11(c) from one integral point, and exactly when they vanish along the* d *parallel rays of Proposition 47.12(ii) (Theorem 48.23(ii)): finitely many closings separate the module.*

(iv) On a subspace with a native direction. *For a family of letters of tables and* $\mathbb{E} = \pi^{-1}(\mathbb{E}_{\mathbf{w}})$ *as above with a native direction* $\mathbf{d}_1$*, an element of* $\mathfrak{M}_{W,\mathbb{E}}$ *is* 0 *exactly when finitely many coefficients of the expansion of its value at the native gauge of* $\mathbf{d}_1$ *vanish (Proposition 47.14(iii), (iv)).*

So every linear relation among the values of a family, with coefficients rational in its data, or in the data whose exponents lie on a linear subspace when those data meet the tube, is a relation of its module, or of its module on those data, a combination of its mark relations: integration by parts in the marks gives every relation that the values satisfy as functions of the masses.

The masses are what the proof uses. At fixed exponents a relation among values, as functions of the masses, is a relation among Mellin transforms, and the Mellin transform is injective; a subspace that fixes a combination of the masses at fixed exponents sees the transform only on a section of the masses, which is the transform of the integral of the integrand along the orbits of a subgroup of the torus, and a nonzero element can integrate to zero there. So on a ray or on the symmetric data of a family with a symmetry the module of the subspace can carry elements of value zero, while in all the data the quotients by submodules of elements of value zero in Proposition 47.12 and in Theorems 48.23, 48.18 and 48.20 are the modules themselves, and the closings along the d parallel rays of a nonzero element do not all vanish.

47.8 The number of masters

The masses that separate the module also make its twisted de Rham complex exact below the top degree. Each mass enters the twisted Euler derivative in its own coordinate alone and with the coefficient one, so with the masses as indeterminates these operators form a regular sequence, and the complex resolves the module. At the generic point of the data the module is therefore the only cohomology of the complex, and at every point off countably many hypersurfaces of the data the top cohomology is the only one, of the same dimension. At such a point the complex computes the cohomology of the local system of rank one formed by the branches of the inverse of the master form, dual to the cycles that carry a branch of the master form, over which the insertions are integrated, the positive orthant with its principal branch among them, with a support that is closed but not compact; the alternating count of that cohomology is the Euler characteristic of the letter complement, one generator for each cell. So the number of masters is the signed Euler characteristic of the letter complement. Far out along a direction the module degenerates onto the functions on the native points of the data, so there are at least as many masters as native points of generic data, and the count of the critical points of a generic master form makes them exactly as many. For the engine the count is a certificate: a spanning set with no more elements than the nondegenerate native points of some data is a set of masters.

Proposition 47.16 (The number of masters)**.** *Let* W *be a family of positive letters (Definition 48.1) and* $r = r_W$*. For* $\mathbf{d} \in \mathbb{D}_W$ *let* $H^i(\mathbf{d})$ *be the cohomology of the twisted algebraic de Rham*

complex of X_W with the differential $d + d\log(\omega_{\mathbf{d}}/dy)$, and $H^i(\mathbb{K}_W)$ that over $\mathbb{K}_W$, whose top one is $\mathfrak{M}_W$ (Theorem 48.3(iii)).

(i) Nothing below the top. *$H^i(\mathbb{K}_W) = 0$ for $i < r$. Off a countable union of proper hypersurfaces of $\mathbb{D}_W$, $H^i(\mathbf{d}) = 0$ for $i < r$ and $\dim H^r(\mathbf{d}) = \mathfrak{m}_W$; on a line of $\mathbb{D}_W$ that lies in none of them, the module of W restricted to the line, the quotient of $\mathbb{C}[X_W]$ over the rational functions of the line by the $(c_e(\mathbf{d}) + \partial_{y_e})g$ read on it, which for a ray of a family of tables is the module of the ray (Proposition 47.5), has the dimension $\mathfrak{m}_W$ over the rational functions of the line.*

(ii) The count. *$\mathfrak{m}_W = (-1)^r \operatorname{eu}(X_W)$,* eu *the Euler characteristic.*

(iii) One master for each native point. *The* native points *of $\mathbf{d}$ are the points of X_W at which every defect $c_e(\mathbf{d})$ vanishes, the critical points of $\omega_{\mathbf{d}}/dy$,* nondegenerate *when the Hessian of $\log(\omega_{\mathbf{d}}/dy)$ in logarithmic coordinates of X_W is nonsingular there: for a direction they are its native gauges (Definition 38.4), and the native gauge of a native direction is one of them (Proposition 47.14(i)). Off a proper algebraic subset of $\mathbb{D}_W$ the native points are finitely many and nondegenerate, and there are $\mathfrak{m}_W$ of them; at every $\mathbf{d}$ the nondegenerate native points are at most $\mathfrak{m}_W$. So a direction off a proper algebraic subset has $\mathfrak{m}_W$ native gauges, all nondegenerate, and every direction at most $\mathfrak{m}_W$ nondegenerate ones.*

(iv) Masters by count. *Insertions whose classes span $\mathfrak{M}_W$ are at least $\mathfrak{m}_W$ in number, and when they are at most as many as the nondegenerate native points of some data, they are $\mathfrak{m}_W$ in number and they are masters. So the spanning set of an accepted box with at most that many elements is a set of masters, with $\mathbf{B}_\mu = \mathbf{A}_{-\mu}$ (Theorem 47.8(i), Theorem 48.3(iv)), and an accepted set of at most that many shifts (Theorem 48.18(iv)) presents $\mathfrak{M}_W$ with $\mathfrak{N} = 0$, its classes ε_λ being masters.*

So the number of masters of a family is a property of its letter complement alone, its signed Euler characteristic, and it is the number of the native points of generic data: there is one master for each critical point of the master form, and at a native direction the native gauge is the one of them on the positive orthant.

The two halves of the count come from different places. The native half, at least one master for each native point, is the degeneration: the relations $\hbar\theta_k + x_k$ interpolate between the module at $\hbar = 1$ and, at $\hbar = 0$, the functions on the native points, and a family of this kind over a discrete valuation ring can lose dimension at its special point but not gain it. The other half, at most one master for each native point of generic data, is topological: the alternating count of the cohomology of a local system of rank one is the Euler characteristic, below the top degree there is nothing, and the critical points of a generic master form are counted by the same Euler characteristic. At an integral or special direction the native points can merge, leave X_W or fill a curve, and then the nondegenerate ones are fewer than the masters; at no data are they more. The countable union in (i) cannot be shrunk to a proper algebraic subset: for the one letter $\alpha_1 + \alpha_2$, $x^{-\mu}(x+1)^w$ is a nonzero element of $H^0(\mathbf{d})$ at every integral $\mathbf{d}$, and the integral data are Zariski dense.

Chapter 48

The module along the tree

Along its tree a family is read as a fibre integral over pins: a quotient of Gamma functions of the shares times the periods of the words of its nodes, each word a family of positive letters whose exponents are shares (Theorems 28.10(iii) and 28.12, Corollary 29.5). The module of Chapter 47 belongs to every family of positive letters. Read on the space of the directions that its Newton sum sees, such a family has a data space, insertions, relations, and a module of finite dimension over the rational functions of its data, with shifts, masters and boxes, whatever its letters. Through such a reading the module of a family is built from the modules of its nodes. Wherever the contours of the reading exist, every value of every element is the same fibre integral with the periods of the nodes replaced by a multilinear form in the values of their masters, its coefficients rational in the data and the shares. The lattice of the data acts through the Kronecker products of the shift matrices of the nodes along the paths of the bases through the tree, the kernel contributing Pochhammer symbols, and a node that recurs up to a bijection of its marks has one module. Along a chain of bunches the chance of a basis is the probability of the path of its stations under the flow of the shares, times the chances of its pieces in the entries of the nodes. Every tree of nested bunches is such a reading, node by node. A letter is also read on its scale, the Mellin transform of its shares: every full node reads on its scales the blocks of any partition of its parts that its seam letters separate, at one point, each block through its transform, so that a repeated block is one transform to a power, and the group of what the word reads there, at any number of scales, is a quotient of the group of its distinct blocks and of the exponentials of their constant parts. Theorem 45.34 is the case of one table at width one, its series and parallel nodes read through their cells. Along every tree the relations of the family ride on the paths of the terms of its letters, so that, modulo the translations along the fibres, the integrand carries the module of the family itself: the module of a family is the direct image of the modules of its nodes, presented node by node from the leaves up, once for each class of subtrees, by eliminations on identities among the products of the masters of the nodes, the values separating the module (Proposition 47.15), and the closings of the node words and of the seam words of the leaves, combined along the tree by flows of integers, tell its zeros. On the scales the same holds block by block: the module of the transform of a block, over the rational functions of the data that it reads and of its scales, is the direct image of the modules of its children modulo the translations along its fibre, each twisted by a monomial in the scales, the scales acting by connections that are combinations of its shifts, up to elements of value zero only where the transform reads a hyperplane of the data of its block; a block without children is a Gramma, read so on its shares. The last section puts these readings in order as one procedure, which stops on every family and reads it in all its data, absent letters and several molecules included.

48.1 Families of positive letters

The letters of a table of positive rank and corank are positive letters, and the seam letters of a piece, the entries of a transfer matrix and the station letters of a room are positive letters or positive constants. Every definition of Chapter 47 is made for a finite family of positive letters, on the space of the directions of its Newton sum.

Definition 48.1 (A family of positive letters)**.** Let B be a finite set and $W = (L_i)_{i\in I}$ a finite nonempty family of nonzero homogeneous polynomials on B with positive coefficients, $L_i = \sum_{\mathbf{t}} c_{i,\mathbf{t}}\, \alpha^{\mathbf{t}}$, in a field $\Bbbk \subseteq \mathbb{C}$: positive letters (Definition 25.1) or positive constants, a constant having the one exponent $\mathbf{0}$ and the degree 0. These are its *letters*, and W is a *family of positive letters*. Fix an exponent $\mathbf{t}_i$ of the support of each L_i.

(i) The *space of directions* $\vec{\mathcal{N}}_W \subseteq \mathbb{R}^B$ is spanned by the differences of two exponents of the support of one letter, over all the letters: the space of the directions of the Newton sum $\sum_i w_i \mathcal{N}_{L_i}$ at any positive exponents. It lies in $\mathbf{1}^\perp$, and W is *full* when it is $\mathbf{1}^\perp$, the Newton sum having the dimension $|B| - 1$. Put $M_W = \vec{\mathcal{N}}_W \cap \mathbb{Z}^B$ and $r_W = \dim \vec{\mathcal{N}}_W$.

(ii) The *data space* of W is

$$\mathbb{D}_W = \Big\{ \mathbf{d} = (\mathbf{m}; \mathbf{w}) \in \mathbb{C}^B \times \mathbb{C}^I : \ \mathbf{m} - \sum_i w_i \mathbf{t}_i \in \vec{\mathcal{N}}_W \otimes \mathbb{C} \Big\},$$

which does not depend on the exponents fixed; for a full family it is the balance hyperplane $m_B = \sum_i w_i \deg L_i$. Its integral points $\mathbb{D}_W(\mathbb{Z})$ are its *lattice*, $\mathbb{D}_W(\mathbb{R})$ is the set of its real points, and its fields of rational functions are $\Bbbk(\mathbb{D}_W) \subseteq \mathbb{K}_W = \mathbb{C}(\mathbb{D}_W)$. The *word* of W at the exponents $\mathbf{w}$ is $W(\mathbf{w}) = \prod_i L_i^{-w_i}$.

(iii) The subtorus of $(\mathbb{C}^\times)^B$ on which every α^u, $u \in M_W$, takes the value 1 acts on $(\mathbb{C}^\times)^B$ by multiplication, every letter being semi-invariant, and the *letter complement* X_W is the quotient by it of the set on which no letter vanishes. Its regular functions, the *insertions* $\mathbb{C}[X_W]$, are the $\mathbb{C}$-span of the $\alpha^u \prod_i L_i^{-a_i}$ with $\mathbf{a} \in \mathbb{N}^I$ and $(u; \mathbf{a}) \in \mathbb{D}_W(\mathbb{Z})$; the *Laurent insertions* are those with $\mathbf{a} = \mathbf{0}$, the span of the α^u, $u \in M_W$. For $\lambda = (v; \mathbf{a}) \in \mathbb{D}_W(\mathbb{Z})$ the *stride* $f_\lambda = \alpha^v \prod_i L_i^{-a_i}$ is a unit of $\mathbb{C}[X_W]$, and $f_\lambda f_\mu = f_{\lambda+\mu}$.

(iv) On $V_W = \mathbb{R}^B / \vec{\mathcal{N}}_W^\perp$, with the lattice $V_W(\mathbb{Z})$, the image of $\mathbb{Z}^B$, and the measure dy for which it has the covolume one, the *master form* at $\mathbf{d} \in \mathbb{D}_W$ is $\omega_{\mathbf{d}} = e^{\langle \mathbf{m}, y\rangle} \prod_i L_i(e^y)^{-w_i}\, dy$, the powers principal: its density is invariant under $\vec{\mathcal{N}}_W^\perp$, so it is a form on V_W, and $f_\lambda\, \omega_{\mathbf{d}} = \omega_{\mathbf{d}+\lambda}$. The *occupations* are the insertions $R_{i,e} = \alpha_e \partial_{\alpha_e} L_i / L_i$, with $0 \le R_{i,e} \le \deg L_i$ on the orthant, and the *defects* are $c_e(\mathbf{d}) = m_e - \sum_i w_i R_{i,e}$; $c_e(\mathbf{d}) = \partial_{y_e} \log(\omega_{\mathbf{d}}/dy)$, $c_e(\lambda) = \partial_{y_e} \log f_\lambda$, and $\sum_e v_e\, c_e(\mathbf{d}) = 0$ on $\mathbb{D}_W$ for every $v \in \vec{\mathcal{N}}_W^\perp$.

(v) The *value* of an insertion g at $\mathbf{d}$ is $\langle g \rangle(\mathbf{d}) = \int_{V_W} g\, \omega_{\mathbf{d}}$, where it converges absolutely, and $\langle 1 \rangle(\mathbf{d}) = P_W(\mathbf{m}; \mathbf{w})$ is the *period* of W. For a full family V_W is read on the chart $y_{e_0} = 0$, and $P_W(\mathbf{m}; \mathbf{w})$ is the period of the word $W(\mathbf{w})$ at $\mathbf{m}$ (Definition 25.1); for every family it is the reduced period of that word, on its pins $\mathbf{m} - \sum_i w_i \mathbf{t}_i \in \vec{\mathcal{N}}_W$ (Theorem 28.12).

Lemma 48.2 (The fan of a family of positive letters)**.** *Let W be as in Definition 48.1, with $\vec{\mathcal{N}}_W$ paired with V_W.*

(i) There are finitely many rational simplicial cones of dimension r_W in V_W, with disjoint interiors, covering V_W, each contained, for every i, in the set $\{v : \ \langle \mathbf{t} - \mathbf{t}', v\rangle \le 0$ for every exponent $\mathbf{t}'$ of the support of $L_i\}$ of one exponent $\mathbf{t} = \mathbf{t}_{i,\pi}$ of that support. Such

cones form a fan *of W, and the primitive vectors of $V_W(\mathbb{Z})$ on their rays are its* generators. *Every ray of the inner normal fan of the Newton sum at positive exponents is a ray of every fan.*

(ii) The wall *of a generator v is the linear form on $\mathbb{D}_W$*

$$\kappa_v(\mathbf{d}) = \Big\langle \mathbf{m} - \sum_i w_i \mathbf{t}_i,\, v \Big\rangle - \sum_i w_i \min_{\mathbf{t}} \langle \mathbf{t} - \mathbf{t}_i, v\rangle,$$

the minimum over the support of L_i. It does not depend on the exponents fixed, it is $\langle \mathbf{m} - \sum_i w_i \mathbf{t}_{i,\pi}, v\rangle$ for every cone π of which v is a generator, and it is integral on $\mathbb{D}_W(\mathbb{Z})$.

(iii) On a cone π with the generators $v_{\pi,1}, \dots, v_{\pi,r_W}$ write $y = -\sum_k u_k v_{\pi,k}$, $u_k \geq 0$, and $q_k = e^{-u_k}$. Then $\mathbf{t}_{i,\pi}$ is unique, and $k_{i,\pi}(q) = \sum_{\mathbf{t}} c_{i,\mathbf{t}} \prod_k q_k^{\langle \mathbf{t} - \mathbf{t}_{i,\pi}, v_{\pi,k}\rangle}$ is a polynomial with nonnegative coefficients and the constant term $c_{i,\mathbf{t}_{i,\pi}} > 0$. For an insertion $g = \alpha^u \prod_i L_i^{-a_i}$, with the walls $\kappa_v(g) = \kappa_v(u; \mathbf{a})$ of its data, and real $\mathbf{d}$, in $[0,\infty]$,

$$\int_{V_W} g\, \omega_{\mathbf{d}} = \sum_{\pi} \big|\det(v_{\pi,1}, \dots, v_{\pi,r_W})\big| \int_{[0,1]^{r_W}} \prod_k q_k^{\kappa_{v_{\pi,k}}(\mathbf{d}) + \kappa_{v_{\pi,k}}(g) - 1} \prod_i k_{i,\pi}(q)^{-w_i - a_i}\, dq,$$

the determinant taken in $V_W(\mathbb{Z})$; both sides are finite exactly when $\kappa_v(\mathbf{d}) + \kappa_v(g) > 0$ for every generator v.

The tube *of g is $\mathcal{T}_g = \{\mathbf{d} \in \mathbb{D}_W : \operatorname{Re} \kappa_v(\mathbf{d}) + \kappa_v(g) > 0$ for every generator $v\}$, the set on which $\langle g\rangle$ converges absolutely; it does not depend on the fan.*

For a full family the generators are read on the section $v_{e_0} = 0$, and the lemma is Lemma S14 with the walls written as linear forms in all the data; the walls of Lemma 32.8(i) are these walls read on an affine subspace of the data.

Theorem 48.3 (The module of a family of positive letters)**.** *Let W be a family of positive letters with a fan.*

(i) Positive directions. *At real data with positive exponents the period converges exactly when $\mathbf{m} - \sum_i w_i \mathbf{t}_i$ lies in the relative interior of $\sum_i w_i(\mathcal{N}_{L_i} - \mathbf{t}_i)$, a polytope of the dimension r_W in $\vec{\mathcal{N}}_W$. There are* positive directions, *points $\mathbf{d}_1 \in \mathbb{D}_W(\mathbb{Z})$ with every exponent $w_{1,i} \geq 1$ and every wall $\kappa_v(\mathbf{d}_1) > 0$; for each, $\eta\, \mathbf{d}_1 \in \mathcal{T}_1$ for every $\eta > 0$.*

(ii) Relations. *For an insertion $g = \alpha^u \prod_i L_i^{-a_i}$ and $\mathbf{d} \in \mathcal{T}_g$ the values $\langle g\rangle(\mathbf{d})$ and $\langle (c_e(\mathbf{d}) + \partial_{y_e}) g\rangle(\mathbf{d})$ converge absolutely and the second is 0, for every $e \in B$; $\langle f_\lambda g\rangle(\mathbf{d}) = \langle g\rangle(\mathbf{d} + \lambda)$ when $\mathbf{d} + \lambda \in \mathcal{T}_g$. The value $\langle g\rangle$ continues to a meromorphic function on $\mathbb{D}_W$, holomorphic on $\mathcal{T}_g$, with its poles on the hyperplanes $\kappa_v(\mathbf{d}) + \kappa_v(g) \in \{0, -1, -2, \dots\}$, v a generator. Extended $\mathbb{K}_W$-linearly to $\mathbb{C}[X_W] \otimes \mathbb{K}_W$ it vanishes identically on the $\mathbb{K}_W$-span $\mathcal{L}_W$ of the $(c_e(\mathbf{d}) + \partial_{y_e})g$, $g \in \mathbb{C}[X_W]$, $e \in B$, and $\langle f_\lambda g\rangle(\mathbf{d}) = \langle g\rangle(\mathbf{d} + \lambda)$ identically. At every real $\mathbf{d} \in \mathcal{T}_1$, $P_W(\mathbf{m}; \mathbf{w}) > 0$.*

(iii) The module. *With the relation space $\mathcal{L}_W$, the module $\mathfrak{M}_W = (\mathbb{C}[X_W] \otimes \mathbb{K}_W)/\mathcal{L}_W$, its shifts $\operatorname{Sh}_\lambda[g \otimes r] = [f_\lambda g \otimes \sigma_\lambda r]$, $\lambda \in \mathbb{D}_W(\mathbb{Z})$, its submodules, masters, shift matrices, reductions and values, and $\mathfrak{M}_{W,\Bbbk}$, are defined as in Definition 47.3, and Theorem 47.4 holds for them: the lattice acts; the values intertwine the shifts;* $\operatorname{Ann}\langle\cdot\rangle$ *is a submodule that does not contain* $[1]$*; the shifts of* $[1]$ *span, and so do the classes of the Laurent insertions; $\mathfrak{M}_W$ has a finite dimension $\mathfrak{m}_W$, being the top cohomology of the twisted algebraic de Rham complex, over $\mathbb{K}_W$, of the smooth affine variety X_W of dimension r_W for the connection $d + d\log(\omega_{\mathbf{d}}/dy)$; the base change holds; and the shift matrices are a cocycle that transports the values of the masters.*

(iv) Boxes. *Definition 47.6, Proposition 47.7 and Theorem 47.8 hold for W with these readings: the symbols are the $(u;\mathbf{a}) \in \mathbb{D}_W(\mathbb{Z})$ with $\mathbf{a} \in \mathbb{N}^I$, evaluated to $\alpha^u \prod_i L_i^{-a_i}$, at the level $\mathbf{a}$, with the walls $\kappa_v(u;\mathbf{a})$ and the wall degree $\max_v(-\kappa_v(g))/\kappa_v(\mathbf{d}_1)$ over the generators; the Laurent symbols are those at the level $\mathbf{0}$; the mark relations are*

$$\mathrm{MR}_e(g) = (m_e + u_e)\, g - \sum_i (w_i + a_i) \sum_{\mathbf{t}} c_{i,\mathbf{t}}\, t_e\, (u + \mathbf{t}; \mathbf{a} + \mathbf{e}_i), \qquad e \in B,$$

and the letter identities $\sum_{\mathbf{t}} c_{i,\mathbf{t}}\, (u + \mathbf{t}; \mathbf{a} + \mathbf{e}_i) - (u;\mathbf{a})$; the level bounds are $\bar{\mathbf{a}} \in \mathbb{N}^I$ with every $\bar{a}_i \geq 1$; and the generators of the lattice are the $(v;\mathbf{0})$, v in a basis of M_W, and the $(\mathbf{t}_i;\mathbf{e}_i)$, $i \in I$.

(v) Families of tables. *A family of tables F is the family of positive letters $(K_j, \Psi_j)_j$ at the exponents $(\mathbf{s},\mathbf{t})$, and its space of directions is $\mathbf{1}^\perp$ exactly when its marks form one molecule. Then the sectors of the orders of $\mathcal{E}$ form a fan, with the generators $\mathbf{1}_U$, U nonempty and proper, and the walls $\kappa_{\mathbf{1}_U} = \kappa_U$; the criterion of (i) is Theorem 25.2, the centre data are a positive direction (the gloss after Definition 47.1), and (ii)–(iv) are Theorems 47.2, 47.4 and 47.8 and Proposition 47.7. For a compound, $\vec{\mathcal{N}}_F^\perp$ is spanned by the indicators of its molecules, every molecule is balanced on $\mathbb{D}_F$, and when the weights factor across the molecules the period read on V_F is the product of the periods of the molecules (Proposition 7.9).*

So the module of Chapter 47 is the module of a family of positive letters that happen to be the letters of tables, and nothing in it used more. The seam word of a piece (Lemma 28.7), the room word of a partner, the word of a node of a chain (Corollary 29.5), the words of the segments of a cyclic chain (Theorem 29.8) and the merged seam words (Lemma 32.8(ii)) are families of positive letters at the shares. Every such family has positive directions, and so a nonempty tube, whatever its letters; a degenerate one is read on its space of directions, where its period is the reduced period of Theorem 28.12, the pins of a degenerate word being part of its data space.

48.2 Share readings

The readings of a family along its tree have one form: a fibre integral of a quotient of Gamma functions of linear forms in the data and the shares, times the periods of families of positive letters at data that are linear in the data and the shares.

Definition 48.4 (A share reading)**.** Let W be a family of positive letters. A *share reading* of W consists of:

(i) *shares* $\mathbf{z} \in \mathbb{C}^J$, J finite, with *pins* $\mathbf{P}\mathbf{z} = \boldsymbol{\pi}(\mathbf{d})$, $\mathbf{P}$ a rational matrix with linearly independent rows and $\boldsymbol{\pi}$ a linear map on $\mathbb{D}_W$ with rational coefficients, such that every $\mathbf{d}$ has shares on its pins; the *share space* $\mathbb{S} = \{(\mathbf{d},\mathbf{z}) \in \mathbb{D}_W \times \mathbb{C}^J :\ \mathbf{P}\mathbf{z} = \boldsymbol{\pi}(\mathbf{d})\}$, with its lattice $\mathbb{S}(\mathbb{Z})$ of integral points, its real points $\mathbb{S}(\mathbb{R})$ and $\mathbb{K}_{\mathbb{S}} = \mathbb{C}(\mathbb{S})$;

(ii) a *kernel* $G = \prod_{k\in A} \Gamma(\ell_k) \big/ \prod_{k\in A'} \Gamma(\ell'_k)$, A and A' finite and the ℓ_k and ℓ'_k linear forms on $\mathbb{S}$ with integral values on $\mathbb{S}(\mathbb{Z})$;

(iii) *nodes* (W_l, ι_l), $l = 1,\dots,p$: families of positive letters W_l with linear maps ι_l of $\mathbb{S}$ onto $\mathbb{D}_{W_l}$, $\iota_l(\mathbb{S}(\mathbb{Z})) \subseteq \mathbb{D}_{W_l}(\mathbb{Z})$;

such that the following holds. Let the *admissible cone* be

$$\mathbb{S}^+ = \big\{(\mathbf{d},\mathbf{c}) \in \mathbb{S}(\mathbb{R}) :\ \ell_k(\mathbf{d},\mathbf{c}) > 0 \text{ for every } k \in A,\ \iota_l(\mathbf{d},\mathbf{c}) \in \mathcal{T}_1(W_l) \text{ for every } l\big\},$$

and call a real $\mathbf{c}$ *admissible* at $\mathbf{d} \in \mathbb{D}_W$ when $(\operatorname{Re}\mathbf{d}, \mathbf{c}) \in \mathbb{S}^+$. At every $\mathbf{d}$ at which some $\mathbf{c}$ is admissible, $\mathbf{d} \in \mathcal{T}_1(W)$ and, for every admissible $\mathbf{c}$, the *reading identity*

$$P_W(\mathbf{d}) = \int_{\mathbf{Pz}=\boldsymbol{\pi}(\mathbf{d})} G(\mathbf{d},\mathbf{z}) \prod_{l=1}^{p} P_{W_l}\big(\iota_l(\mathbf{d},\mathbf{z})\big)$$

holds, the fibre integral through $\mathbf{c}$ (Definition 4.1) converging absolutely. The reading is *positive* when $\mathbb{S}^+$ is not empty.

The admissible cone is an open convex cone, cut out by finitely many strict linear inequalities, and at a real $\mathbf{d}$ the contour through $\mathbf{c}$ is $\mathbf{c} + iV$, V the real space of the directions of the pins.

Theorem 48.5 (The module along a share reading)**.** *Let a family of positive letters W have a positive share reading with the nodes $(W_l, \iota_l)_{l\le p}$, and let $\mathbb{D}'_W(\mathbb{Z})$ be the image of $\mathbb{S}(\mathbb{Z})$ in $\mathbb{D}_W(\mathbb{Z})$. In this statement σ_μ is the translation of rational functions by μ on whichever space they live.*

(i) The kernel. *For $(\lambda,\tau) \in \mathbb{S}(\mathbb{Z})$, $G\big((\mathbf{d},\mathbf{z}) + (\lambda,\tau)\big) = R_{\lambda,\tau}(\mathbf{d},\mathbf{z})\, G(\mathbf{d},\mathbf{z})$ with*

$$R_{\lambda,\tau} = \prod_{k\in A} (\ell_k)_{\ell_k(\lambda,\tau)} \Big/ \prod_{k\in A'} (\ell'_k)_{\ell'_k(\lambda,\tau)} \in \mathbb{Q}(\mathbb{S}),$$

$(x)_n = \Gamma(x+n)/\Gamma(x)$ the Pochhammer symbol at an integer n, and $R_{\mu+\nu} = \sigma_\mu(R_\nu)\, R_\mu$.

(ii) The integrand module. *The tensor product over $\mathbb{K}_\mathbb{S}$ of the modules of the nodes with their coefficients read through the ι_l,*

$$\mathfrak{J} = \bigotimes_{l=1}^{p} \big(\mathfrak{M}_{W_l} \otimes_{\mathbb{K}_{W_l}} \mathbb{K}_\mathbb{S}\big),$$

has the dimension $\prod_l \mathfrak{m}_{W_l}$, and $\mathbb{S}(\mathbb{Z})$ acts on it by the semilinear maps $\operatorname{Sh}_{(\lambda,\tau)} = R_{\lambda,\tau} \bigotimes_l \operatorname{Sh}_{\iota_l(\lambda,\tau)}$. For masters $\mathbf{g}^{(l)}$ of the nodes the products $\bigotimes_l [g_{i_l}^{(l)}]$ are a basis, on which $\operatorname{Sh}_{(\lambda,\tau)}$ has the matrix $R_{\lambda,\tau} \bigotimes_l \iota_l^* \mathbf{A}^{(l)}_{\iota_l(\lambda,\tau)}$, the Kronecker product of the shift matrices of the nodes read through the ι_l, times $R_{\lambda,\tau}$. The value *of $\bigotimes_l x_l$ is $G \prod_l \langle x_l\rangle \circ \iota_l$, extended $\mathbb{K}_\mathbb{S}$-linearly, a meromorphic function on $\mathbb{S}$, and the value of $\operatorname{Sh}_{(\lambda,\tau)} t$ at $(\mathbf{d},\mathbf{z})$ is that of t at $(\mathbf{d},\mathbf{z}) + (\lambda,\tau)$.*

(iii) Values. *Let $[1]^\otimes = \bigotimes_l [1]$. For $(\lambda,\tau) \in \mathbb{S}(\mathbb{Z})$, a real $\mathbf{d}$ and an admissible $\mathbf{c}$ at $\mathbf{d}$ such that $\mathbf{c}+\tau$ is admissible at $\mathbf{d}+\lambda$,*

$$\langle \operatorname{Sh}_\lambda[1]\rangle(\mathbf{d}) = P_W(\mathbf{d}+\lambda) = \int_{\mathbf{Pz}=\boldsymbol{\pi}(\mathbf{d})} G\, R_{\lambda,\tau} \prod_{l=1}^{p} \big(\boldsymbol{\rho}^{(l)}_{\iota_l(\lambda,\tau)} \cdot \langle \mathbf{g}^{(l)}\rangle\big) \circ \iota_l,$$

the value of $\operatorname{Sh}_{(\lambda,\tau)}[1]^\otimes$ integrated through $\mathbf{c}$, with $\boldsymbol{\rho}^{(l)}_\mu$ the reduction of $\operatorname{Sh}_\mu[1]$ on the masters $\mathbf{g}^{(l)}$ and $\langle \mathbf{g}^{(l)}\rangle$ the column of their values. So the value of an element $x = \sum_\lambda r_\lambda \operatorname{Sh}_\lambda[1]$, $r_\lambda \in \mathbb{K}_W$, of the span $\mathfrak{M}'_W$ of the shifts of $[1]$ by $\mathbb{D}'_W(\mathbb{Z})$, for any choice of the τ_λ with $(\lambda,\tau_\lambda) \in \mathbb{S}(\mathbb{Z})$, is at $\mathbf{d}$ the fibre integral of the value of $t_x = \sum_\lambda r_\lambda \operatorname{Sh}_{(\lambda,\tau_\lambda)}[1]^\otimes \in \mathfrak{J}$ through a point admissible at $\mathbf{d}$ whose translates by the τ_λ are admissible at the $\mathbf{d}+\lambda$: a multilinear form in the values of the masters of the nodes against the kernel, with coefficients in $\mathbb{K}_\mathbb{S}$ read off the reductions and the shift matrices of the nodes. For every $(\mathbf{d}_1,\mathbf{c}_1) \in \mathbb{S}^+$, every real $\mathbf{d}$ and every finite set of the (λ,τ_λ) such points exist at $\mathbf{d} + \eta\mathbf{d}_1$ for all large η. Every element of $\mathfrak{M}_W$ is a sum of shifts $\operatorname{Sh}_{\lambda_c} x_c$, $x_c \in \mathfrak{M}'_W$, over representatives λ_c of the classes of $\mathbb{D}_W(\mathbb{Z})$ modulo $\mathbb{D}'_W(\mathbb{Z})$, so its value is a sum of such fibre integrals at the points $\mathbf{d}+\lambda_c$.

(iv) Fibre translations. *For* $(0,\tau) \in \mathbb{S}(\mathbb{Z})$ *and* $\mathbf{c}$ *and* $\mathbf{c}+\tau$ *admissible at* $\mathbf{d}$*, the values of* $\mathrm{Sh}_{(0,\tau)}[1]^{\otimes}$ *and of* $[1]^{\otimes}$ *have one fibre integral through* $\mathbf{c}$*, the period* $P_W(\mathbf{d})$*.*

(v) Recurring nodes. *An isomorphism of two families of positive letters, a bijection of their marks and one of their letters carrying each letter to the other's, carries the data space, the lattice, the insertions, the relations, the module, its masters, shift matrices, reductions and boxes of one to those of the other. So the modules of the nodes of a reading are found once for each class of nodes under isomorphism, by one box each (Theorem 48.3(iv)).*

(vi) Composition. *Let the node* W_{l_0} *have a positive share reading with the shares* $\mathbf{z}'$*, the pins* $\mathbf{P}'\mathbf{z}' = \boldsymbol{\pi}'(\mathbf{d}')$*, the kernel* G' *and the nodes* (V_k, ι'_k)*, and let* $\mathbb{S}''$ *be the space of the* $(\mathbf{d}, \mathbf{z}, \mathbf{z}')$ *with* $(\mathbf{d}, \mathbf{z}) \in \mathbb{S}$ *and* $(\iota_{l_0}(\mathbf{d}, \mathbf{z}), \mathbf{z}')$ *in the share space of that reading. If there are points* $(\mathbf{d}, \mathbf{c}, \mathbf{c}')$ *with* $(\mathbf{d}, \mathbf{c}) \in \mathbb{S}^+$ *and* $(\iota_{l_0}(\mathbf{d}, \mathbf{c}), \mathbf{c}')$ *in its admissible cone, and at every* $\mathbf{d} \in \mathbb{D}_W$ *and every* $(\mathbf{c}, \mathbf{c}')$ *with* $(\mathrm{Re}\,\mathbf{d}, \mathbf{c}, \mathbf{c}')$ *such a point the iterated fibre integral at* $\mathbf{d}$ *through* $(\mathbf{c}, \mathbf{c}')$ *converges absolutely, then* $\mathbb{S}''$*, both pins, the kernel* $G \cdot G'(\iota_{l_0}(\mathbf{d}, \mathbf{z}), \mathbf{z}')$ *and the nodes* (W_l, ι_l)*,* $l \neq l_0$*, and* $(V_k, \iota'_k(\iota_{l_0}(\mathbf{d}, \mathbf{z}), \mathbf{z}'))$*, are a positive share reading of* W*, with these points as its admissible cone.*

So the algebra of a family is the algebra of the nodes of any of its share readings. The masters, the shift matrices and the certificates that the values need are those of the distinct nodes; the lattice of the data acts on the integrand through Kronecker products of the shift matrices of the nodes, with a rational factor from the kernel; and, at the points with an admissible point whose translates are admissible, which exist along $\mathbf{d} + \eta\mathbf{d}_1$ for all large η (part (iii)), a value of the family at a lattice translate of a point is the fibre integral of the masters of the nodes at that point, against the kernel, with coefficients that are rational functions. The family's own masters are not needed for this. The fibre integral identifies more than the nodes do, the translations along the fibres among others (part (iv)); along a tree, modulo these translations, the integrand carries the module of the family itself, and a relation among values of a family of tables, as functions of all its data, is a relation of its module (Proposition 47.15), told by closings (Theorem 47.11) that the tree computes from the closings of its node words (Theorem 48.18).

48.3 Paths through a chain of bunches

Along a chain of bunches every basis of a table runs through one station of each bunch, and every lattice vector of the data of a molecule is carried by these runs to the shares.

Definition 48.6 (The path of a basis)**.** Let $\varnothing = S_0 \subset S_1 \subset \cdots \subset S_L = \mathcal{E}$, $L \geq 2$, be a chain of bunches of a family of tables with the steps $B_{l-1} = S_l \setminus S_{l-1}$ and the stations $\mathcal{D}(S_l)$ of room sides (Theorem 29.3), and let T be a basis of table j. For $1 \leq l \leq L-1$ the room side $T \setminus S_l$ of S_l lies in one station $D_l(T)$. The *path* of T is the sequence $D_1(T), \ldots, D_{L-1}(T)$, and its *entries* are the entries $(D_{l-1}(T), D_l(T))$ of the transfer matrices $\mathbf{N}^K_{l,j}$ and $\mathbf{N}^\Psi_{l,j}$, $2 \leq l \leq L-1$, and the entry $D_{L-1}(T)$ of the columns y_j and y^*_j of the last node. The *pieces* of T are $T \cap S_1$, a basis of the room child of the station $D_1(T)$, whose letter $K_{j,(D_1(T))}$ has the monomial $\alpha^{T \cap S_1}$ and the cobasis letter $\Psi_{j,(D_1(T))}$ the monomial $\alpha^{S_1 \setminus T}$, and the $T \cap B_{l-1}$, $2 \leq l \leq L$, whose monomials $\alpha^{T \cap B_{l-1}}$ and $\alpha^{B_{l-1} \setminus T}$ occur in the entries of the path at the node l of K_j and of Ψ_j. With the shares of Corollary 29.5, the *path vectors* τ_T and τ^*_T put 1 on the share of every entry of the path of T, of K_j and of Ψ_j respectively, and 0 on every other share.

Theorem 48.7 (A chain of bunches is a share reading)**.** *Let F be a family of tables whose marks form one molecule, with a chain of bunches $\varnothing = S_0 \subset S_1 \subset \cdots \subset S_L = \mathcal{E}$, $L \geq 2$, read as the family of positive letters of Theorem 48.3(v) with every letter opened, as in Corollary 29.5.*

(i) The reading. *Corollary 29.5 is a positive share reading of F, with: the shares $e^{(l)}_{jD'D}$ and $f^{(l)}_{jD'D}$, one for each nonzero entry of $\mathbf{N}^K_{l,j}$ and of $\mathbf{N}^\Psi_{l,j}$, $2 \leq l \leq L$, the last ones the columns y_j and y^*_j; the pins, the letter totals, the conservation of the loads at the stations of $S_2, \dots, S_{L-1}$, and the pins of the space of directions of the first bunch and of every node, less the homogeneity of one of them, those of a node W_l taken on a basis of the lattice $\vec{\mathcal{N}}^\perp_{W_l} \cap \mathbb{Z}^{B_{l-1}}$ that contains $\mathbf{1}_{B_{l-1}}$ (Theorem 28.12), with their right-hand sides $\boldsymbol{\pi}$; the kernel*

$$\prod_j \frac{\prod_{l=2}^L \prod_{D',D} \Gamma(e^{(l)}_{jD'D})}{\Gamma(s_j) \prod_{l=2}^{L-1} \prod_D \Gamma(a^{(l)}_{jD})} \cdot \frac{\prod_{l=2}^L \prod_{D',D} \Gamma(f^{(l)}_{jD'D})}{\Gamma(t_j) \prod_{l=2}^{L-1} \prod_D \Gamma(b^{(l)}_{jD})};$$

and the nodes W_1 on $B_0 = S_1$, the seam letters $K_{j,(D)}$ and $\Psi_{j,(D)}$ of S_1 at the exponents $a^{(1)}_{jD}$ and $b^{(1)}_{jD}$, and W_l on B_{l-1}, $2 \leq l \leq L$, the nonzero entries at the exponents $e^{(l)}$ and $f^{(l)}$, with $\iota_1 = (\mathbf{m}_{B_0}; \mathbf{a}^{(1)}, \mathbf{b}^{(1)})$ and $\iota_l = (\mathbf{m}_{B_{l-1}}; \mathbf{e}^{(l)}, \mathbf{f}^{(l)})$.

(ii) Paths. *For a basis T of table j the vectors (λ^K_T, τ_T) and $(\lambda^\Psi_T, \tau^*_T)$ lie in $\mathbb{S}(\mathbb{Z})$, $\lambda^K_T = (\mathbf{1}_T; \mathbf{e}_j, \mathbf{0})$ and $\lambda^\Psi_T = (\mathbf{1}_{\mathcal{E}\setminus T}; \mathbf{0}, \mathbf{e}_j)$ being the data of the strides α^T/K_j and $\alpha^{\mathcal{E}\setminus T}/\Psi_j$. Each node moves by the data of the stride of the piece of T in its entry, $\iota_l(\lambda^K_T, \tau_T)$ being the data of $\alpha^{T\cap B_{l-1}}/\mathbf{N}^K_{l,j}(D_{l-1}(T), D_l(T))$ (of $\alpha^{T\cap B_{L-1}}/\mathsf{y}_{j,D_{L-1}(T)}$ at the last node) and $\iota_1(\lambda^K_T, \tau_T)$ that of $\alpha^{T\cap S_1}/K_{j,(D_1(T))}$, and the kernel moves by*

$$R_{\lambda^K_T, \tau_T} = \frac{a^{(1)}_{jD_1(T)}}{s_j} \prod_{l=2}^{L-1} \frac{e^{(l)}_{jD_{l-1}(T)D_l(T)}}{a^{(l-1)}_{jD_{l-1}(T)}},$$

the probability of the path of T for the chain on the stations that starts at $D \in \mathcal{D}_j(S_1)$ with the probability $a^{(1)}_{jD}/s_j$ and moves from D' to D with the probability $e^{(l)}_{jD'D}/a^{(l-1)}_{jD'}$; likewise for the cobasis, with f, b and t_j. So the chance $\mathbb{P}_j(T) = \theta_{j,T}\alpha^T/K_j$ of T (Definition 38.1) has the value

$$\langle \mathbb{P}_j(T) \rangle(\mathbf{d}) = \int_{pins} G\, R_{\lambda^K_T, \tau_T} \prod_{l=1}^{L} \big\langle \mathbb{P}^{(l)}(T) \big\rangle \big(\iota_l(\mathbf{d}, \mathbf{z})\big),$$

$\mathbb{P}^{(l)}(T)$ the chance of the piece of T in its entry at the node l, its term divided by the entry, at every real $\mathbf{d}$ with a point admissible at $\mathbf{d}$ whose translate by τ_T is admissible at $\mathbf{d} + \lambda^K_T$; the coefficients of the pieces in their entries multiply to $\theta_{j,T}$.

(iii) The lattice. $\mathbb{S}(\mathbb{Z})$ *maps onto $\mathbb{D}_F(\mathbb{Z})$, every lattice vector of the data being the image of an integral combination of the (λ^K_T, τ_T) and $(\lambda^\Psi_T, \tau^*_T)$. So $\mathfrak{M}'_F = \mathfrak{M}_F$, and the value of every element of $\mathfrak{M}_F$ is the fibre integral of a multilinear form in the values of the masters of the nodes, as in Theorem 48.5(iii).*

(iv) Repetition. *Nodes $S^{(\cdot)}_l$ that are one piece up to bijections of marks keeping seam letters (Theorem 29.3(iii)) have isomorphic families of positive letters, the stations corresponding, and so one module (Theorem 48.5(v)). The algebra of the chain is that of the first bunch, of one node for each class of the nodes and of the last node, whatever the length of the chain.*

(v) Locality. *Let e be a mark of the step B_{l-1}, $1 \le l \le L$, and j a table. For the entries E of K_j at the node l, with their shares z_E (the share $e^{(l)}_{jD'D}$ of the entry (D', D), and at the first bunch the stations D with the shares $a^{(1)}_{jD}$) and the occupations $R^{(l)}_{E,e}$ of e in their letters,*

$$s_j \langle R_{j,e} \rangle(\mathbf{d}) = \int_{pins} G \sum_E z_E \langle R^{(l)}_{E,e} \rangle\big(\iota_l(\mathbf{d}, \mathbf{z})\big) \prod_{l' \ne l} P_{W_{l'}}\big(\iota_{l'}(\mathbf{d}, \mathbf{z})\big),$$

through every point admissible at $\mathbf{d}$ whose translates by the path vectors of the bases of table j through e are admissible at the translates of $\mathbf{d}$; likewise for Ψ_j, with t_j, the shares of its entries and the occupations in the letters of Ψ_j. So, through a point admissible at $\mathbf{d}$ whose translates by the τ_T, $T \ni e$, and the τ^*_T, $T \not\ni e$, in every table, are admissible at the translates of $\mathbf{d}$, the defect $c_e(\mathbf{d})$ of F is read as the defect of the node l at its data: the mark relation of the period of F at e is that of the node l, the other nodes entering only through their periods.

For a molecule with a connected table, whose trees of bunches are chains (Corollary 20.8), this is the module of the family along the chain of the seam procedure (Definition 29.9): one box for the first bunch, a family of tables on B_0 at the shares, one for each class of the transfer nodes and one for the last node, and every value of every element of $\mathfrak{M}_F$, at a lattice translate of a point with admissible contours (Theorem 48.5(iii)), is the word of Corollary 29.5 with the periods of the nodes replaced by rows of their reductions and shift matrices times the values of their masters. The chance of a basis reads as a flow: the shares route the exponent of each letter through the stations, the path of the basis is chosen with the probabilities of that flow, and each node contributes the chance of the piece of the basis in its entry. The glue across one seam (Theorems 28.10(iii) and 28.12) is the chain with $L = 2$, its two nodes the seam word of the bunch and the room word.

48.4 Shares and scales

A letter is opened in one of two ways: on its shares, $\Gamma(w)\big(\sum_l X_l\big)^{-w} = \int_{|\mathbf{a}|=w} \prod_l \Gamma(a_l) X_l^{-a_l}$, one share for each term and the one pin $|\mathbf{a}| = w$ (Corollary 4.4), or on its scale, $\Gamma(w)\big(\sum_l X_l\big)^{-w} = \int_0^\infty \xi^{w-1} \prod_l e^{-\xi X_l}\, d\xi$, one scale at which every term is read. The two are the two sides of one Gramma (Proposition 4.2). A pin that conserves the shares of a letter among blocks that own them is, on the scale of the letter, one point at which the blocks meet, each through its own transform, and equal blocks meet there as one transform to a power. The transforms are exponential periods: each converges on the data whose real parts lie in an open cone, and each generates a module of finite rank over the rational functions of its scales, so that what a word reads on its scales is counted by a group, at any number of scales.

Lemma 48.8 (Exponential periods: their domains and their modules)**.** *Let B be a finite set, $h_1, \dots, h_q$ nonzero polynomials on B with nonnegative coefficients, $Y \subseteq (\mathbb{C}^\times)^B$ the set on which none of them vanishes, and $R_1, \dots, R_p \in \mathbb{C}[Y]$ of the form $R_i = \alpha^{\mathbf{w}_i} P_i \prod_k h_k^{-n_{ik}}$, with $\mathbf{w}_i \in \mathbb{Z}^B$, $n_{ik} \in \mathbb{N}$ and P_i a nonzero polynomial with nonnegative coefficients. For data $\boldsymbol{\nu} = (\mathbf{m}, \mathbf{c}) \in \mathbb{C}^B \times \mathbb{C}^q$, an insertion $g \in \mathbb{C}[Y]$ and scales $\boldsymbol{\xi} \in (0, \infty)^p$ put*

$$\langle g \rangle_{\boldsymbol{\nu}}(\boldsymbol{\xi}) = \int_{(0,\infty)^B} g\, \alpha^{\mathbf{m-1}} \prod_{k=1}^q h_k^{-c_k} \exp\Big(- \sum_{i=1}^p \xi_i R_i \Big)\, d\alpha.$$

For a polynomial h with nonnegative coefficients write $\operatorname{top}_h(v)$ for the largest value of $\langle \mathbf{t}, v\rangle$ over its exponents $\mathbf{t}$, and put

$$\rho_i(v) = \langle \mathbf{w}_i, v\rangle + \operatorname{top}_{P_i}(v) - \sum_k n_{ik} \operatorname{top}_{h_k}(v), \qquad \varphi_{\boldsymbol{\nu}}(v) = \langle \operatorname{Re}\mathbf{m}, v\rangle - \sum_k \operatorname{Re} c_k \operatorname{top}_{h_k}(v),$$

and $C_0 = \{v \in \mathbb{R}^B : \rho_i(v) \le 0$ for every $i\}$, a closed cone.

(i) Domain. *$\langle 1\rangle_{\boldsymbol{\nu}}(\boldsymbol{\xi})$ converges absolutely at one $\boldsymbol{\xi}$ exactly when $\varphi_{\boldsymbol{\nu}} < 0$ on $C_0 \setminus \{0\}$, and then at every $\boldsymbol{\xi}$, locally uniformly in $(\boldsymbol{\nu}, \boldsymbol{\xi})$. So its domain $\mathcal{D}$ is the set of the data whose real parts lie in an open convex cone, it does not depend on the scales, and $\langle \alpha^{\mathbf{u}} \prod_k h_k^{-n_k}\rangle_{\boldsymbol{\nu}} = \langle 1\rangle_{\boldsymbol{\nu}+(\mathbf{u},\mathbf{n})}$ converges exactly on $\mathcal{D} - (\mathbf{u}, \mathbf{n})$.*

(ii) Module. *At every $\boldsymbol{\nu} \in \mathcal{D}$ the derivatives $\partial^{\mathbf{a}}\langle 1\rangle_{\boldsymbol{\nu}} = (-1)^{|\mathbf{a}|}\langle \prod_i R_i^{a_i}\rangle_{\boldsymbol{\nu}}$, $\mathbf{a} \in \mathbb{N}^p$, span a vector space over $\mathbb{C}(\boldsymbol{\xi})$ closed under the ∂_{ξ_i}, of dimension at most that of the top cohomology of the twisted algebraic de Rham complex of Y over $\mathbb{C}(\boldsymbol{\xi}, \boldsymbol{\nu})$ for the connection $d + d\log\left(\alpha^{\mathbf{m}} \prod_k h_k^{-c_k} e^{-\sum_i \xi_i R_i}\right)$, which is finite.*

(iii) Quotients. *If the integrand is invariant under a rational subtorus of $(0,\infty)^B$, its integral over the quotient, with the quotient of $d\alpha/\alpha$ by the Haar measure for which the integer points of the subtorus have the covolume one, is on a section an integral of the same kind on fewer marks, at data linear in $\boldsymbol{\nu}$, and (i) and (ii) hold for it.*

A Gramma is the case without denominators, its monomials the R_i, its configuration their exponents and its coefficients the scales: C_0 is the cone on which every exponent of the configuration is nonpositive, and (i) is its domain (Theorem 2.2). The transforms read below are of the general kind, with the absent letters of the children of a node in the denominators.

Definition 48.9 (The group at several scales; the inputs and the group of a word)**.** Let $\mathcal{E}$ be a finite set of scales, and $\mathbb{C}(\mathbf{y}) = \mathbb{C}(y_e : e \in \mathcal{E})$ with the derivations ∂_{y_e}.

(i) A *differential module* over $\mathbb{C}(\mathbf{y})$ is a vector space N of finite dimension over it with commuting connections ∇_e, $\nabla_e(rv) = (\partial_{y_e} r)\, v + r\, \nabla_e v$. Its solutions near a point $x \in (0,\infty)^{\mathcal{E}}$ off its singular locus form $\operatorname{Sol}_x N$, and its *group* $G_N \subseteq \operatorname{GL}(\operatorname{Sol}_x N)$ is the group of the automorphisms of the field generated over $\mathbb{C}(\mathbf{y})$ by these solutions and their derivatives that fix $\mathbb{C}(\mathbf{y})$ and commute with every ∂_{y_e}; when N is regular singular along its singular locus it is the Zariski closure of the monodromy of the solutions on the complement of that locus. Its Lie algebra, its unipotent part and its reductive part are named as in Definition 45.24. A function f on an open subset of $(0,\infty)^{\mathcal{E}}$ whose derivatives span a space N_f of finite dimension over $\mathbb{C}(\mathbf{y})$ *generates* the differential module N_f, with $\nabla_e = \partial_{y_e}$, and its *group* is G_{N_f}.

(ii) The *inputs* of a word are the densities of its Trailmoments, a Trailmoment on r scales having its density on $(0,\infty)^r$ in the coordinates the word writes; inputs on r scales with one density are one input, at whatever indices and cuts they are read, and a product or a power of Trailmoments has the inputs of its factors. A period of a family of positive letters that the word keeps, an integral over the space V_W of its directions at data linear in the shares (Definition 48.1(v)), is read as that period and not as a Trailmoment. When the density of every input generates a module, the *group of the word* is the product, over the numbers r of scales of its inputs, of the groups of the sums over $\mathbb{C}(y_1, \dots, y_r)$ of the modules of its distinct inputs on r scales; a word without inputs has the trivial group.

At one scale this is Definitions 45.24 and 45.32: every input read on one scale is a function on $(0,\infty)$, and their modules are summed over $\mathbb{C}(y)$.

Proposition 48.10 (Powers add nothing, at any number of scales)**.** *(i) Propositions 45.25(i)–(iii) and 45.26 hold for differential modules over* $\mathbb{C}(\mathbf{y})$*.*

(ii) Let functions $F_1, \dots, F_q$ *on one open subset of* $(0,\infty)^{\mathcal{E}}$ *generate the modules* $M_1, \dots, M_q$*. For exponents* $m_u \in \mathbb{N}$ *the product* $\prod_u F_u^{m_u}$ *generates a submodule of the image of* $\bigotimes_u \operatorname{Sym}^{m_u} M_u$ *under the multiplication of functions. So the sum of the modules of any finitely many such products is a subquotient of a construction from* $M_1 \oplus \cdots \oplus M_q$*, and its group is the image of the group of* $M_1 \oplus \cdots \oplus M_q$ *acting on its solutions, a quotient of that group, whatever the exponents.*

48.5 Trees of nested bunches

A tree of nested bunches is read node by node. On its shares a node meets its children through their seam functions at their loads, and the whole tree is one share reading. On its scales a full node meets the blocks of any partition of its parts that its seam letters separate, at one point, each block through its transform; every node separates the partition into one block.

Definition 48.11 (A tree of nested bunches)**.** Let F be a family of tables whose marks form one molecule of the family of its active tables, read as the family of positive letters formed by its active letters (Proposition 48.21(i), Theorem 48.23(i)); its marks then form one molecule, more tables only adding links. A *tree of nested bunches* of F is a finite family $\mathcal{L}$ of proper bunches S of F, each with $\sum_j (s_j + t_j) c_j(S) > 0$, any two of them disjoint or nested. Its *nodes* are its members and the *root* $\mathcal{E}$; the *children* of a node are the maximal members of $\mathcal{L}$ properly inside it, its *own marks* Z_S are the marks in none of its children, and a node without children is a *leaf*. In this definition and below, L is an active letter of a table j (Definition 28.5), s_L its exponent, s_j or t_j, and $\epsilon_L(D)$ is $i(D)$ for $L = K_j$ and $c_j(S') - i(D)$ for $L = \Psi_j$, at a station D of a bunch S' in table j; the seam letters V_{LD} of a bunch are its $K_{j,(D)}$ and its $\Psi_{j,(D)}$, the two letters of a station D of table j being taken up to one positive constant c_{jD}, by which its room station letters are divided (the remark after Definition 28.1), its shares a_{LD} the a_{jD} and the b_{jD} of Definition 28.5, and its extreme excess sum V_L^{ext} is $V_j^{(0)}$ for $L = K_j$ and $V_j^{*(c_j)}$ for $L = \Psi_j$.

(i) *Transfer tensors.* The *node* of a node $S \neq \mathcal{E}$ with the children $S_1, \dots, S_k$ is the piece $S^{(\mathbf{x}_1,\dots,\mathbf{x}_k)}$ on $Z_S \sqcup \{g_1, \dots, g_k\}$ of Theorem 29.2(ii), and that of the root is the stand-in core of its children (Theorem 29.1). Its seam letters at the stations D of S, its letters at the root, are polynomials in α_{Z_S} and in the stand-ins, linear in the coordinates of each seam point:

$$V^S_{LD} = \sum_{\mathbf{D}} \mathbf{N}_{S,L}(D;\mathbf{D}) \prod_{l=1}^{k} x_{l,LD_l}\, \alpha_{g_l}^{\epsilon_L(D_l)},$$

the sum over the tuples $\mathbf{D} = (D_l)_l$ of stations of the children in the table of L; the *entries* $\mathbf{N}_{S,L}(D;\mathbf{D})$ are polynomials on Z_S with nonnegative coefficients, constants when Z_S is empty, and form the *transfer tensor* of the node; at the root D is dropped. Read at the seam points of the children, $V_{LD} = \sum_{\mathbf{D}} \mathbf{N}_{S,L}(D;\mathbf{D}) \prod_l V^{(l)}_{LD_l}$ for the seam letters $V^{(l)}$ of the children: the seam letters of a node are multilinear in those of its children.

(ii) *Shares and loads.* Open every seam letter of the node with one share $e_{S,LD\mathbf{D}}$ for each nonzero entry, $\sum_{\mathbf{D}} e_{S,LD\mathbf{D}} = a_{S,LD}$ the share of the seam letter, at the root its exponent s_L. The *load* of the child S_l at its station D' is $a_{S_l,LD'} = \sum e_{S,LD\mathbf{D}}$ over the $(D,\mathbf{D})$ with $D_l = D'$. The *node word* $W_S(\mathbf{e})$ is the family on Z_S of the nonzero entries at their shares, with the

masses $\mathbf{m}_{Z_S}$; when Z_S is empty it is a family of positive constants on the empty set of marks, read as in Definition 48.1, the one exception to Definition 1.1(i). At a leaf the entries are its seam letters and its node word is its seam word.

A choice of these constants at every node other than the root is a *normalization* of the tree, and a node is *full* when its seam word is full (Definition 48.1(i)). A chain of bunches $S_1 \subset \cdots \subset S_{L-1}$ is a tree of nested bunches whose nodes have one child each, the steps their own marks, and, in the normalization of Definition 28.1, the transfer matrices their transfer tensors and the words of the nodes of Corollary 29.5 their node words; at width one the bunches of the subtree cells of a hinge tree form one (Proposition 21.3).

A bunch with its seam letters so taken is a piece whose glue with its room is the family (Definition 28.4), and the results on pieces hold for it. Its seam letters, the entries and the station transforms move by constants: the entries of a node are multiplied by the constants of its station and divided by those of the stations of its children in them, and the station transform becomes $\mathbf{p} \mapsto \mathcal{I}(\mathbf{c} \circ \mathbf{p})$ (Definition 28.21). Its seam function at shares on its pins is multiplied by $\prod_{j,D} c_{jD}^{-a_{jD}-b_{jD}}$ (Lemma 28.7), and its law is moved by a fixed bijection of its seam torus with a density, as after Definition 28.5. Seam functions enter below only on the pins, so every statement below holds in every normalization. A node whose seam function converges at some shares is full (Theorem 25.2), and for a family with a native gauge the seam function of a full node converges at the native split (Lemma 28.9); the root is full, its seam word being the family.

Theorem 48.12 (A node on its shares; a tree of nested bunches is a share reading)**.** *Let F have a tree of nested bunches, real data on its balance wall with $s_j, t_j \geq 0$, not all zero, every proper wall positive and a native gauge.*

(i) A node. *Let $S \neq \mathcal{E}$ be a full node with the children $S_1, \ldots, S_k$, $k \geq 0$, at shares $\mathbf{a}_S$ on the pins of its seam (Lemma 28.7). On contours of shares $e_{S,LD\mathbf{D}}$ with positive real parts at which the seam functions of the children at their loads and the node word converge,*

$$\int_{\Delta_S} (\boldsymbol{\varrho}_S^{\rho})^{-\mathbf{a}_S}\, d\phi_S^{\rho} = \int_{pins} \prod_{L,D} \Gamma_{1}^{n_{LD}} \begin{bmatrix} \mathbf{e}_{S,LD} \\ a_{S,LD} \end{bmatrix} \; P_{W_S(\mathbf{e})}(\mathbf{m}_{Z_S}) \prod_{l=1}^{k} \int_{\Delta_{S_l}} (\boldsymbol{\varrho}_{S_l}^{\rho})^{-\mathbf{a}_{S_l}}\, d\phi_{S_l}^{\rho},$$

n_{LD} the number of the nonzero entries at (L, D) and $\mathbf{a}_{S_l}$ the loads of S_l, the fibre pinned by $\sum_{\mathbf{D}} e_{S,LD\mathbf{D}} = a_{S,LD}$, by the scale pins of the children (Lemma 28.7) and by the pins of directions of the node word, with transverse pins where its Newton sum is degenerate (Theorem 28.12), less the homogeneity of the node word, which the others imply, or less one scale pin when Z_S is empty. At the root the same holds for $P_F(\mathbf{m}; \mathbf{s}, \mathbf{t})$, with the stacked Gammas $\Gamma_{1}^{n_L} \begin{bmatrix} \mathbf{e}_{\mathcal{E},L} \\ s_L \end{bmatrix}$ and the letter totals. With one child this is Theorem 29.6(iii), and at a leaf it is Lemma 28.7; with the node word opened on its monomials (Proposition 4.2) the node contributes stacked Gammas and powers of the coefficients of its seam letters alone, and at width one for one table on its centre ray, in the normalization of Theorem 48.14(iii), this is Proposition 42.26(iii) at the root and (v) below it.

(ii) The tree. *Opened along the tree, P_F is a positive share reading (Definition 48.4) of the family of positive letters formed by the active letters of F, whose period it is, its nodes the node words and the seam words of the leaves at their loads, its kernel the product of the stacked Gammas of all the nodes, its pins the letter totals at the root, the conservation $\sum_{\mathbf{D}} e_{S,LD\mathbf{D}} = a_{S,LD}$ at every station of every node other than the root and the leaves, and the pins of directions of*

the node words and of the seam words of the leaves, with transverse pins where their Newton sums are degenerate, less one homogeneity. Where the nodes are full it is (i) composed node by node. For a full node $S \neq \mathcal{E}$, the seam function of S at shares on the pins of its seam, the period of its seam word (Lemma 28.7), is likewise a positive share reading of its seam word along the subtree of S, with $\sum_{\mathbf{D}} e_{S,LD\mathbf{D}} = a_{S,LD}$ in place of the letter totals. The lattice of the reading of P_F maps onto the lattice of the data of the family of the active letters, so the value of every element of the module of that family (Theorem 48.3(iii)) is a fibre integral of a multilinear form in the values of the masters of the node words and of the leaves (Theorem 48.5(iii)), as along a chain (Theorem 48.7(iii)).

(iii) Repetition. *Nodes carried to one another by bijections of their marks keeping their seam letters, the stations of their children corresponding, have isomorphic node words, and leaves so carried have isomorphic seam words; so the modules of a tree are found once for each class of its node words and leaves (Theorem 48.5(v)).*

(iv) Complex data. *Let the data of F be complex, with real parts as in this theorem and every exponent of a letter of F of positive real part. Then (i) holds at complex shares $\mathbf{a}_S$ on the pins of the seam whose real parts are shares at which it holds at the real parts, on the contours through the real shares at which it holds there, both sides converging absolutely and being holomorphic in the data and the shares; and (ii) holds as stated, the reading identity of Definition 48.4 being read at complex data.*

So every Foreman tree, read as a tree of nested bunches with the childcules of a peel as the pieces of the core (Definition 29.9), is a share reading, and the module of the family is read through the modules of its distinct node words and leaves. Opening a node word on its monomials pays for it in work, a fibre of Gamma functions; keeping it pays for it through the masters of its class.

Definition 48.13 (Blocks of a node; its scales and the transforms of its blocks)**.** In Definition 48.11 let S be a node with the children $S_1, \dots, S_k$ and the own marks $Z = Z_S$, its *parts* its children and its own marks, and $M = Z \sqcup \{g_1, \dots, g_k\}$ the marks of its node. Fix for every active letter L an *absent station* $D^\circ_{l,L}$ of every child, a station of S_l in the table of L, and an *absent exponent* $u_{z,L} \in \mathbb{N}$ of every own mark, and put $A_L = \prod_l x_{l,LD^\circ_{l,L}} \alpha_{g_l}^{\epsilon_L(D^\circ_{l,L})} \prod_z \alpha_z^{u_{z,L}}$. A part is *absent* from a monomial $c\,\alpha_Z^{\mathbf{q}} \prod_l x_{l,LD_l} \alpha_{g_l}^{\epsilon_L(D_l)}$ of a seam letter V^S_{LD} of the node when $D_l = D^\circ_{l,L}$, for a child, or $q_z = u_{z,L}$, for an own mark, and *present* in it otherwise.

(i) *Blocks.* The node *separates* a partition $\mathcal{P}$ of its parts into *blocks* when no monomial of a seam letter of its node has present parts in two blocks. Then

$$V^S_{LD} = A_L\Big(n_L(D) + \sum_{P \in \mathcal{P}} \beta_{P,LD}\Big),$$

with the *constant part* $n_L(D) \geq 0$, the coefficient of A_L, and the *reading* $\beta_{P,LD}$ of the block P, the sum of the monomials in which some part of P is present, divided by A_L: a polynomial with nonnegative coefficients in the ratios $x_{l,LD'} \alpha_{g_l}^{\epsilon_L(D')} / \big(x_{l,LD^\circ_{l,L}} \alpha_{g_l}^{\epsilon_L(D^\circ_{l,L})}\big)$, $D' \neq D^\circ_{l,L}$, of the children of P and the powers $\alpha_z^{q-u_{z,L}}$, $q \neq u_{z,L}$, of its own marks; at the root D is dropped. The partitions that the node separates are the coarsenings of the partition into the classes of the equivalence relation generated by two parts being present in one monomial; among them is the partition into one block. The node is *separable* when it separates the partition into single parts.

(ii) *Scales.* The *scales* of S are $\boldsymbol{\xi} = (\xi_{LD})_{(L,D)\in\Sigma_S}$, one for each pair at which some block is present, the set Σ_S. Every reading at (L, D) is homogeneous of the *degree* $\delta_{LD} = \deg V^S_{LD} - \deg A_L$ under the common scaling $\alpha_M \mapsto e^t\alpha_M$ of the marks of the node, which acts on the scales by $\xi_{LD} \mapsto e^{-t\delta_{LD}}\xi_{LD}$. The node is *seen by its scales* when some δ_{LD}, $(L, D) \in \Sigma_S$, is not zero; then this action is free, and the *scale quotient* Ξ_S is $(0,\infty)^{\Sigma_S}$ modulo it, with the quotient of $d\boldsymbol{\xi}/\boldsymbol{\xi}$ by dt; otherwise $\Xi_S = (0,\infty)^{\Sigma_S}$, and when S is full the only partition it separates is the one block.

(iii) *Transforms.* The *transform* of a block P, with the children S_l, $l \in P$, and the own marks $z \in P$, is

$$\mathcal{T}_P(\boldsymbol{\xi}) = \int_{\mathcal{O}_P} \prod_{l\in P} \Big(\alpha_{S_l}^{\mathbf{m}_{S_l}-\mathbf{1}} \prod_L \big(V^{(l)}_{LD^\circ_{l,L}}\big)^{-s_L}\Big) \prod_{z\in P} \alpha_z^{m_z-\sum_L s_L u_{z,L}-1} \times \exp\Big(-\sum_{(L,D)\in\Sigma_S} \xi_{LD}\,\widehat{\beta}_{P,LD}\Big)\, d\alpha$$

in $[0,\infty]$, over the orthant $\mathcal{O}_P$ of the marks of its children and its own marks, $\widehat{\beta}_{P,LD}$ being its reading with every ratio of a child replaced by the ratio $V^{(l)}_{LD'}/V^{(l)}_{LD^\circ_{l,L}}$ of the seam letters of the child. When the node is not seen by its scales the transform of the partition into one block is taken over the quotient of $\mathcal{O}_P$ by the common scaling $\alpha_{S_l} \mapsto e^t\alpha_{S_l}$, $\alpha_z \mapsto e^t\alpha_z$ of the marks of all the parts, with the quotient of $d\alpha/\alpha$ by dt. A block without children has as its transform a Gramma on its own marks, its configuration the exponents $q - u_{z,L}$ of its readings and its coefficients linear in the scales (Definition 2.1). Blocks are *equal* when a bijection of their marks keeping the seam letters and the masses of their children and own marks, with corresponding absent stations and exponents, carries the readings of one to those of the other; equal blocks have one transform.

Theorem 48.14 (A node on its scales)**.** *Let S be a node of a tree of nested bunches of F, with real data on the balance wall and every proper wall positive, and $\mathcal{P}$ a partition of its parts that it separates, the partition into one block when S is not seen by its scales, which for a full node is no restriction (Definition 48.13(ii)).*

(i) One point. *At real shares* $\mathbf{a}$ *on the pins of the seam of S with $a_{LD} > 0$ on Σ_S, in $[0,\infty]$,*

$$\prod_{(L,D)\in\Sigma_S} \Gamma(a_{LD}) \prod_{(L,D)\notin\Sigma_S} n_L(D)^{a_{LD}} \int_{\Delta_S} (\boldsymbol{\varrho}^\rho_S)^{-\mathbf{a}}\, d\phi^\rho_S = \int_{\Xi_S} \boldsymbol{\xi}^{\mathbf{a}}\, e^{-\langle\boldsymbol{\xi},\mathbf{n}\rangle} \prod_{P\in\mathcal{P}} \mathcal{T}_P(\boldsymbol{\xi})\, \frac{d\boldsymbol{\xi}}{\boldsymbol{\xi}},$$

$\mathbf{n} = (n_L(D))_{\Sigma_S}$, *the form on the right being invariant under the common scaling; at complex shares whose real parts are such shares at which the left side is finite, the same holds with the right side converging absolutely. At the root the same holds for $P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ at the exponents s_L. At complex data whose real parts are as here, every exponent of a letter of F having a positive real part, the same holds at shares whose real parts are shares at which the left side is finite at the real parts, at the root included, both sides being holomorphic in the data and the shares. So the node reads its blocks at one point of its scales, each through its transform, and q equal blocks enter as one transform to the power q: one integral over the scale quotient, whatever the multiplicities.*

(ii) The transforms. *The transform of a block depends on its children only through their walls and their laws. If the left side of (i) is finite at some shares, then every $\mathcal{T}_P$ converges, with*

all its derivatives, at every $\boldsymbol{\xi}$*, its data lying in the domain of Lemma 48.8, and generates a differential module of finite rank over* $\mathbb{C}(\boldsymbol{\xi})$*; so does its restriction to a section of the scale quotient by a monomial map, over the rational functions of the section. When the left side of (i) is finite at some shares and the children of* P *are full, on every contour of shares* $z_{LD\tau}$*, one for each monomial* τ *of each reading* $\beta_{P,LD}$*,* $(L,D) \in \Sigma_S$*, with positive real parts, on which the loads of every child* S_l *of* P*, the sums of the* $z_{LD\tau}$ *over the monomials in which it is present at its station* D' *and* s_L *less these at its absent station, have positive real parts, its seam function converges there, and the* pins of the block *hold, the scale pin of every child of* P *and, for every own mark* z *of* P*,* $\sum z_{LD\tau}(q_{z,\tau} - u_{z,L}) = m_z - \sum_L s_L u_{z,L}$*, less one when* S *is not seen by its scales,*

$$\mathcal{T}_P(\boldsymbol{\xi}) = \int_{pins} \prod_{L,D,\tau} \Gamma(z_{LD\tau}) \big(\xi_{LD} c_\tau\big)^{-z_{LD\tau}} \prod_{l \in P} \int_{\Delta_{S_l}} (\boldsymbol{\varrho}^\rho_{S_l})^{-\mathbf{a}_l} \, d\phi^\rho_{S_l},$$

c_τ the coefficient of τ, $q_{z,\tau}$ the exponent of α_z in it and $\mathbf{a}_l$ the loads of S_l: the inverse Mellin transform of the seam functions of its children, with one Gamma for each monomial of its readings, a fibre integral of the dimension of the number of these monomials less the number of the pins; with a native gauge, the native split of the node refined to the monomials of the readings of P is a point of such a contour.

(iii) Width one. *Let one table at exponents $s, t > 0$, or the family F_{m} of Proposition 42.26(i), whose two tables have the bases of one table and whose active letters are its letter K and the cobasis letter with the norms, have a hinge tree at width one with weights factoring across its bunches of width one (Theorem 23.16), read as a tree of nested bunches by the bunches of its subtree cells, the cells of at least two marks directly below a node being its children and the marks left in place its own marks, in the normalization in which the seam letters of the bunch of every subtree cell are the letters of the two hinge minors of that cell with its weights (Definition 23.15). A series or a parallel node (Definition 23.13) is separable, with the absent stations of the excess* 1 *at a series node and* 0 *at a parallel node, in both letters, and seen by its scales, its readings and its constant parts being weights of its core. With the weights* 1 *its scale quotient is one scale, read as $y = \xi_K \xi_\Psi$ on the section $\xi_K = 1$ at a series node and $\xi_\Psi = 1$ at a parallel node, and the transforms of its cells are their transforms $f_{\mathcal{A}}(y)$ at a series node and their dual transforms $\check{f}_{\mathcal{A}}(y)$ at a parallel node (Definition 23.1), those of its marks the transforms of the one-mark cells (Definition 23.19(1)), and (i) is the rule of Definition 23.19(2) and (5); at a series node it is the series connection of Proposition 20.37(i), whose transforms these are. On the centre ray of the table, with its norms in its cobasis letter (Proposition 42.26(i)), (i) is Proposition 42.26(vi) below the root and (vii) at the root: a mark left in place at a parallel root is read at its norm m_e in Ψ, through $\mathsf{g}(\mathsf{m}_e y)$, and at a series root every part is read in Ψ at the product M of the norms divided by its own, through $\mathsf{g}(y/\mathsf{m}_e)$ and $f_{\mathcal{A}}(y)$ in the coordinate $y = M\xi_K\xi_\Psi$, on the section $\xi_K = M^{-1}$, with the constant M^{-k}.*

So every full node is read on its scales through every partition of its parts that it separates. Its seam letters factor into the absent letters of its parts, which go to the powers s_L of the letter totals, and brackets in which one block at a time is present, which go to the scales; on its shares the blocks own their shares, joined by the conservation at the stations of the node, and on its scales they meet at one point. The finest partition that a node separates is read off its seam letters once its absent stations are chosen; a separable node is the general form of a series and of a parallel node, and the partition into one block reads the node through one transform of all its parts.

48.6 What the word along a tree reads

The word of a tree of nested bunches reads on its scales the transforms of the blocks of the nodes it reads there, and on its shares the node words and the leaves of the others; its group, its work and its price follow the distinct blocks and the distinct nodes.

Theorem 48.15 (What the word along a tree reads: inputs, group, work and price)**.** *Let F be as in Theorem 48.12, with a tree of nested bunches in a normalization and a set Σ of full nodes, each with a partition of its parts that it separates (Theorem 48.14). Read every node of Σ on its scales (Theorem 48.14(i)), on a section of its scale quotient by a monomial map with positive constant coefficients; the transform of every block with children, all of them full, of a node of Σ by Theorem 48.14(ii), the seam functions of its children read by their own words, and that of every other block with children as its exponential period (Definition 48.13(iii)), which integrates over the subtrees of its children, so that their nodes are not read and none of them is in Σ; and every other node, the leaves among them, on its shares, each part of the tree between the nodes of Σ, under the root or under a full child of a block, opened along it as in Theorem 48.12(ii), with the nodes of Σ directly below it read by their seam functions, its node words opened on their monomials or kept. A node read on its shares is read* alone *when it and its children in that part are full, by Theorem 48.12(i); the others are read* jointly*, each maximal set of them joined through parents and children by one fibre of Theorem 48.12(ii). In this statement node words, leaves and blocks are counted once for each class under bijections of their marks keeping their seam letters and their data, a block together with its absent stations, its absent exponents and its readings; the word writes the sections of the nodes of Σ of one class in one set of coordinates; and an input is counted once for each density as the word writes it, the product of the transforms of the classes of its blocks to their multiplicities, the transform of a block without children written as its Gramma on the section, and the exponential of its constant parts. The classes, and with them the multiplicities, are those of the normalization: that of Definition 28.1 puts in one class the nodes carried to one another by bijections that carry the family, and that of Theorem 48.14(iii) the subtrees that are equal as cells with their weights.*

(i) What it reads. *The value is a word whose inputs are, at every node S of Σ, the function $e^{-\langle \boldsymbol{\xi},\mathbf{n}\rangle}\prod_P \mathcal{T}_P^{q_P}$ on the section of its scale quotient, a function on $(0,\infty)^r$, $r=\dim \Xi_S$: the product over its distinct blocks of their transforms raised to their multiplicities q_P, a block without children bringing a Gramma, and the exponential of its constant parts. Everything else in it is stacked Gammas of linear forms in the data and the shares, rational constants and powers of positive constants, fibre integrals over shares, the exponential periods of the blocks read as such, and the periods of the node words kept and of the seam words of the leaves kept, each at lattice translates of its data a combination with coefficients in $\mathbb{K}_{\mathbb{S}}$ of the periods of the $\mathfrak{m}_k$ masters of its class (Theorem 48.5(iii),(v)); these masters can be taken among the $\alpha^u f_{N\mathbf{d}_1}$, α^u a Laurent insertion and $\mathbf{d}_1$ a positive direction of the class with N at least the wall degree of every α^u (Theorem 48.3(iii),(iv)), whose walls are nonnegative and whose values converge wherever the period of the class does.*

(ii) Group. *Every input generates a differential module of finite rank. For every r let N_r be the sum over $\mathbb{C}(y_1,\dots,y_r)$ of the modules of the distinct transforms of the blocks of the nodes of Σ whose scale quotients have the dimension r, and of the exponentials of their constant parts, each read on its section and counted once. The group of the sum of the modules of the distinct inputs on r scales is the image of G_{N_r} acting on its solutions, a quotient of G_{N_r}, whatever the multiplicities; so the group of the word (Definition 48.9) is a quotient of $\prod_r G_{N_r}$.*

(iii) Work. *The work is the sum of the dimensions of the fibres of Theorem 48.12(i) of the distinct nodes read alone, and of the joint fibres of the distinct sets of nodes read jointly, with the shares inside the entries where a node word is opened; of* $\mathfrak{m}_k \dim V_{W_k}$ *for the distinct classes* k *of the node words and seam words of leaves kept; of* r *for every distinct input on* r *scales; of the dimensions of the fibres of Theorem 48.14(ii) of the distinct transforms of blocks with full children; and of the dimension of the orthant of every other distinct block with children, less one when its node is not seen by its scales. It does not grow with the multiplicities of the blocks, which enter as powers, nor with those of the nodes read alone, leaves, transforms and inputs, each read once; a node read jointly enters the joint fibre of its set with its multiplicity.*

(iv) Price. *The price is at most that of the tree, of its transfer tensors, and of the absent stations, absent exponents and readings of the blocks of the nodes of* Σ*, each distinct one written once and referred to by index (Definition 33.2); plus, for every class of node words and leaves kept, that of its masters, of the reduction of* $[1]$ *on them and of its shift matrices at the generators of its lattice, and of the isomorphisms onto it; plus the exponent matrices and the coefficients of the sections, the lattice bases of the pins of directions, the* $\lceil \log_2(q_P + 1) \rceil$ *bits of every multiplicity, and the coefficients of the elements of the integrand modules integrated.*

(v) Complex data. *At complex data whose real parts are as in Theorem 48.12, every exponent of a letter of* F *having a positive real part, the period is the word of (i) read at those data: its fibres are taken through the real shares at which they converge at the real parts, its inputs are read at those data, and every integral of it converges absolutely, the word being holomorphic in the data on the tube over the real data of Theorem 48.12. Every input there generates a differential module of finite rank, and (ii)–(iv) hold as stated.*

Corollary 48.16 (The word along the canonical tree)**.** *In the setting of Theorem 45.34, the bunches of the subtree cells of the canonical hinge tree are a tree of full nested bunches of the family* F_{m} *of Proposition 42.26(i), in the normalization of Theorem 48.14(iii), whose series and parallel nodes are separable and seen by their scales, each with one scale. With* Σ *the nodes of* S *and the classes below the root, each with the partition into its cells, and every other node read on its shares with its node word opened on its monomials, Theorem 48.15 is Theorem 45.34: its inputs, on one scale, are those of (i) there, the constant* M^{-k} *of a series root in* S *being written there as the factors* m_e^{-k} *of its inputs; its group is bounded as in (ii) there, and is the group of (ii) there when* S *is empty; and its work is that of (iii) there.*

So Theorem 45.34 is the reading of one table at width one on the scales of its series and parallel nodes, and its mechanism is a pin read as a scale. A node conserves the loads of its blocks by its pins, one at each of its stations, and on the scales of its letters those pins are one point at which every block is read through its transform; so a repeated block is one transform to a power, and the group of what the node reads is a quotient of the group of its distinct blocks and of the exponential of its constant parts (Proposition 48.10). A series or a parallel node at width one is the case of one scale and single cells, each read through its transform or its dual transform, and its classes are the case of single marks, each read through g. At any width and at every node the same holds on as many scales as the pairs of a letter and a station at which a block is present, less the scaling when the node sees it. The transforms have modules of finite rank because each is an exponential period on an open cone of data, whose integration by parts closes in a twisted de Rham cohomology of finite dimension (Lemma 48.8): the finiteness that gives the module of Chapter 47 its finite dimension on the shares. These modules are read off the children of the blocks on their shares, once for each class of blocks (Theorem 48.20).

48.7 The module of a family from its nodes

A share reading reads every value of a family through the masters of its nodes (Theorem 48.5(iii)), and its fibre integral identifies more than the nodes do: a translation of the shares along the fibre leaves the integral unchanged. Along a tree the relations of the family ride on the paths of the terms of its letters. A letter identity of the family is the letter identities of its nodes, the probabilities of the paths under the flow of the shares summing to one, and a mark relation of the family is that of the node of the mark, the paths through each of its entries carrying together the share of the entry. So, modulo the translations along the fibres, the integrand carries the module of the family itself, the values separating the module (Proposition 47.15). The module of a family is the direct image of the modules of its nodes, found node by node from the leaves up, once for each class of subtrees, by eliminations over the rational functions of the data on identities among the products of the masters of the nodes; and its zeros are told by the closings of the node words and of the seam words of the leaves, combined along the tree by flows of integers.

Definition 48.17 (Paths; the direct image of a reading)**.** Let F be a family of tables with the exponents fixed at 0 named, at least one exponent not fixed at 0, whose marks form one molecule of the family of its active tables, with a tree of nested bunches in a normalization. Its letters, the K_j and the Ψ_j whose exponents are not fixed at 0, form the family W_F of positive letters (Proposition 48.21(i)), a family of letters of tables (Theorem 48.23); every family of letters of tables is the W_F of the family of the tables of its letters, with the exponents of the letters of these tables that it does not contain fixed at 0. The data of F are those of W_F, its data space $\mathbb{D}_{W_F}$ being the balance hyperplane in the masses and the exponents of the letters (Definition 48.1, Theorem 48.23(i)), with its lattice $\mathbb{D}_{W_F}(\mathbb{Z})$; its module is $\mathfrak{M}_{W_F}$ (Theorem 48.3(iii)), its closings are those of Theorem 48.23(ii), and P_F is the period of W_F (Definition 48.1(v)). The active letters of Definition 48.11 are the letters of F, and a node is full when its seam word, formed by the seam letters of the letters of F, is full; the two letters of a table have exponents complementary in its marks and so one space of directions, and this is the fullness of the seam word with both letters of every active table. A realization of the active tables with the exponents of the letters positive and the others 0 (Definition 9.1), as with the exponents 1 and the gauge $\mathbf{1}$, has the usage at its gauge as its masses, so that the gauge is native (Proposition 8.22), and every proper wall positive, the active tables forming one molecule (Proposition 9.2); so by Theorem 48.12(ii) at it, where the active letters are the letters of F, the readings below are positive share readings (Definition 48.4). When every letter of every table is a letter of F, W_F is F read as in Definition 47.1, and the realization with the exponents 1 and the gauge $\mathbf{1}$ is the centre data. Let W be either W_F, with the reading of P_F along the tree, its *top* the root and its letters ℓ the letters L of F at the exponents $w_\ell = s_L$; or the seam word of a full node $S \neq \mathcal{E}$, with the reading of its period, the seam function of S on the pins of its seam, along the members of the tree inside S (Theorem 48.12(ii)), its top S and its letters the seam letters $\ell = V^S_{LD}$ at the exponents $w_\ell = a_{S,LD}$. The reading has the shares $\mathbf{z}$, the share space $\mathbb{S}$, the kernel G and the nodes (W_k, ι_k), the node words and the seam words of the leaves. Let every node carry a *module* $\mathfrak{V}_k$: its module $\mathfrak{M}_{W_k}$, or the quotient of it by a submodule of elements of value zero, with the shifts and the values that it inherits.

(i) *Paths.* A *path* π of a letter ℓ of W of the active letter L, $\ell = L$ at the root and $\ell = V^S_{LD}$ at a full node S, assigns to every node S' below the top a station $D_{S'}(\pi)$ of that table, and to every node S' that is not a leaf, the top included, the entry $E_{S'}(\pi) = \mathbf{N}_{S',L}\big(D_{S'}(\pi); (D_{S'_i}(\pi))_i\big)$ of its seam letter at its station into the stations of its children S'_i, which is to be nonzero; the station of the top is D for $\ell = V^S_{LD}$, and at the root it is dropped. The *factors* of π are these entries and the seam letters $V^{(S')}_{LD_{S'}(\pi)}$ of the leaves; a *term* of π is a product $c\,\alpha^{\mathbf{t}}$ of one

monomial of each factor, c the product of their coefficients, and ℓ is the sum of the terms of its paths (Definition 48.11(i)). The *path vector* τ_π puts 1 on the share of every entry of π and 0 on every other share, and the *probability* of π is

$$R_\pi = \prod_{S'} \frac{z_{E_{S'}(\pi)}}{a_{S',LD_{S'}(\pi)}},$$

over the nodes that are not leaves, the share of the entry of π over the load of its station, the load at the top being w_ℓ. A term $c\,\alpha^{\mathbf{t}}$ of π is *lifted* to $\big((\mathbf{t};\mathbf{e}_\ell),\tau_\pi\big)$: the data of its stride $\alpha^{\mathbf{t}}/\ell$, with the path vector of its path.

(ii) The *integrand module* is $\mathfrak{J} = \bigotimes_k (\mathfrak{V}_k \otimes \mathbb{K}_{\mathbb{S}})$, with the shifts $\mathrm{Sh}_{(\lambda,\tau)}$ and the values of Theorem 48.5(ii), and $[1]^{\otimes} = \bigotimes_k [1]$. The *fibre translations* are the $(\mathbf{0},\tau) \in \mathbb{S}(\mathbb{Z})$.

(iii) The *integrand span* $\mathfrak{J}^\natural$ is the $\mathbb{K}_W$-span in $\mathfrak{J}$ of the $\mathrm{Sh}_{(\lambda,\tau)}[1]^{\otimes}$, $(\lambda,\tau) \in \mathbb{S}(\mathbb{Z})$, the rational functions of the data of W being read on $\mathbb{S}$ through its projection; the shifts map it onto itself. $\mathfrak{F} \subseteq \mathfrak{J}^\natural$ is the $\mathbb{K}_W$-span of the $(\mathrm{Sh}_{(\mathbf{0},\tau)} - 1)\,t$, $t \in \mathfrak{J}^\natural$ and $(\mathbf{0},\tau)$ a fibre translation.

(iv) The *direct image* of the reading is $\mathfrak{H} = \mathfrak{J}^\natural/\mathfrak{F}$, with the *shifts* $\mathrm{Sh}_\lambda[t] = [\mathrm{Sh}_{(\lambda,\tau)}\,t]$, $(\lambda,\tau) \in \mathbb{S}(\mathbb{Z})$, the classes $e_\lambda = [\mathrm{Sh}_{(\lambda,\tau)}[1]^{\otimes}]$, and the *fibre integral* $\int \big[\sum_j r_j\,\mathrm{Sh}_{(\lambda_j,\tau_j)}[1]^{\otimes}\big] = \sum_j r_j\,P_W(\cdot+\lambda_j)$, $r_j \in \mathbb{K}_W$, a meromorphic function on $\mathbb{D}_W$.

Theorem 48.18 (The module of a family from its nodes)**.** *In Definition 48.17:*

(i) The relations ride on the paths. *The lift of a term of a path π lies in $\mathbb{S}(\mathbb{Z})$, moves the kernel by R_π and every node by the data of the stride of its monomial in its factor, and in $\mathfrak{J}$, the sums running over the paths of ℓ and their terms,*

$$\sum_{\pi,\ c\alpha^{\mathbf{t}}} c\,\mathrm{Sh}_{((\mathbf{t};\mathbf{e}_\ell),\tau_\pi)}[1]^{\otimes} = [1]^{\otimes}, \qquad m_e\,[1]^{\otimes} - \sum_\ell w_\ell \sum_{\pi,\ c\alpha^{\mathbf{t}}} c\,t_e\,\mathrm{Sh}_{((\mathbf{t};\mathbf{e}_\ell),\tau_\pi)}[1]^{\otimes} = 0,$$

for every letter ℓ of W and every mark e of W: the letter identities and the mark relations of W at its data (Theorem 48.3(iv)), lifted along the paths, hold in the integrand. The first is the letter identities of the nodes, the probabilities of the paths of ℓ summing to 1 by the pins. The second is the mark relation of the node whose word has the mark e, the paths of the letters of one active letter through an entry E of that word carrying together its share z_E: Theorem 48.7(v) in the integrand, along every tree.

(ii) The module is the direct image. $\mathbb{S}(\mathbb{Z})$ *maps onto* $\mathbb{D}_W(\mathbb{Z})$. *The shifts, the classes e_λ, $\lambda \in \mathbb{D}_W(\mathbb{Z})$, and the fibre integral are well defined on $\mathfrak{H}$, with $\int \mathrm{Sh}_\lambda\,h = \sigma_\lambda \int h$, so that its elements of value zero form a submodule; the classes e_λ span it, and*

$$O\Big(\sum_\lambda r_\lambda\,\mathrm{Sh}_\lambda[1]\Big) = \sum_\lambda r_\lambda\,e_\lambda$$

is a well-defined map of $\mathfrak{M}_W$ onto $\mathfrak{H}$ that commutes with the shifts, with $\int O(m) = \langle m \rangle$. So the kernel of O consists of elements of value zero, and, the values separating $\mathfrak{M}_W$ (Proposition 47.15), O is an isomorphism: $\dim_{\mathbb{K}_W} \mathfrak{H} = \mathfrak{m}_W = (-1)^{r_W}\,\mathrm{eu}(X_W)$, *the number of the native points of generic data (Proposition 47.16), and the masters, the shift matrices and the reductions of $\mathfrak{H}$ are those of $\mathfrak{M}_W$. The quotient of the module of a node by a submodule of elements of value zero is that module itself, for the same reason.*

(iii) Node by node. *Replacing the module of a node by its quotient by a submodule of elements of value zero replaces $\mathfrak{H}$ by its quotient by a submodule of elements of value zero. Let Σ be a set of full nodes that contains the root. For $S \in \Sigma$ the* tree of S down to Σ *is formed by the members of the tree properly inside S that lie properly inside no member of Σ properly inside S; in it the members of Σ nearest below S are leaves. For $S \in \Sigma$, from the leaves up, let $\mathfrak{H}_S$ be the module of the seam word of S when S is a leaf of the tree, and otherwise the direct image of the reading of the seam word of S, of P_F at the root, along the tree of S down to Σ, its leaves in Σ carrying their $\mathfrak{H}$, or the modules presented by accepted sets of them ((iv)), and its other nodes their modules. Then every $\mathfrak{H}_S$ is the quotient of the module of the seam word of S, and $\mathfrak{H}_{\mathcal{E}}$ that of $\mathfrak{M}_{W_F}$, by a submodule of elements of value zero, which is 0 (Proposition 47.15): $\mathfrak{H}_S$ is the module of the seam word of S, and $\mathfrak{H}_{\mathcal{E}}$ is $\mathfrak{M}_{W_F}$. A bijection of the marks of two members of Σ that carries the members of the tree and of Σ inside one to those inside the other, keeping their seam letters, carries the one $\mathfrak{H}$ to the other (Theorem 48.5(v)), so each $\mathfrak{H}_S$ is found once for each class of such subtrees, and the modules of the node words and of the leaves once for each of their classes, by one box each (Theorem 48.3(iv)). With Σ the full nodes, every node that is not full is read jointly with the others of its set, as in Theorem 48.15; with $\Sigma = \{\mathcal{E}\}$ the tree is one reading.*

(iv) Boxes on the shares. *Let $\mathcal{G}$ consist of a basis of $\mathbb{D}_W(\mathbb{Z})$ and its negatives, with lifts $(\mu, \tau_\mu) \in \mathbb{S}(\mathbb{Z})$ ((ii)), and let $\Lambda \ni \mathbf{0}$ be a finite subset of $\mathbb{D}_W(\mathbb{Z})$ with lifts (λ, τ_λ), $\tau_{\mathbf{0}} = \mathbf{0}$. Λ is* accepted *when for every $\mu \in \mathcal{G}$ and $\lambda \in \Lambda$ there are $r_{\lambda'}^{\mu,\lambda} \in \mathbb{K}_W$, $\lambda' \in \Lambda$, finitely many $t_k \in \mathfrak{J}^\natural$ and fibre translations $(\mathbf{0}, \sigma_k)$ with*

$$\mathrm{Sh}_{(\lambda+\mu,\tau_\lambda+\tau_\mu)}[1]^{\otimes} - \sum_{\lambda' \in \Lambda} r_{\lambda'}^{\mu,\lambda}\, \mathrm{Sh}_{(\lambda',\tau_{\lambda'})}[1]^{\otimes} = \sum_k \big(\mathrm{Sh}_{(\mathbf{0},\sigma_k)} - 1\big) t_k$$

in $\mathfrak{J}$, the certificate*: an identity of vectors over $\mathbb{K}_{\mathbb{S}}$ on the products of the masters of the modules of the nodes, every shift of $[1]^{\otimes}$ in it being a Pochhammer quotient of the kernel times the Kronecker product of the reductions of the shifts of $[1]$ of the nodes (Theorem 48.5(ii)). Then the classes e_λ, $\lambda \in \Lambda$, span $\mathfrak{H}$, $\mathrm{Sh}_\mu\, e_\lambda = \sum_{\lambda'} r_{\lambda'}^{\mu,\lambda} e_{\lambda'}$, and $P_W(\cdot + \lambda + \mu) = \sum_{\lambda'} r_{\lambda'}^{\mu,\lambda} P_W(\cdot + \lambda')$ as meromorphic functions on $\mathbb{D}_W$. Let Sh_μ be the σ_μ-semilinear map of $\mathbb{K}_W^\Lambda$, with the basis (ε_λ), given by $\mathrm{Sh}_\mu\big(\sum_\lambda q_\lambda \varepsilon_\lambda\big) = \sum_{\lambda,\lambda'} \sigma_\mu(q_\lambda)\, r_{\lambda'}^{\mu,\lambda} \varepsilon_{\lambda'}$, let $\rho(\lambda)$ be the image of $\varepsilon_{\mathbf{0}}$ under the maps of the steps of a path in $\mathcal{G}$ from $\mathbf{0}$ to λ, fixed for each λ, extended linearly, and let $\mathfrak{N} \subseteq \mathbb{K}_W^\Lambda$ be the smallest subspace that these maps carry into itself and that contains, for $\mu, \nu \in \mathcal{G}$ and $\lambda \in \Lambda$, $\mathrm{Sh}_\mu \mathrm{Sh}_\nu\, \varepsilon_\lambda - \mathrm{Sh}_\nu \mathrm{Sh}_\mu\, \varepsilon_\lambda$, $\mathrm{Sh}_{-\mu} \mathrm{Sh}_\mu\, \varepsilon_\lambda - \varepsilon_\lambda$ and $\varepsilon_\lambda - \rho(\lambda)$, and the images under ρ of the letter identities and of the mark relations of W, $\sum_{\mathbf{t}} c_{\ell,\mathbf{t}}\, \rho((\mathbf{t}; \mathbf{e}_\ell)) - \varepsilon_{\mathbf{0}}$ and $m_e \varepsilon_{\mathbf{0}} - \sum_\ell w_\ell \sum_{\mathbf{t}} c_{\ell,\mathbf{t}} t_e\, \rho((\mathbf{t}; \mathbf{e}_\ell))$, over the monomials $c_{\ell,\mathbf{t}} \alpha^{\mathbf{t}}$ of ℓ; $\mathfrak{N}$ does not depend on the paths chosen. The* module presented *by Λ, $\widehat{\mathfrak{H}} = \mathbb{K}_W^\Lambda / \mathfrak{N}$, found by finitely many eliminations, is a module with the induced shifts, with masters among the ε_λ and their shift matrices at $\mathcal{G}$; $\mathrm{Sh}_\lambda[1] \mapsto \rho(\lambda)$ maps $\mathfrak{M}_W$ onto it and $\varepsilon_\lambda \mapsto e_\lambda$ maps it onto $\mathfrak{H}$, so it is the quotient of $\mathfrak{M}_W$ by a submodule of elements of value zero, that is $\mathfrak{M}_W$ itself (Proposition 47.15), with its masters among the ε_λ and their shift matrices, and it may stand for $\mathfrak{H}$ in (iii). Accepted sets exist, and a search through the finite sets of points with lifts and of supports of certificates, in any order that reaches each, testing each by one elimination over $\mathbb{K}_W$, stops.*

(v) Closings through the tree. *For a node S, integral masses $\mathbf{m}_S$ and loads $A_{LD} \in \mathbb{N}$, one for each seam letter of S, let $\mathsf{C}_S(\mathbf{m}_S; \mathbf{A})$ be the coefficient of $\alpha^{\mathbf{0}}$ in $\alpha^{\mathbf{m}_S} \prod_{L,D} (V_{LD}^S)^{A_{LD}}$, the* closing *of the seam word of S at the exponents $-\mathbf{A}$, and $\mathsf{C}_{W_S}(\mathbf{m}_{Z_S}; \boldsymbol{\varepsilon})$ that of its node word at the exponents $-\boldsymbol{\varepsilon}$ of its entries, the product of the entries to the powers $\boldsymbol{\varepsilon}$ when Z_S is*

empty. When S is not a leaf,

$$\mathsf{C}_S(\mathbf{m}_S;\mathbf{A}) = \sum_{\boldsymbol{\varepsilon}} \prod_{L,D} \frac{A_{LD}!}{\prod_{\mathbf{D}} \varepsilon_{LD\mathbf{D}}!}\ \mathsf{C}_{W_S}(\mathbf{m}_{Z_S};\boldsymbol{\varepsilon}) \prod_i \mathsf{C}_{S_i}\big(\mathbf{m}_{S_i};\mathbf{A}_i(\boldsymbol{\varepsilon})\big),$$

the sum over the $\boldsymbol{\varepsilon} = (\varepsilon_{LD\mathbf{D}})$ in $\mathbb{N}$, one for each nonzero entry, with $\sum_{\mathbf{D}} \varepsilon_{LD\mathbf{D}} = A_{LD}$, $\mathbf{A}_i(\boldsymbol{\varepsilon})$ being the loads $\sum \varepsilon_{LD\mathbf{D}}$, over the $(D,\mathbf{D})$ with $D_i = D'$, that $\boldsymbol{\varepsilon}$ puts on the stations D' of the child S_i. At the root, D dropped and $A_L = N_L$, $\mathsf{C}_{\mathcal{E}}(\mathbf{m};\mathbf{N})$ is the closing $\mathsf{C}(1)(\mathbf{d})$ of W_F at the integral data $\mathbf{d}$ with the masses $\mathbf{m}$ and the exponents $-N_L$ of its letters, the constant term on the torus of X_{W_F} (Theorem 48.23(ii)). Write $\mathsf{C}_S(\mathbf{d}) = \mathsf{C}_S(\mathbf{m}_S;-\mathbf{w})$ at the integral data $\mathbf{d} = (\mathbf{m}_S;\mathbf{w})$ of the seam word with $\mathbf{w} \le \mathbf{0}$. The seam word of a full node is, at its shares, the family of its seam letters, the letters of the room children of its stations, with the weights of the normalization, one for each letter of F and each station in its table: a family of letters of tables whose marks form one molecule of the family of these tables, the node being full (Theorem 48.23(i)). So Proposition 47.10 and Theorem 47.11 hold for it, as for W_F, and for their quotients by submodules of elements of value zero (Theorem 48.23(ii); a full node of one mark has a module of dimension one and no nonzero element of value zero). So an element $\sum_\lambda r_\lambda \operatorname{Sh}_\lambda[1]$ of $\mathfrak{M}_{W_F}$ or of the module of the seam word of a full node S, or its image in a direct image $\mathfrak{H}_S$ of (iii), has the value zero, that is, is 0 (Proposition 47.15), exactly when $\sum_\lambda r_\lambda(\mathbf{d})\, \mathsf{C}_S(\mathbf{d}+\lambda)$ vanishes along the rays of Theorem 47.11(c), in the positive directions of Theorem 48.3(i): the elements of value zero are told by the closings of the node words and of the seam words of the leaves, combined along the tree by flows of integers, the closings of a seam word being found once for each class of the subtree of its node at each integral point.

So the module of a family is read off its nodes. The engine holds one box for each class of node words and leaves, over the rational functions of their data, and one module for each class of subtrees, presented by one accepted set of shifts whose certificate is an identity among the products of the masters of the nodes of that subtree, with coefficients rational in its data and its shares. Every such module is the module of the seam word of its node, the values separating the module (Proposition 47.15), so it stands for that module at the parent, and the masters and the shift matrices of the family are those of the module at the root; the closings of the node words and of the seam words of the leaves, combined along the tree by flows of integers, tell its zeros. Nothing in this asks whether a spanning set is free: the module presented by an accepted set is a quotient of the module of the family by elements of value zero and maps onto the direct image, so it is the module itself. No step integrates, and no step needs a box on all the marks of the family or of any subtree: the algebra, like the word, is paid once for each distinct subtree, and a subtree that recurs is referred to by its class. Theorem 33.3 priced repetition by the word at full leans, in series closures and along chains; Theorem 48.15 prices it along every tree, at every width, in the word, and Theorem 48.18 pays the algebra once for each class of node words, leaves and subtrees.

The paths are where this happens. A letter of the family is the sum of the terms of its paths, and the flow of the shares chooses a path with the probabilities of the shares of its entries over the loads of their stations; the letter identity of the family is the letter identities of its nodes averaged over the paths, and its mark relation is the mark relation of the node of the mark, whose entries the flow uses in the proportions of their shares. The fibre translations then identify the lifts of one stride along different paths. The value of every element is the fibre integral of its class, and a relation among the classes in the direct image is a relation among the values of the family. A letter whose exponent is fixed at 0 has no paths and enters no node word, no seam word and no closing: the family is read through its letters alone.

48.8 The module of a transform from its block

The transform of a block is an exponential period (Lemma 48.8): its derivatives in its scales close over the rational functions of its scales and its data, in the twisted de Rham module of its orthant. Read on the shares of its block (Theorem 48.14(ii)), a scale times a monomial of its reading, with its coefficient, is the share of that monomial, the share side of the Gramma: $\Gamma(z)C^{-z}\cdot C = z\,\Gamma(z)C^{-z}$ after the share is moved by one. So a derivative in a scale multiplies the integrand by minus the total of the shares at that scale over the scale, and a translation along the fibre that moves the totals is a monomial in the scales. The mark relations of the transform ride on the shares as those of a family ride on its paths (Theorem 48.18(i)): at an own mark of the block they are its pins, and at a mark of a child they are the mark relation of the child. Modulo the translations along the fibre, each twisted by its monomial in the scales, the integrand of the block carries the module of its transform, with the scales acting by connections, over the rational functions of the data that the transform reads and of its scales, the values separating that module as they separate the module of a family (Proposition 47.15) wherever the transform reads all the data of its block; it is found from the modules of the children, once for each class of blocks. A block without children is a Gramma, and there this is Theorem 2.4 read on the shares: the pins are its exchange relations, the connections its ladder, and its toric relations say that a class does not depend on the lift that writes it.

Definition 48.19 (The module of a transform; the twisted direct image of a block)**.** Let F, its tree and the normalization be as in Definition 48.17, let S be a full node with a partition of its parts that it separates (Definition 48.13), and let P be one of its blocks whose children S_l, $l\in P$, are full, the marks of its parts forming the set B_P. For an active letter L write $h_{lL} = V^{(l)}_{LD^\circ_{l,L}}$ for the absent letter of the child S_l and $H_L = \prod_{l\in P} h_{lL}$ for their product, and for a monomial τ of the reading $\beta_{P,LD}$, $(L,D)\in\Sigma_S$, with the coefficient c_τ, write $r_\tau = \prod_l V^{(l)}_{LD_l(\tau)}/h_{lL}\,\prod_z \alpha_z^{q_{z,\tau}-u_{z,L}}$, the product over the children present in τ, at their stations $D_l(\tau)$, and over the own marks of P, so that $\widehat\beta_{P,LD} = \sum_\tau c_\tau r_\tau$.

(i) *Data.* The *data* of the block are $\mathbf{d}_P = (\mathbf{m}_P;\mathbf{w})$: masses on B_P, the masses of the marks of the children and, at an own mark z, the mass m'_z that the transform reads as $m_z - \sum_L s_L u_{z,L}$, and, when P has children, an exponent w_L of H_L for every active letter L, which the transform reads as s_L. They range over $\mathbb{D}_P = \mathbb{C}^{B_P}\times\mathbb{C}^{A_P}$, A_P the set of the active letters when P has children and empty otherwise, on the balance hyperplane $\sum_{e\in B_P} m_e = \sum_L w_L \deg H_L$ when S is not seen by its scales, with the lattice $\mathbb{D}_P(\mathbb{Z})$ of its integral points and the fields $\mathbb{K}_P = \mathbb{C}(\mathbb{D}_P)$ and $\mathbb{K}_P(\boldsymbol\xi)$, $\boldsymbol\xi = (\xi_{LD})_{\Sigma_S}$ the scales. The data that the transform reads, as the data of F vary over $\mathbb{D}_{W_F}$, form a linear subspace $\mathbb{E}_P$ of $\mathbb{D}_P$: all of $\mathbb{D}_P$, except when S is the root, seen by its scales, and P, with children, is its one block, when $\mathbb{E}_P$ is the hyperplane of the balance of F.

(ii) *The module of the transform.* On the set $Y_P\subseteq(\mathbb{C}^\times)^{B_P}$ on which no H_L vanishes, with the insertions $\mathbb{C}[Y_P]$, spanned by the strides $f_\lambda = \alpha^{\mathbf{u}}\prod_L H_L^{-n_L}$, $\lambda = (\mathbf{u};\mathbf{n})\in\mathbb{D}_P(\mathbb{Z})$, the *module of the transform* is

$$\mathfrak{M}_P = \big(\mathbb{C}[Y_P]\otimes\mathbb{K}_P(\boldsymbol\xi)\big)/\mathcal{L}_P,\qquad \omega_e = m_e - \sum_L w_L\,\alpha_e\partial_{\alpha_e}\log H_L - \sum_{(L,D)\in\Sigma_S}\xi_{LD}\,\alpha_e\partial_{\alpha_e}\widehat\beta_{P,LD},$$

m_e being the mass m'_z at an own mark z and $\mathcal{L}_P$ the span of the $(\partial_{y_e}+\omega_e)g$, $g\in\mathbb{C}[Y_P]$, $e\in B_P$, $y=\log\alpha$: the top cohomology of the twisted de Rham complex of Lemma 48.8(ii).

It carries the *shifts* $\mathrm{Sh}_\lambda[g\otimes r]=[f_\lambda g\otimes\sigma_\lambda r]$, the *connections* $\nabla_{LD}[g\otimes r]=[g\otimes\partial_{\xi_{LD}}r-\widehat{\beta}_{P,LD}\,g\otimes r]$ and the *values* $\langle g\rangle=\int_{\mathcal{O}_P} g\,\alpha^{\mathbf{m-1}}\prod_L H_L^{-w_L}\exp\big(-\sum\xi_{LD}\widehat{\beta}_{P,LD}\big)\,d\alpha$ on the domain of Lemma 48.8(i); the value of [1] at the data that the transform reads is $\mathcal{T}_P$. When S is not seen by its scales, P is the one block, and Y_P, its insertions and its relations are those of the quotient by the common scaling (Lemma 48.8(iii)), read as for a family of positive letters on its space of directions: the insertions invariant under it and the relations of its marks, which sum to its homogeneity.

(iii) *The share reading of the transform.* The *shares* are the $z_{LD\tau}$ of Theorem 48.14(ii), one for each monomial τ of each reading at $(L,D)\in\Sigma_S$, the set I_P, with the totals $Z_{LD}=\sum_\tau z_{LD\tau}$; the *share space* $\mathbb{S}_P\subseteq\mathbb{D}_P\times\mathbb{C}^{I_P}$ is the set of the $(\mathbf{d}_P,\mathbf{z})$ on the pins of the block, $\sum z_{LD\tau}(q_{z,\tau}-u_{z,L})=m'_z$ at every own mark z and the scale pin of every child at its loads, the load of S_l at a station at which it is present in some monomial being the sum of the shares of those monomials and at its absent station w_L less the shares of the monomials of L in which it is present, less one pin when S is not seen by its scales; its lattice is $\mathbb{S}_P(\mathbb{Z})$, its fibre translations are the $(\mathbf{0},\delta)\in\mathbb{S}_P(\mathbb{Z})$, and $\mathbb{D}'_P(\mathbb{Z})$ is the image of $\mathbb{S}_P(\mathbb{Z})$ in $\mathbb{D}_P(\mathbb{Z})$. The *kernel* is $G_P=\prod\Gamma(z_{LD\tau})\,c_\tau^{-z_{LD\tau}}$, the *nodes* are the seam words W_l of the children at their masses and loads, each carrying a module $\mathfrak{V}_l$, its module or the quotient of it by a submodule of elements of value zero, as the $\mathfrak{H}_{S_l}$ of Theorem 48.18(iii), and the *integrand module* $\mathfrak{J}_P=\bigotimes_l(\mathfrak{V}_l\otimes\mathbb{K}_{\mathbb{S}_P})$ carries the shifts $\mathrm{Sh}_{(\lambda,\tau)}$ of Theorem 48.5(ii) for the kernel G_P, its powers of the constants c_τ moving by constants.

(iv) *The twisted direct image.* For τ a vector of shares write $Z(\tau)$ for its totals and $\boldsymbol{\xi}^{-Z(\tau)}=\prod\xi_{LD}^{-Z_{LD}(\tau)}$. The *scaled integrand span* $\mathfrak{J}_P^{\boldsymbol{\xi}}$ is the $\mathbb{K}_P(\boldsymbol{\xi})$-span in $\mathfrak{J}_P\otimes_{\mathbb{K}_{\mathbb{S}_P}}\mathbb{K}_{\mathbb{S}_P}(\boldsymbol{\xi})$, the shifts fixing $\boldsymbol{\xi}$, of the $\boldsymbol{\xi}^{-Z(\tau)}\,\mathrm{Sh}_{(\lambda,\tau)}[1]^\otimes$, $(\lambda,\tau)\in\mathbb{S}_P(\mathbb{Z})$, and $\mathfrak{F}_P^{\boldsymbol{\xi}}$ is the $\mathbb{K}_P(\boldsymbol{\xi})$-span of the *twisted translations* $\boldsymbol{\xi}^{-Z(\delta)}\,\mathrm{Sh}_{(\mathbf{0},\delta)}\,t-t$, $t\in\mathfrak{J}_P^{\boldsymbol{\xi}}$. The *twisted direct image* of the block is $\mathfrak{H}_P=\mathfrak{J}_P^{\boldsymbol{\xi}}/\mathfrak{F}_P^{\boldsymbol{\xi}}$, with the classes $e_\lambda=\big[\boldsymbol{\xi}^{-Z(\tau)}\,\mathrm{Sh}_{(\lambda,\tau)}[1]^\otimes\big]$, $\lambda\in\mathbb{D}'_P(\mathbb{Z})$, the shifts $\mathrm{Sh}_\mu[t]=\big[\boldsymbol{\xi}^{-Z(\sigma)}\,\mathrm{Sh}_{(\mu,\sigma)}\,t\big]$, the connections

$$\nabla_{LD}[t]=\big[\partial_{\xi_{LD}}t-\xi_{LD}^{-1}Z_{LD}\,t\big],$$

$\partial_{\xi_{LD}}$ acting on the coefficients and Z_{LD} being the function on $\mathbb{S}_P$, and the *scale integral* $\int\big[\sum_j r_j\,\boldsymbol{\xi}^{-Z(\tau_j)}\,\mathrm{Sh}_{(\lambda_j,\tau_j)}[1]^\otimes\big]=\sum_j r_j\,\langle f_{\lambda_j}\rangle$, $r_j\in\mathbb{K}_P(\boldsymbol{\xi})$, the values of the transform at the shifted data. The submodule that the connections generate from $e_{\mathbf{0}}=[[1]^\otimes]$ is $\mathfrak{H}_P^\partial$.

Theorem 48.20 (The module of a transform from its block)**.** *In Definition 48.19:*

(i) The relations ride on the shares. *Write $c_\tau r_\tau$ over H_L,*

$$c_\tau r_\tau=\frac{c_\tau}{H_L}\prod_l V^{(l)}_{LD_l(\tau)}\prod_{l'}h_{l'L}\prod_z\alpha_z^{q_{z,\tau}-u_{z,L}},$$

over the children l present in τ and the children l' of P absent from it, and expand the numerator over the monomials of its letters. Every term, a stride f_λ times its coefficient, lifts to $(\lambda,\mathbf{e}_\tau)\in\mathbb{S}_P(\mathbb{Z})$, $\mathbf{e}_\tau$ the unit vector of the share of τ, and in $\mathfrak{J}_P\otimes_{\mathbb{K}_{\mathbb{S}_P}}\mathbb{K}_{\mathbb{S}_P}(\boldsymbol{\xi})$

$$\sum_{\text{terms of } c_\tau r_\tau}(\textit{coefficient})\;\boldsymbol{\xi}^{-Z(\mathbf{e}_\tau)}\,\mathrm{Sh}_{(\lambda,\mathbf{e}_\tau)}[1]^\otimes=\xi_{LD}^{-1}\,z_{LD\tau}\,[1]^\otimes:$$

a monomial of a reading, with its coefficient, is the share of the monomial over its scale. The strides $\alpha^{\mathbf{t}}/H_L$ of the monomials $c_{\mathbf{t}}\alpha^{\mathbf{t}}$ of H_L lift with the share vector $\mathbf{0}$, and

$\sum_{\mathbf{t}} c_{\mathbf{t}} \operatorname{Sh}_{((\mathbf{t};\mathbf{e}_L),\mathbf{0})}[1]^{\otimes} = [1]^{\otimes}$*: the letter identity of* H_L *is the letter identities of the absent letters of the children. Write the terms of* ω_e *over powers of the* H_L*, and lift those that carry a scale* ξ_{LD} *with the share vector* $\mathbf{e}_\tau$ *of their monomial* τ *and the others with* $\mathbf{0}$*. Then the mark relation* $(\partial_{y_e} + \omega_e)1$ *of the transform lifts to* $\big(m'_z - \sum z_{LD\tau}(q_{z,\tau} - u_{z,L})\big)[1]^{\otimes}$ *at an own mark* z*, which is* 0 *by the pin of* z*, and at a mark* e *of a child* S_l *to the class* $\big[c_e^{(l)}(\iota_l)\cdot 1\big] \otimes \bigotimes_{l'\neq l}[1]$ *of the defect of* e *in the seam word of* S_l *at its masses and loads (Definition 48.1(iv)), which is* 0*, the mark relation of the child. The same holds from every point* (λ, τ_λ) *of* $\mathbb{S}_P(\mathbb{Z})$*, with* $\operatorname{Sh}_{(\lambda,\tau_\lambda)}$ *applied to both sides.*

(ii) The span of the shifts of [1] is the twisted direct image. $\mathbb{D}'_P(\mathbb{Z})$ *contains the data of every term of every* $c_\tau r_\tau$*, so the span* $\mathfrak{M}'_P$ *of the shifts of* [1] *by it contains* [1] *and is carried into itself by the connections; it contains every derivative of* [1] *in the scales. The shifts, the classes* e_λ*, the connections and the scale integral are well defined on* $\mathfrak{H}_P$*; the connections commute with one another and with the shifts,* $\int \nabla_{LD} h = \partial_{\xi_{LD}} \int h$ *and* $\int \operatorname{Sh}_\lambda h = \sigma_\lambda \int h$*, and the classes* e_λ *span* $\mathfrak{H}_P$*. The map*

$$O_P\Big(\sum_\lambda r_\lambda \operatorname{Sh}_\lambda[1]\Big) = \sum_\lambda r_\lambda\, e_\lambda, \qquad \lambda \in \mathbb{D}'_P(\mathbb{Z}),$$

is a well-defined map of $\mathfrak{M}'_P$ *onto* $\mathfrak{H}_P$ *that commutes with the shifts and the connections, with* $\int O_P(m) = \langle m\rangle$*. So* $\mathfrak{H}_P$ *is a differential module over* $\mathbb{K}_P(\boldsymbol{\xi})$*, as in Definition 48.9(i) with this field in the place of* $\mathbb{C}(\mathbf{y})$*, with the shifts of* $\mathbb{D}'_P(\mathbb{Z})$*, of dimension at most* $\dim \mathfrak{M}_P$*, finite; the kernel of* O_P *consists of elements of value zero, and the values separate* $\mathfrak{M}_P$*, as they separate the module of a family (Proposition 47.15): an element of value zero is* 0*. So* O_P *is an isomorphism of* $\mathfrak{M}'_P$ *onto* $\mathfrak{H}_P$*.*

(iii) The connections are shifts. *On the classes,* $\nabla_{LD} e_\lambda = -\operatorname{Sh}_\lambda O_P\big(\widehat{\beta}_{P,LD}\big)$*, and* $O_P(\widehat{\beta}_{P,LD})$ *is the combination, with the coefficients of (i), of the classes of the terms of the* $c_\tau r_\tau$*; so the matrices of the connections on classes* e_λ *are combinations of shift matrices. Theorem 48.18(iv) holds for* $\mathfrak{H}_P$ *with* $\mathbb{K}_P(\boldsymbol{\xi})$ *in the place of* $\mathbb{K}_W$*, the twisted translations in the place of the fibre translations and* $\mathbb{D}'_P(\mathbb{Z})$ *in the place of* $\mathbb{D}_W(\mathbb{Z})$*, the letter identities and the mark relations being those of (i), and with the subspace* $\mathfrak{N}$ *also carried into itself by the connections so read: an accepted set of shifts, whose certificates are identities among the products of the masters of the modules of the children over the rational functions of the data, the shares and the scales, presents a quotient of* $\mathfrak{M}'_P$ *by a submodule of elements of value zero,* $\mathfrak{M}'_P$ *itself by (ii), that maps onto* $\mathfrak{H}_P$*, with its shift matrices and its connection matrices, and a search for it stops.*

(iv) At the data that the transform reads. *Read over* $\mathbb{E}_P$ *and the share space* $\mathbb{S}_P \cap (\mathbb{E}_P \times \mathbb{C}^{I_P})$ *over it, with the rational functions of that share space and those of* $\mathbb{E}_P$ *and the scales in the place of* $\mathbb{K}_{\mathbb{S}_P}$ *and* $\mathbb{K}_P(\boldsymbol{\xi})$*, the definitions give the integrand module, its spans, the twisted translations and the twisted direct image* $\mathfrak{H}_P$ *with its classes* e_λ*,* $\lambda \in \mathbb{D}'_P(\mathbb{Z})$*, its connections and its scale integral, every* $\boldsymbol{\xi}^{-Z(\tau)} \operatorname{Sh}_{(\lambda,\tau)}[1]^{\otimes}$*,* $(\lambda,\tau) \in \mathbb{S}_P(\mathbb{Z})$*, being defined there though a shift by a point not in* $\mathbb{E}_P$ *is not; and (i) and (ii) hold for them, with the module* $\mathfrak{M}_P$ *of the transform over the rational functions of* $\mathbb{E}_P$ *and the scales, but for the shifts by the points of* $\mathbb{D}'_P(\mathbb{Z})$ *not in* $\mathbb{E}_P$ *and, when* $\mathbb{E}_P$ *is the hyperplane of the balance of* F*, for the separation of* $\mathfrak{M}_P$ *by the values: there* O_P *maps* $\mathfrak{M}'_P$ *onto* $\mathfrak{H}_P$ *with a kernel of elements of value zero, and (vii) tells the elements of value zero among the combinations of the derivatives of the input of* S*. The scale integral of* $\mathfrak{H}_P^\partial$ *is the span of the derivatives of* $\mathcal{T}_P$ *in its scales over the rational functions of* $\mathbb{E}_P$ *and the scales, and at the data of* F *off a proper algebraic subset of them,*

on a section of the scale quotient by a monomial map, $\mathfrak{H}_P^{\partial}$ maps onto the differential module that $\mathcal{T}_P$ generates (Definition 48.9(i)). On the classes $\nabla_{LD} e_\lambda = -\sum(\text{coefficient})\, e_{\lambda+\mu}$, over the terms of $\widehat{\beta}_{P,LD}$ and their data μ. Let $\Lambda \ni \mathbf{0}$ be a finite subset of $\mathbb{D}'_P(\mathbb{Z})$ with lifts, and let certificates, identities as in (iii) whose unknown coefficients are rational functions of $\mathbb{E}_P$ and of the scales, each found by one elimination over these once the denominators in the fibre coordinates are cleared, write every $e_{\lambda+\mu}$, $\lambda \in \Lambda$, on the $e_{\lambda'}$, $\lambda' \in \Lambda$. They give connections on the vectors over the rational functions of $\mathbb{E}_P$ and the scales with the basis $(\varepsilon_\lambda)_{\lambda\in\Lambda}$; modulo the smallest subspace that these carry into itself and that contains their commutators on the basis, they present a differential module whose submodule generated by $\varepsilon_{\mathbf{0}}$ maps onto $\mathfrak{H}_P^{\partial}$, $\varepsilon_\lambda \mapsto e_\lambda$, with a kernel of elements of value zero, which is 0 when $\mathbb{E}_P = \mathbb{D}_P$ by (ii). Such sets exist, and a search through the finite sets of points with lifts and of supports of certificates, in any order that reaches each, stops. When $\mathbb{E}_P = \mathbb{D}_P$ these are the objects of (ii) and (iii).

(v) A block without children is a Gramma. *If P has no children, $\mathcal{T}_P = \mathsf{G}_{\mathbf{m}'_P;t}\big((\xi_{LD} c_\tau)_\tau\big)$, the configuration t being the exponents $q_{z,\tau} - u_{z,L}$ of its readings (Definition 48.13(iii)), the Gramma on a section, on one mark fewer, when S is not seen by its scales (Lemma 48.8(iii)), $\mathfrak{J}_P = \mathbb{K}_{\mathbb{S}_P}$, and the share reading is the share side of the Gramma (Proposition 4.2). Then $e_{t_\tau} = \big[(\xi_{LD} c_\tau)^{-1} z_{LD\tau}\big]$, and Theorem 2.4 is read on the shares: the exchange relation at an own mark is its pin, the ladder, summed over the monomials of one scale, is the connection, and a toric relation $\partial^{\mathbf{v}^+}\mathsf{G} = \pm\partial^{\mathbf{v}^-}\mathsf{G}$ says that the class of the shift of the index by $t\mathbf{v}^+ = t\mathbf{v}^-$ does not depend on the lift, $\mathbf{v}^+$ or $\mathbf{v}^-$, that writes it.*

(vi) Once for each class. *A bijection of the marks of two blocks keeping their seam letters, the absent stations, the absent exponents and the readings, with the subtrees of their children carried to one another, carries the one $\mathfrak{H}_P$ to the other; so the modules of the transforms are found once for each class of blocks, from the modules of the classes of the children, each found once (Theorem 48.18(iii)). With Proposition 48.10(ii) the input of every node of Σ in Theorem 48.15 whose blocks with children have full children generates a subquotient of a construction from the $\mathfrak{H}_P^{\partial}$ of its distinct blocks, read as in (iv), and the module of rank one of the exponential of its constant parts; and, at the data of F off a proper algebraic subset, every module N_r of Theorem 48.15(ii) of such nodes is the image under the values of a module presented by connection matrices over the rational functions of the data of F and the scales of the sections, found from the modules of the children of the blocks without integrating, its group being the image of the group of that module.*

(vii) Elements of value zero. *Let $S \in \Sigma$ have the input ϕ, read as a function of its scales and of its data: the masses of the marks of S and the exponents s_L, free of the balance of F except at a root not seen by its scales, whose transform is taken on the quotient by the scaling. Let $W_S^\sharp$ be the family of positive letters on the marks of S formed by its seam letters V_{LD}^S, $(L,D) \in \Sigma_S$, read at the seam points of its children, at the exponents a_{LD}, and by the products $H_L^S = \prod_l h_{lL}$ of the absent letters of its children, one for each active letter L (none when S has no children), at the exponents w_L, with the masses of its children's marks and $m_z^\sharp = m_z - \sum_L u_{z,L} w_L$ at its own marks. Every letter of $W_S^\sharp$ is a letter of a table on the marks of S: V_{LD}^S of the room child of the station D, and H_L^S of the direct sum of the room children of the absent stations of the children, the own marks being loops in it for a letter K_j and coloops for a letter Ψ_j. On the balance of $W_S^\sharp$,*

$$\int_{\Xi_S} \boldsymbol{\xi}^{\mathbf{a}}\, \phi\, \frac{d\boldsymbol{\xi}}{\boldsymbol{\xi}} = \prod_{\Sigma_S} \Gamma(a_{LD})\; P_{W_S^\sharp}(\mathbf{a}, \mathbf{w}), \qquad w_L = s_L - \sum_{D\colon (L,D)\in\Sigma_S} a_{LD},$$

which on the pins of the seam of S is Theorem 48.14(i), $W_S^\sharp$ being there its seam word with the powers of its constant parts. Read S on a section whose coordinates $\mathbf{y}$ are a basis of the monomials in its scales that the scaling keeps, $\vartheta_i = y_i\partial_{y_i}$. An element $E = \sum_{\mathbf{k},\mathbf{b}} c_{\mathbf{kb}}\, \mathbf{y}^{\mathbf{k}}\vartheta^{\mathbf{b}}\phi$, its coefficients rational in the data of ϕ and its denominators in $\mathbf{y}$ cleared, then vanishes identically exactly when the element

$$E^\sharp = \sum_{\mathbf{k},\mathbf{b}} c_{\mathbf{kb}}\, (-\boldsymbol{\nu}(\mathbf{a}) - \mathbf{k})^{\mathbf{b}}\, R_{\mathbf{k}}\, \mathrm{Sh}_{\lambda_{\mathbf{k}}}[1]$$

of the module of $W_S^\sharp$ has the value zero, the $c_{\mathbf{kb}}$ read on its data through $s_L = w_L + \sum_D a_{LD}$ and $m_z = m_z^\sharp + \sum_L u_{z,L} w_L$; $W_S^\sharp$ being a family of letters of tables, finitely many of its closings tell whether it has (Theorem 48.23), and it has exactly when it is 0 in the module of $W_S^\sharp$ (Proposition 47.15). Here $\mathbf{y}^{\mathbf{k}} = \boldsymbol{\xi}^{\mu_{\mathbf{k}}}$ on the section; $\lambda_{\mathbf{k}}$ moves $\mathbf{a}$ by $\mu_{\mathbf{k}}$, $\mathbf{w}$ by minus its totals $T_L(\mu_{\mathbf{k}}) = \sum_D \mu_{\mathbf{k},LD}$ and every own mass $m_z^\sharp$ by $\sum_L u_{z,L} T_L(\mu_{\mathbf{k}})$, a point of the lattice of $W_S^\sharp$; $\boldsymbol{\nu}(\mathbf{a})$, linear in $\mathbf{a}$, is the index of the section, $\boldsymbol{\xi}^{\mathbf{a}}\, d\boldsymbol{\xi}/\boldsymbol{\xi}$ being a nonzero constant, fixed on the balance, times $\mathbf{y}^{\boldsymbol{\nu}(\mathbf{a})}\, d\mathbf{y}/\mathbf{y}$ there; and $R_{\mathbf{k}}$ is the quotient of the Gammas at the moved exponents over those at $\mathbf{a}$. At every node but a root seen by its scales with children the data of F and $\mathbf{a}$ reach all the data of $W_S^\sharp$, so that this tells the elements of value zero over the data of F. At such a root the data of ϕ and $\mathbf{a}$ reach all of them, which tells the elements of value zero over the data of ϕ, and the data of F and $\mathbf{a}$ reach the hyperplane $\mathbb{E}_S^\sharp$ on which $\sum_L \delta_L w_L = 0$, δ_L the degree of the reading at L (Definition 48.13(ii)) and 0 off Σ_S, the balance of F read on the data of $W_S^\sharp$: E, its coefficients read at the data of F, vanishes there exactly when $E^\sharp$, its coefficients read on $\mathbb{E}_S^\sharp$, has the value zero on $\mathbb{E}_S^\sharp$, that is, exactly when $E^\sharp$ is 0 in the module of $W_S^\sharp$ on $\mathbb{E}_S^\sharp$, a hyperplane cut out by a condition on the exponents alone that meets the tube (Proposition 47.15); Proposition 47.14 decides this by finitely many coefficients of the expansion at the native gauge of a native direction of $\mathbb{E}_S^\sharp$ in which every H_L^S with $\delta_L \neq 0$ has the exponent 0, a native gauge whose coordinates are algebraic over the field of the weights and which can be taken rational when the weights are rational.

So the scale side of a node is read off its children as its share side is. A block reads its children through their seam functions at loads that are linear in its shares (Theorem 48.14(ii)); a scale of the block enters the integrand raised to minus the total of its shares, and a derivative in a scale multiplies the integrand by minus that total over the scale; so the module of the transform is the span of the twisted shifts of $[1]^\otimes$ in the integrand module of the block, a tensor product of the modules of its children with Pochhammer quotients of its Gammas, modulo the translations along its fibre, each twisted by a monomial in the scales, and its values separate it over all the data of the block. The certificate that presents it is an identity among the products of the masters of the children, and its connections are combinations of its shifts. The elements of value zero of the input of a node, among the combinations of its derivatives with coefficients rational in its data, are read on the shares: integrated against the powers of its scales, the input is, up to Gammas, the period of the family formed by the seam letters of its node and the products of the absent letters of its children, its seam word on the pins of the seam (Theorem 48.14(i)), so the closings of that family tell them (vii). The module of a transform is found over the rational functions of the data that it reads, those of $\mathbb{E}_P$, the data of F read on the block (part (iv)). The modules that the group of a word asks for (Theorem 48.15(ii)) are therefore found in the same way as the module of the family (Theorem 48.18): one box for each class of node words and leaves, one module for each class of subtrees, and one module for each class of blocks, each from the ones below it. At width one a series or parallel node reads its cells through their transforms $f_{\mathcal{A}}$ and dual transforms $\check{f}_{\mathcal{A}}$

(Theorem 48.14(iii)), whose modules are, up to elements of value zero, the twisted direct images of the blocks of the cells, read through the modules of the families of the two hinge minors of the cells, and its marks through Grammas without children, which on the centre ray are g, with $\vartheta^2\mathsf{g} = y\,\mathsf{g}$ (Theorem 45.28(ii)). A block whose children are not all full is read as its exponential period (Theorem 48.15), whose module is defined as in Definition 48.19(ii); the choice of Σ can always avoid such blocks, a node with a child that is not full being read on its shares.

48.9 The procedure in all the data

Every piece of the reading of a family is now stated over the rational functions of its data: the module, its boxes, its masters and its closings (Chapter 47), the module along the tree from the modules of the node words (Section 48.7), the modules of the transforms of the blocks (Section 48.8), and the word along the tree with its inputs, group, work and price (Theorem 48.15). What is left is the question that a form asks. Its letters are those with an exponent that is not zero, they may form several molecules, and the data may be off the balance wall. The handbook answers each case with the period of a family of letters of tables on its data space. Off the balance wall the pseudointegral of the form is the period at the target, or on a pole hyperplane the constant term of the period along the ray of the masses, along the rays of the masses of the active molecules when they are several. The interest is a product of Gamma functions times the period of the letters with the sum of the marks of each molecule added. On the balance wall several molecules carry nothing but their reduced period, at the masses at which every molecule is balanced, and when the weights do not factor across the molecules the reduced period is read through its molecules on a factorization of the weights, one share for each term. The values separate the module of every family of positive letters (Proposition 47.15), so every module presented from a box or on the shares is the module itself, as is the module that an accepted set of shifts presents for a transform that reads all the data of its block (Theorem 48.20(iii)), and an element of such a module has the value zero only when it is 0; the closings tell which elements are 0 for every family of letters of tables, by the proof of Theorem 39.57, and a box gives masters once its matrices are invertible. The procedure below puts the pieces in order, and its theorem says that it stops on every family and returns its reading in finite matrices over rational functions of the data, and in words at real data.

Proposition 48.21 (The question at every data)**.** *Let $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^{N}$ be a family on $\mathcal{E}$, $n \geq 2$. Its* letters *are the K_j and the Ψ_j whose exponents are not zero, its* active tables *those with a letter, and its* active molecules *$M_1, \dots, M_q$ the molecules of the family of its active tables (Definition 7.4).*

(i) The letters. *The form $W\, d\alpha_{\mathbf{m}} = \alpha^{\mathbf{m-1}} \prod_j K_j^{-s_j} \Psi_j^{-t_j}\, d\alpha$ is that of the family W of positive letters formed by its letters (Definition 48.1). Its space of directions is the space of the vectors of zero sum on every active molecule, so that V_W is $\mathbb{R}^{\mathcal{E}}$ modulo the indicators of the active molecules, and its data space $\mathbb{D}_W$ is the set of the data at which every active molecule is balanced (Theorem 48.23(i)). For $q = 1$ it is the balance hyperplane in the masses and the exponents of the letters, and W is the family W_F of Definition 48.17.*

(ii) The interest. *Let W^+ be the family of positive letters formed by the letters of F and the sums $|\alpha_{M_i}| = \sum_{e \in M_i} \alpha_e$ at the exponents κ_{M_i}, $|\alpha_{M_i}|$ being the letter K of the table of rank one on $\mathcal{E}$ whose bases are the marks of M_i. It is a family of letters of tables with the active molecules of F, and its data space is the image of all the data of F, every M_i being balanced in W^+. At data with $\operatorname{Re} \kappa_{M_i} > 0$ for every i and every wall κ_U, U a nonempty proper subset*

of an active molecule, of positive real part,

$$J_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \prod_{i=1}^{q} \Gamma(\kappa_{M_i})\ P_{W^+}(\mathbf{m};\mathbf{s},\mathbf{t}),$$

$$P_{W^+}(\mathbf{m};\mathbf{s},\mathbf{t}) = \int_{\prod_i \Delta_{M_i}} u^{\mathbf{m}-\mathbf{1}} \prod_j K_j(u)^{-s_j} \Psi_j(u)^{-t_j} \prod_i d\omega_{M_i}(u_i),$$

and elsewhere as meromorphic functions. For $q = 1$ this is $J_F = \Gamma(\kappa_{\mathcal{E}})P_F$, P_F being the period of W^+ at every data (Theorem 8.7).

(iii) Off the balance wall. *Let $q = 1$ and $\kappa_{\mathcal{E}} \neq 0$. The form is not projective (Definition 16.4). At real data with $\mathbf{m} > 0$ and $s_j, t_j \geq 0$, not all zero, its pseudointegral is $\mathrm{CT}_{\eta=0}\, P_F(\boldsymbol{\tau} + \eta\mathbf{m};\mathbf{s},\mathbf{t})$ at the target $\boldsymbol{\tau} = \lambda\mathbf{m}$, $\lambda = \sum_j (s_j r_j + t_j r_j^*)/m_{\mathcal{E}}$, the masses slid along their ray into the balance wall (Definition 16.10, Theorem 16.8(ii)). It is the period at the target, $P_F(\boldsymbol{\tau};\mathbf{s},\mathbf{t})$, when the target lies on no pole hyperplane (Theorem 16.15, Corollary 16.16), and on a pole hyperplane the constant term at $\eta = 0$ of the period of W^+ along the line $\boldsymbol{\tau} + \mathbb{C}\mathbf{m}$ of its data space. With $q \geq 2$, whatever the weights, let $r_{j,i}$ be the number of the marks of M_i in a basis of an active table j, the same for every basis (Lemma 7.10), $r^*_{j,i} = |M_i| - r_{j,i}$, and slide the masses of every active molecule along its own ray: $\boldsymbol{\tau}_{M_i} = \lambda_i \mathbf{m}_{M_i}$, $\lambda_i = \sum_j (s_j r_{j,i} + t_j r^*_{j,i})/m_{M_i}$. Then $\boldsymbol{\tau}$ balances every active molecule, the period of W^+ along $\boldsymbol{\tau} + \sum_i \eta_i \mathbf{m}_{M_i}$ has its poles on hyperplanes on which one η_i is constant, and its constant term at $\boldsymbol{\eta} = 0$, the* pseudointegral *of the form for several active molecules, which Definition 16.10 gives only when the weights factor, is the reduced period $P_{V_F}(\boldsymbol{\tau};\mathbf{s},\mathbf{t})$ of (iv) off the pole hyperplanes; with factoring weights it is the product of the pseudointegrals of the molecules, each at its own target (Definition 16.10).*

(iv) Several active molecules. *Let $q \geq 2$, whatever the weights. On the balance wall one of κ_S, $\kappa_{\mathcal{E}\setminus S}$, S a union of active molecules, has real part at most 0, and the integral of the form diverges (Proposition 8.16); P_F vanishes there as a meromorphic function (Theorem 16.17). Proposition 16.12 holds with the product $\prod_i P_{F_i}(\mathbf{m}_i^0;\mathbf{s},\mathbf{t})$ replaced by the* reduced period

$$P_{V_F}(\mathbf{m}^0;\mathbf{s},\mathbf{t}) = \int_{\prod_i \Delta_{M_i}} u^{\mathbf{m}^0-\mathbf{1}} \prod_j K_j(u)^{-s_j} \Psi_j(u)^{-t_j} \prod_i d\omega_{M_i}(u_i)$$

at masses $\mathbf{m}^0$ at which every active molecule is balanced and every wall κ_U, U a nonempty proper subset of an active molecule, is positive: on the balance wall the form carries nothing but its reduced period, the working interest*. It is the period of W on $\mathbb{D}_W$, and when the weights factor across the active molecules it is $\prod_i P_{F_i}$ (Proposition 7.9).*

(v) One active molecule. *On the balance wall the period converges exactly on its tube, the data at which every proper wall has positive real part, which is not empty, and elsewhere it is its continuation, meromorphic, with its poles on the hyperplanes $\kappa_U \in \{0, -1, -2, \dots\}$ (Theorems 8.7, 47.2 and 48.3(ii)).*

So every question that the form asks is the period of W or of W^+, a family of letters of tables, on its data space: at a point, along a line or along the affine subspace of the rays of the masses of the active molecules, or times Gamma functions of linear forms in the data.

Definition 48.22 (A factorization of the weights; the molecule families)**.** Let the active molecules of F be $M_1, \dots, M_q$, $q \geq 2$. Every active table is the direct sum of its restrictions $\mathcal{B}_j|M_i$, its bases

the unions $T = T_1 \sqcup \cdots \sqcup T_q$ of bases T_i of the restrictions (Proposition 7.9). A *factorization* of the weights is, for every active table, a finite set R_j and weights $\theta_{j,r}^{(i)} > 0$ on all the bases of $\mathcal{B}_j|M_i$, $r \in R_j$, $i \le q$, with

$$\theta_{j,T} = \sum_{r \in R_j} \prod_{i=1}^{q} \theta_{j,r}^{(i)}(T \cap M_i)$$

for every basis T of table j. The *molecule family* $F^{(i)}$ is the family on M_i of the tables $(\mathcal{B}_j|M_i, \theta_{j,r}^{(i)})$, $r \in R_j$, j active, with the letters $K_{j,r}^{(i)}$ when K_j is a letter of F and $\Psi_{j,r}^{(i)}$ when Ψ_j is, so that

$$K_j = \sum_{r \in R_j} \prod_{i=1}^{q} K_{j,r}^{(i)}, \qquad \Psi_j = \sum_{r \in R_j} \prod_{i=1}^{q} \Psi_{j,r}^{(i)}.$$

The weights *factor* across the active molecules exactly when they have a factorization with one element in every R_j.

The marks of a molecule family form one molecule. An active molecule of one mark, a loop or a coloop in every active table, has a molecule family of monomial letters, a point as its space V, the period $\prod c^{-z}$ of the coefficients of its letters, and a module of dimension one, as a full node of one mark does (Theorem 48.18(v)).

Theorem 48.23 (The closings for every family of letters of tables)**.** *Let W be a family of positive letters each of which is a letter K_j or Ψ_j of a table $(\mathcal{B}_j, \theta_j)$ on $\mathcal{E}$, with any weights, its active tables those with a letter in W and its active molecules the molecules of the family of its active tables.*

(i) Directions and fan. *The differences of two exponents of one letter generate the lattice M_W; so $\vec{\mathcal{N}}_W^{\perp}$ is spanned by the indicators of the active molecules, V_W is $\mathbb{R}^{\mathcal{E}}$ modulo them, and the subtorus of Definition 48.1(iii) is the set on which α is constant on every active molecule. The products of the sectors of the orders of the active molecules form a fan of W, with the generators $\mathbf{1}_U$ and the walls κ_U, U a nonempty proper subset of an active molecule.*

(ii) Value zero. *A line of $\mathbb{D}_W$ with an integral origin and a positive direction carries a ray and the module of that ray, the restrictions of Definition 47.3 and Proposition 47.5 read with Theorem 48.3(iii) in the place of Theorem 47.4, and its closings are those of Definition 47.9, the constant terms on the torus of X_W. Along such a line Propositions 39.34 and 39.35(ii) and Theorems 39.57 and 44.16 hold, with $n-1$ replaced by r_W, the number of the marks less that of the active molecules, the orders of $\mathcal{E}$ by the tuples of orders of the active molecules, and V_1 by the product over the active molecules of their sums $\sum_\pi \prod_l \kappa_{1,U_l}^{-1}$. So Proposition 47.10, Theorem 47.11 and Proposition 47.12 hold for the module of W (Theorem 48.3(iii)) and its quotients by submodules of elements of value zero, the module itself (Proposition 47.15), with the positive directions of Theorem 48.3(i) and the generators of Theorem 48.3(iv). When every active molecule has one mark, V_W is a point and the module has dimension one.*

So whether two elements of the module of a family of letters of tables have the same value as functions of all its data is decided by finitely many closings, whatever its letters and its weights.

The two places at which the proof of Theorem 39.57 used one molecule, the definiteness of the Hessian at the native gauge and the single point of the torus at which every letter has its largest modulus, hold for every family of letters of tables once its space V_W is taken modulo its active molecules. For a family of positive letters whose exponent differences generate a sublattice of M_W of index h, the torus has h such points; for the letters of tables $h = 1$.

Theorem 48.24 (Several active molecules through their molecule families)**.** *Let the active molecules of F be $M_1, \dots, M_q$, $q \geq 2$.*

(i) Factorizations exist. *For an active table j and $\delta > 0$ let $c_j^{(\delta)}$ be the coordinates of θ_j on the products $\bigotimes_i (\mathbf{e}_{T_i} + \delta \mathbf{1})$ of vectors on the bases of the restrictions,*

$$c_j^{(\delta)} = \bigotimes_{i=1}^{q} \left(\mathbf{I}_{j,i} - \frac{\delta}{1 + \delta b_{j,i}} \mathbf{J}_{j,i} \right) \theta_j,$$

$b_{j,i}$ the number of the bases of $\mathcal{B}_j | M_i$, $\mathbf{I}_{j,i}$ the identity and $\mathbf{J}_{j,i}$ the square matrix of ones on them. As $\delta \to 0$ its entries tend to those of θ_j, so for small δ they are positive; then R_j the bases T' of table j, $\theta^{(1)}_{j,T'} = c^{(\delta)}_{j,T'}(\mathbf{e}_{T'_1} + \delta \mathbf{1})$ and $\theta^{(i)}_{j,T'} = \mathbf{e}_{T'_i} + \delta \mathbf{1}$, $i \geq 2$, are a factorization.

(ii) The reading. *For every factorization, at data $(\mathbf{m}; \mathbf{s}, \mathbf{t})$ in the tube of the reduced period with the letters' exponents of positive real parts, and real shares $c_{j,r}, c^*_{j,r} > 0$ with $\sum_r c_{j,r} = \operatorname{Re} s_j$ and $\sum_r c^*_{j,r} = \operatorname{Re} t_j$,*

$$P_{V_F}(\mathbf{m}; \mathbf{s}, \mathbf{t}) = \int_{pins} \prod_j \Gamma_{|R_j|} \begin{bmatrix} \mathbf{z}_j \\ s_j \end{bmatrix} \Gamma_{|R_j|} \begin{bmatrix} \mathbf{z}^*_j \\ t_j \end{bmatrix} \prod_{i=1}^{q} P_{F^{(i)}}(\mathbf{m}_{M_i}; \mathbf{z}, \mathbf{z}^*),$$

the fibre pinned by $\sum_r z_{j,r} = s_j$ and $\sum_r z^*_{j,r} = t_j$ and taken through $(\mathbf{c}, \mathbf{c}^*)$, converging absolutely, the factors of a letter that is not a letter of F and of a table with $|R_j| = 1$ being 1; $P_{F^{(i)}}(\mathbf{m}_{M_i}; \mathbf{z}, \mathbf{z}^*)$ is the period of the molecule family at the exponents $z_{j,r}$ of $K^{(i)}_{j,r}$ and $z^*_{j,r}$ of $\Psi^{(i)}_{j,r}$. Its data lie on its balance wall, and its walls are the walls κ_U of F, $U \subseteq M_i$, whatever the shares. So this is a positive share reading of the reduced period (Definition 48.4) with the molecule families as its nodes, its lattice maps onto $\mathbb{D}_W(\mathbb{Z})$, and Theorem 48.5 holds for it: every value of every element of the module of the reduced period is a fibre integral of a multilinear form in the values of the masters of the molecule families, each read in all its data, and isomorphic molecule families have one module. With factoring weights there are no shares and $P_{V_F} = \prod_i P_{F^{(i)}}$.

The same holds for the period of W^+, whose molecule families carry the letters $|\alpha_{M_i}|$ at the exponents κ_{M_i}.

So several active molecules are read as one node above their molecule families, whose letters are the terms of the factorization: a molecule family is a family on one molecule, read by the procedure below, and the shares of the terms are the only fibre that the factorization adds. The fewer the terms, the smaller the fibre; with factoring weights there is none.

Definition 48.25 (The procedure in all the data)**.** *Given*: a family $F = ((\mathcal{B}_j, \theta_j); s_j, t_j)_{j=1}^N$ on $\mathcal{E}$, $n \geq 2$, its weights in a field $\Bbbk \subseteq \mathbb{C}$, at least one exponent not fixed at 0, and the form $\alpha^{\mathbf{m-1}} \prod_j K_j^{-s_j} \Psi_j^{-t_j} \, d\alpha$, with its masses and exponents as coordinates and the exponents fixed at 0 named. *The question*, from the tables alone (Proposition 48.21):

(1) *Letters*: the letters, the active tables and the active molecules, and the families W and W^+ of letters of tables, with their data spaces.

(2) *The interest*: $\prod_i \Gamma(\kappa_{M_i})$ times the period of W^+.

(3) *On the balance wall*: the period of W when the active molecules are one; when they are several, return the certificate of Proposition 48.21(iv), and the working interest is the period of W on $\mathbb{D}_W$.

(4) *Off the balance wall*, one active molecule: return the target; the pseudointegral is the period of W there off the pole hyperplanes, and on them the constant term at $\eta = 0$ of the period of W^+ along $\boldsymbol{\tau} + \eta\mathbf{m}$; for several active molecules, the targets of the molecules, and the pseudointegral is the period of W at them off the pole hyperplanes and on them the constant term at $\boldsymbol{\eta} = 0$ of the period of W^+ along $\boldsymbol{\tau} + \sum_i \eta_i \mathbf{m}_{M_i}$, the product over the molecules when the weights factor (Proposition 48.21(iii)).

Each period so named, of a family V of letters of tables on its data space, is read as follows.

(5) *Several active molecules*: masters of the module of V from its box (Proposition 47.13, Theorem 48.3(iv)), an element having the value zero exactly when it is 0 (Proposition 47.15), as its closings also tell (Theorem 48.23), and its reading through the molecule families (Theorem 48.24(ii)) of the factorization with one term in every table when the weights factor and otherwise of Theorem 48.24(i) at the largest $\delta = 1/k$, $k \in \mathbb{N}$, at which it is one; a molecule family of one mark is read directly, and every other by (6)–(14).

Classification of one active molecule, from the tables alone:

(6) the Foreman tree and the label (Definition 16.14, steps (1)–(5)), read as a tree of nested bunches, the childcules of a peel being the pieces of the core (Definition 29.9), in the normalization of Definition 28.1: the seam letters, the transfer tensors, the node words, the seam words of the leaves and the full nodes (Definition 48.11);

(7) at every full node seen by its scales, absent stations and exponents and the finest partition that it separates, with the blocks, their readings and the constant parts (Definition 48.13);

(8) the classes of the node words, the leaves, the subtrees and the blocks under the bijections of their marks that keep their seam letters (Theorems 48.5(v), 48.18(iii) and 48.20(vi)).

Reading, over the rational functions of the data:

(9) for each class of the node words and of the leaves, masters with their shift matrices at the generators and their negatives, from a box, with its certificates (Proposition 47.13, Theorem 48.3(iv)); the spanning set of an accepted box with at most as many elements as the nondegenerate native points of some rational data of the word is a set of masters, with no presentation needed (Proposition 47.16(iv));

(10) the module: from the leaves up, at every full node S, once for each class of its subtree down to the full nodes, an accepted set on the shares, presenting the module $\widehat{\mathfrak{H}}_S$ of its seam word, that of V at the root, with its shift matrices and certificates (Theorem 48.18(iii), (iv), V being the family W_F of the letters of its tables); an accepted set with at most as many shifts as the nondegenerate native points of some rational data of the seam word, or of V at the root, presents it with $\mathfrak{N} = 0$, its classes ε_λ being masters, so that the quotient asks for no elimination (Proposition 47.16(iv));

(11) a set Σ of full nodes, each with a partition of its parts that it separates, the one block when it is not seen by its scales, and the children of its blocks full, to be read on their scales, the node words of the nodes read on their shares being kept: among the finitely many, one of least work (Theorem 48.15(iii)), the dimensions of the kept classes being those of (9);

(12) for every node of Σ and every class of its blocks with children, an accepted set of shifts presenting the module of its transform with its connection matrices over the data that it reads (Theorem 48.20(iii), (iv)); a block without children is a Gramma (Theorem 48.20(v));

(13) value zero: an element of a module of (5), (9) or (10), or of (12) when the transform reads all the data of its block, has the value zero exactly when it is 0, which its reduction on

the masters shows (Proposition 47.15, Theorem 48.20(ii)), and, in a module of (5) or (10), or of a leaf in (9), exactly when finitely many of its closings vanish (Theorem 48.23), at a full node and at the root of one active molecule computed from the closings of the node words and of the leaves combined along the tree (Theorem 48.18(v)); a combination E of the derivatives of the input of a node S of Σ vanishes identically over the data of the input exactly when the element $E^\sharp$ of the module of $W_S^\sharp$ is 0, which its reduction on masters of that module from its box shows (Propositions 47.13 and 47.15), as finitely many of its closings also do (Proposition 47.12), and, at a root seen by its scales with children, over the data of V exactly when finitely many coefficients of the expansion of $E^\sharp$ at the native gauge of a native direction of the hyperplane $\mathbb{E}_S^\sharp$ vanish, rational when the weights are rational (Theorem 48.20(vii), Propositions 47.14 and 47.15);

(14) the word along the tree with the nodes of Σ read on their scales, at real data and at complex data whose real parts are such: its inputs, the modules N_r whose group bounds the group of the word, its work and its price (Theorem 48.15).

Output: the certificate, the target and the Gamma factors that the question returns; for each period read, its tree and label, masters of the module of (10), or of (5) for several active molecules, over $\Bbbk(\mathbb{D}_V)$ with their shift matrices at the generators of the lattice and their negatives and the certificates of every relation used, the reduction of every insertion, the closings, the masters of the modules of the families $W_S^\sharp$ and the coefficients of the expansions at native gauges that decide the value zero of the combinations of the derivatives of the inputs, the modules of the transforms of the blocks with their connection matrices, and the word with its inputs, the presented modules N_r, its work and its price. Every output is a word, a finite set or a finite matrix over rational functions of the data; no value is computed.

Theorem 48.26 (The procedure in all the data reads every family)**.** *Let F be a family on $\mathcal{E}$, $n \geq 2$, with its weights in $\Bbbk$ and at least one exponent not fixed at* 0*.*

(i) It stops. *Every step is a finite computation over $\Bbbk$ and over fields of rational functions over $\Bbbk$ of the data of W and W^+, of the molecule families, of the node words, of the families $W_S^\sharp$ and their hyperplanes $\mathbb{E}_S^\sharp$, and of the data, shares and scales of the blocks, the expansions of Proposition 47.14 being over the finite extension of $\Bbbk$ generated by a native gauge, which is $\Bbbk$ when the weights are rational and the gauge is taken rational; and the procedure stops.*

(ii) The question. *Its certificates, targets and Gamma factors are those of Proposition 48.21, and every question it returns is the period of W or W^+ at a point, along a line or, for several active molecules, along the affine subspace of the rays of their masses, or times those factors.*

(iii) The module. *For each period read, the module that it presents is the module of V itself, a quotient of it by elements of value zero being the module (Proposition 47.15), with $\mathfrak{m}_V = (-1)^{r_V} \operatorname{eu}(X_V)$ masters, one for each native point of generic data (Proposition 47.16), and their shift matrices at the generators and their negatives (Theorem 48.18(iv), Proposition 47.13). The matrices carry the values from a point to every lattice translate, every insertion is reduced (Theorem 47.4(v), with Theorem 48.3(iii)), and every relation used has a certificate: those of the boxes, identities of functions on the letter complements over the rational functions of the data (Theorem 47.8(ii)), those of the presentations of Proposition 47.13, and those of the accepted sets, identities among products of masters (Theorem 48.18(iv)).*

(iv) Value zero. *An element of that module has the value zero as a function of all the data exactly when it is* 0*, which its reduction on the masters shows, and exactly when finitely many closings vanish, rational numbers when the weights and the element are rational (Proposition 47.15,*

Theorem 48.23); so whether two insertions have the same value is decided, and every relation among the values is a relation of the module. A combination E of the derivatives of the input of a node S of Σ vanishes as a function of the data of the input exactly when the element $E^\sharp$ of the module of $W_S^\sharp$ is 0*, which its reduction on masters of that module from its box shows (Proposition 47.13), and exactly when finitely many closings of $E^\sharp$ vanish; at a root seen by its scales with children it vanishes as a function of the data of V exactly when $E^\sharp$ is* 0 *in the module of $W_S^\sharp$ on the hyperplane $\mathbb{E}_S^\sharp$, which finitely many coefficients of the expansion at the native gauge of a native direction decide, rational functions over the field generated by the weights, the coefficients of the element and that native gauge, and over $\mathbb{Q}$ when the weights and the element are rational and the native gauge is taken rational (Theorem 48.20(vii), Propositions 47.15 and 47.14).*

(v) The word. *For one active molecule, at real data on the balance wall with $s_j, t_j \geq 0$, not all zero, every proper wall positive and a native gauge, and at complex data whose real parts are such data, every exponent of a letter having a positive real part, the period is the word, with the inputs, the group bounded by the modules N_r, the work and the price of Theorem 48.15, the modules N_r being presented from the modules of the transforms (Theorem 48.20(vi)); at every lattice translate of such a point the value is carried by the shift matrices, and at every other data the period is its continuation (Theorems 47.2(ii) and 48.3(ii)). For several active molecules the reduced period is the fibre integral of Theorem 48.24(ii) against the periods of its molecule families, each read in all its data by its module and, along the contour of the shares, in words: there every molecule family has data whose real parts lie on its balance wall with its exponents and its proper walls positive, at which Theorem 48.15(v) reads it.*

(vi) Repetition. *Every module, closing and transform is found once for each class (Theorems 48.5(v), 48.18(iii) and 48.20(vi)).*

So the form $\alpha^{\mathbf{m}-\mathbf{1}} \prod_j K_j^{-s_j} \Psi_j^{-t_j}\, d\alpha$ is read in all its data, its period, its interest and its pseudointegral: by finite matrices over rational functions of the data everywhere and by words at the data whose real parts are real data inside the walls, with, for several active molecules, the certificate that on the balance wall it carries nothing but a working interest read so.

The procedure chooses: the absent stations and exponents, the set Σ, the factorization of weights that do not factor, the positive direction, level bounds and generators of each box, the accepted sets and their lifts, the origin and the direction of Proposition 47.12, and the native direction of Proposition 47.14 with its native gauge, rational when the weights are rational. The theorem holds for every choice. Every step is a statement of this handbook, with its certificate, and no step depends on the family beyond its tables and the names of its letters: a program that carries out the procedure carries out the handbook, step for step, on every family.

Part IX

The family as inference

Chapter 49

The family as inference

A family is a model of data in two ways. A sample of bases, drawn from the basis and cobasis laws of the tables of a family at an unknown gauge, is itself a question: its counts are the masses, the sizes of its parts are the exponents, and its chance as a function of the tilt is the integrand of the period. The law of a question is then the conjugate prior of the tilt, and every posterior, every predictive chance and every evidence is a ratio of periods; read at a bunch, a sample is a sample of the children at the shares it realizes, and each of its walls is a sum of independent excesses of the levels and colevels of its draws over their floors, whose law the Skeleton polynomials give. A sample of tilts drawn from the law of a question makes the period the cumulant function of an exponential family. Between the two sits the family word read at Dirichlet draws: the negative logarithms of its letters have the Grey law, whose Laplace transform in the exponents is the period divided by the stacked Gamma of the masses over their total; the pseudo-MGF and the pseudoexpectation are that Laplace transform fixed at the Foreman's question and at the centre. A draw of the shape law, read as a vector of numbers, has an order that is a sector of the period, best and worst bases that are functions of the order, and entropies and moments that are steps of the data. What a bunch all of whose subsets are patterns reads of its room is its interaction (Definition 12.18), the total over the scales of the bunch of the joint cumulants of the use of its marks under the basis and cobasis laws, weighted by the exponents; for a regression design the interaction of a split of the prior marks into two blocks is minus the logarithm of the generalized variance inflation factor.

49.1 Samples of bases

Proposition 49.1 (A sample of bases is a question)**.** *For a family at a gauge $\alpha = e^{2z}$ draw, for every table j, s_j bases $T_{j,1}, \dots, T_{j,s_j}$ from its basis law $\mathbb{P}_{j,\alpha}$ and t_j bases $T'_{j,1}, \dots, T'_{j,t_j}$ from its cobasis law $\mathbb{P}^*_{j,\alpha}$, all independent, let m_e count the $T_{j,i}$ that hold e and the $T'_{j,i}$ that miss e, and let $\theta_{\mathrm{draws}} = \prod_{j,i} \theta_{j,T_{j,i}} \prod_{j,i} \theta_{j,T'_{j,i}}$ be the product of the weights of the drawn bases.*

(i) As a function of the tilt z, the chance of the sample is

$$\theta_{\mathrm{draws}} \cdot \exp\Big(2\langle \boldsymbol{\mu}_\perp, z\rangle - \sum_j \big(\sigma_j E_j(z) + \delta_j O_j(z)\big)\Big),$$

$2^{1-n}\theta_{\mathrm{draws}}$ times the integrand of the period of the question $(\mathbf{m}; \mathbf{s}, \mathbf{t})$, of pair coordinates $(\boldsymbol{\mu}_\perp; \boldsymbol{\sigma}, \boldsymbol{\delta})$ (Definition 17.1): the counts are the masses, the sizes of the parts are the exponents, and $m_{\mathcal{E}} = \sum_j (s_j r_j + t_j r_j^*)$ puts the question on the balance wall.

(ii) Its logarithmic gradient in z is $2\big(\mathbf{m}-\sum_j (s_j R_j(\alpha)+t_j R_j^*(\alpha))\big)$, twice the excess of the masses over the usage at α. For a connected family the maximum likelihood tilt is the native gauge of the question, and it exists, unique on $\mathcal{T}$, exactly when every proper wall of the question is positive.

(iii) $\kappa_S = \sum_j \Big(\sum_{i=1}^{s_j} \big(|T_{j,i}\cap S| - d_j(S)\big) + \sum_{i=1}^{t_j} \big(|S\setminus T'_{j,i}| - d_j^*(S)\big)\Big) \geq 0$: a wall is the excess of the sample's use of S over its least use.

Proposition 49.2 (The conjugate posterior)**.** *Let F be a connected family. Take as prior on the tilt of the gauge the law of a question $(\mathbf{m}_0;\mathbf{s}_0,\mathbf{t}_0)$ with every proper wall positive, and observe a sample as in Proposition 49.1, with counts $\mathbf{m}$, sizes $\mathbf{s},\mathbf{t}$ and the product θ_{draws} of the weights of the drawn bases.*

(i) The posterior is the law of the question $(\mathbf{m}_0+\mathbf{m};\mathbf{s}_0+\mathbf{s},\mathbf{t}_0+\mathbf{t})$: the masses add and the exponents add.

(ii) The chance of the sample with the tilt integrated out is

$$\theta_{\text{draws}} \cdot \frac{P_F(\mathbf{m}_0+\mathbf{m};\mathbf{s}_0+\mathbf{s},\mathbf{t}_0+\mathbf{t})}{P_F(\mathbf{m}_0;\mathbf{s}_0,\mathbf{t}_0)}.$$

(iii) At the posterior data $(\mathbf{m}';\mathbf{s}',\mathbf{t}')$ the chance that one more draw from the basis law of table j is T is $\theta_{j,T}\,P_F(\mathbf{m}'+\mathbf{1}_T;\mathbf{s}'+\mathbf{e}_j,\mathbf{t}')/P_F(\mathbf{m}';\mathbf{s}',\mathbf{t}')$, and from its cobasis law $\theta_{j,T}\,P_F(\mathbf{m}'+\mathbf{1}_{\mathcal{E}\setminus T};\mathbf{s}',\mathbf{t}'+\mathbf{e}_j)/P_F(\mathbf{m}';\mathbf{s}',\mathbf{t}')$.

(iv) The posterior mean of the usage $\sum_j (s'_j R_j + t'_j R_j^*)$ at the posterior exponents is the posterior masses $\mathbf{m}_0+\mathbf{m}$.

(v) Every wall of the posterior is the wall of the prior plus the excess of Proposition 49.1(iii): a prior inside its walls gives a posterior inside its walls for every sample, the empty one included.

Proposition 49.3 (What the data see of the bases)**.** *(i) For a circuit C of $k\geq 2$ marks of a table and each $e\in C$ some basis has $T\cap C = C\setminus e$: $r(C)=k-1$, every $(k-1)$-subset of C is a pattern of C and C is not; for $k\geq 3$ every two marks of C lie in a common basis, and C in none.*

(ii) For a sample of a family at a gauge α as in Proposition 49.1 and $S\subseteq\mathcal{E}$, the level $|T_{j,i}\cap S|$ of every basis draw of table j lies in $[d_j(S),r_j(S)]$ and the colevel $|S\setminus T'_{j,i}|$ of every cobasis draw in $[d_j^*(S),|S|-d_j(S)]$; the chance that no basis draw of table j reaches the largest level $r_j(S)$ of its window is $(1-p_j)^{s_j}$ with $p_j=\mathbb{P}_{j,\alpha}(|T\cap S|=r_j(S))>0$, and likewise at the floor $d_j(S)$ and for the cobasis draws at the ends of their window, with the cobasis law and t_j.

Proposition 49.4 (The exact laws of a sample of bases)**.** *Let a sample of a family be drawn at a gauge α as in Proposition 49.1, s_j basis and t_j cobasis draws of table j, with counts $\mathbf{m}$, and let B be a bunch with room R.*

(i) For a basis draw of table j, $\mathbb{P}_{j,\alpha}(T) = \pi_{j,p}(\alpha)\,\mathbb{P}_{j,(p),\alpha_R}(T\setminus p)$ with $p=T\cap B$, and for a cobasis draw $\mathbb{P}^*_{j,\alpha}(T) = \pi^*_{j,p}(\alpha)\,\mathbb{P}^*_{j,(p),\alpha_R}(T\setminus p)$, with the pattern probabilities $\pi_{j,p}(\alpha) = \alpha_B^p K_{j,(p)}(\alpha_R)/K_j(\alpha)$ and $\pi^*_{j,p}(\alpha)=\alpha_B^{B\setminus p}\Psi_{j,(p)}(\alpha_R)/\Psi_j(\alpha)$ (Theorem 12.8) and the basis and cobasis laws of the child (j,p) at α_R. So the numbers $a_{j,p}$ of the basis draws and $b_{j,p}$ of the cobasis draws of table j that meet B in p are independent multinomial vectors with the chances $\pi_{j,p}(\alpha)$ and $\pi^*_{j,p}(\alpha)$; they are shares of B, $|\mathbf{a}_j|=s_j$ and $|\mathbf{b}_j|=t_j$ (Definition 12.24);

the counts on the bunch are their loads, $m_e = \mathrm{load}_e$ for $e \in B$; and given them the parts in the room are a sample of the children $F_B(\mathbf{a}, \mathbf{b})$ at α_R, $a_{j,p}$ basis and $b_{j,p}$ cobasis draws of the child (j,p), with the counts $\mathbf{m}|_R$. The mean shares are $s_j \pi_{j,p}(\alpha)$ and $t_j \pi^*_{j,p}(\alpha)$, at a native gauge the native split (Definition 12.25).

(ii) Given $\mathbf{m}$, each sample with these counts has the probability θ_{draws} divided by the coefficient of $\alpha^{\mathbf{m}}$ in $\prod_j K_j(\alpha)^{s_j} \Psi_j(\alpha)^{t_j}$, free of the gauge.

(iii) For every nonempty proper S the wall κ_S of the sample (Proposition 49.1(iii)) is the sum of the independent excesses of the levels of its basis draws and of the colevels of its cobasis draws over their floors, with the generating function

$$\mathbb{E}\big[x^{\kappa_S}\big] = \prod_j \mathsf{Q}^K_{j,S}(x;\alpha)^{s_j}\, \mathsf{Q}^{\Psi}_{j,S}(x;\alpha)^{t_j}$$

of the Skeleton polynomials (Definition 12.10). Its values fill $\{0, 1, \dots, \sum_j (s_j + t_j) c_j(S)\}$; its mean is the excess $\sum_j \big(s_j R_j(\alpha) + t_j R^*_j(\alpha)\big)_S - \sum_j \big(s_j d_j(S) + t_j d^*_j(S)\big)$ of the usage at α over the least use, and its cumulants of order $k \geq 2$ are $\partial^k_S \Phi(\log \alpha)$, $\partial_S = \sum_{e \in S} \partial_{y_e}$ (Proposition 12.12); it vanishes, every draw sitting at the floor of its window on S, with the chance $\prod_j \mathsf{Q}^K_{j,S}(0;\alpha)^{s_j} \mathsf{Q}^{\Psi}_{j,S}(0;\alpha)^{t_j} > 0$; and when the Skeleton spectra of S are positive it is distributed as a sum of independent $\{0,1\}$-valued variables whose means are the coins, s_j copies of the coins of $\mathsf{Q}^K_{j,S}$ and t_j of those of $\mathsf{Q}^{\Psi}_{j,S}$ (Proposition 12.11(iv)).

Proposition 49.5 (Tests that do not see the gauge)**.** *For a family F draw a sample at a gauge α as in Proposition 49.1, with counts $\mathbf{m}$, and let $\Theta_F(\mathbf{m})$ be the coefficient of $\alpha^{\mathbf{m}}$ in $\prod_j K_j(\alpha)^{s_j} \Psi_j(\alpha)^{t_j}$, the total of θ_{draws} over the set $\mathfrak{F}_F(\mathbf{m})$ of the samples with these counts.*

(i) Given $\mathbf{m}$, the sample has the law $\theta_{\mathrm{draws}}/\Theta_F(\mathbf{m})$ on $\mathfrak{F}_F(\mathbf{m})$, free of the gauge; for a family of lists it is uniform, and $|\mathfrak{F}_F(\mathbf{m})| = \Theta_F(\mathbf{m})$.

(ii) A test of F that rejects on an event A whose samples with counts $\mathbf{m}$ carry at most $\varepsilon\, \Theta_F(\mathbf{m})$ of the weight θ_{draws}, for every $\mathbf{m}$, has size at most ε at every gauge.

(iii) If every basis of every table of a family F' on $\mathcal{E}$ is a basis of the same table of F, with the same weight, then given $\mathbf{m}$ the chance under F that every draw is a basis of its table in F' is $p_{F'|F}(\mathbf{m}) = \Theta_{F'}(\mathbf{m})/\Theta_F(\mathbf{m})$, and rejecting F when this happens and $p_{F'|F}(\mathbf{m}) \leq \varepsilon$ has size at most ε at every gauge; one draw that is a basis of its table in F and not in F' rejects F' without error.

(iv) If each family of a collection has a test as in (ii), the families not rejected contain the true family with probability at least $1 - \varepsilon$, at every gauge.

Corollary 49.6 (The evidence of a family)**.** *Let every family F of a collection on $\mathcal{E}$, each with N tables, carry as prior the law of its centre of strengths $\boldsymbol{\sigma}_0 = (\sigma_{0,j})_j$, the question $(\sigma_0 \mathbf{1}; \boldsymbol{\sigma}_0, \boldsymbol{\sigma}_0)$ with $\sigma_0 = \sum_j \sigma_{0,j}$, inside its walls. For a sample as in Proposition 49.5, with the sizes $(s_j, t_j)_j$ and counts $\mathbf{m}$, the probability of the sample under F with the gauge integrated out is*

$$\mathrm{evidence}(F) = \theta^F_{\mathrm{draws}}\, \mathbf{1}[\textit{every draw is a basis of its table of } F]\, \frac{P_F(\sigma_0 \mathbf{1} + \mathbf{m}; \boldsymbol{\sigma}_0 + \mathbf{s}, \boldsymbol{\sigma}_0 + \mathbf{t})}{P_F(\sigma_0 \mathbf{1}; \boldsymbol{\sigma}_0, \boldsymbol{\sigma}_0)},$$

$\theta^F_{\mathrm{draws}}$ the product of the weights in F of the drawn bases, 1 for lists; and if the family is drawn from the collection with the chances $p(F)$, the posterior chance of F is proportional to $p(F)\, \mathrm{evidence}(F)$.

A sample of bases asks the family a question: the counts are its masses and the sample sizes its exponents, and a wall of the question is how far the sample's use of a set exceeds the least use any basis makes of it, a sum of the independent excesses of the levels and colevels of the draws over their floors, whose generating function is the product of the Skeleton polynomials of the set raised to the sizes. Read at a bunch, a sample is a sample of the children at the shares it realizes: the loads of these shares are the counts of the bunch, and their means at a native gauge are the native split. The law of a question is the conjugate prior of the tilt, so the posterior, the predictive chances and the evidence of a family are ratios of periods, and a prior inside its walls stays inside them. Given the counts, a sample has a law that does not see the gauge, uniform for a family of lists, so a test built on the samples with those counts has a size that no gauge can change.

49.2 Samples of tilts

Proposition 49.7 (A sample of tilts: the period is the cumulant function)**.** *Let a question* $(\mathbf{m};\mathbf{s},\mathbf{t})$ *of pair coordinates* $(\boldsymbol{\mu}_\perp;\boldsymbol{\sigma},\boldsymbol{\delta})$ *have every proper wall positive, let* $Z_1,\dots,Z_q$ *be the tilts of independent draws from* $\mathrm{Breta}^\circ(F;\mathbf{m};\mathbf{s},\mathbf{t})$*, and let* $\bar Z$*,* $\bar E_j$*,* $\bar O_j$ *be the sample means of* Z_i*,* $E_j(Z_i)$*,* $O_j(Z_i)$*. In this statement* $\mathbb{E}$ *is the expectation of* $U\sim\mathrm{Breta}^\circ(F;\mathbf{m};\mathbf{s},\mathbf{t})$ *and* Z *is its tilt.*

(i) The sample has the density

$$2^{q(n-1)}\exp\Big(q\Big[2\langle\boldsymbol{\mu}_\perp,\bar Z\rangle-\sum_j\big(\sigma_j\bar E_j+\delta_j\bar O_j\big)\Big]\Big)\Big/P_F(\mathbf{m};\mathbf{s},\mathbf{t})^q$$

on $\mathcal{T}^q$*, so* $(\bar Z;\bar E_j,\bar O_j)_j$ *is sufficient for the question.*

(ii) The means are $\mathbb{E}[Z]=\frac12\nabla_{\boldsymbol{\mu}_\perp}\log P_F(\mathbf{m};\mathbf{s},\mathbf{t})$*,* $\mathbb{E}[E_j(Z)]=-\partial_{\sigma_j}\log P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ *and* $\mathbb{E}[O_j(Z)]=-\partial_{\delta_j}\log P_F(\mathbf{m};\mathbf{s},\mathbf{t})$*, the derivatives of Definition 17.1, and the likelihood equations equate them to the sample means.*

(iii) Against a second question $(\mathbf{m}';\mathbf{s}',\mathbf{t}')$ *of pair coordinates* $(\boldsymbol{\mu}'_\perp;\boldsymbol{\sigma}',\boldsymbol{\delta}')$ *the logarithm of the likelihood ratio is*

$$q\Big[2\langle\boldsymbol{\mu}'_\perp-\boldsymbol{\mu}_\perp,\bar Z\rangle-\sum_j\big((\sigma'_j-\sigma_j)\bar E_j+(\delta'_j-\delta_j)\bar O_j\big)\Big]-q\log\frac{P_F(\mathbf{m}';\mathbf{s}',\mathbf{t}')}{P_F(\mathbf{m};\mathbf{s},\mathbf{t})}.$$

(iv) The sums $q\bar Z$*,* $q\bar E_j$*,* $q\bar O_j$ *have as Laplace transform that of Corollary 17.2 raised to the power* q*.*

Definition 49.8 (The Foreman's question; the pseudo-MGF)**.** Let $\omega=W\,d\alpha_{\mathbf{m}}$ have real data on a connected family, $s_j,t_j\ge0$ not all zero and $\mathbf{m}>0$, with target $\boldsymbol{\tau}$. The *Foreman's question* of ω is the question $(\boldsymbol{\tau};\mathbf{s},\mathbf{t})$ at its target, of pair coordinates $\big(\boldsymbol{\tau}-\frac{\tau\varepsilon}{n}\mathbf{1};\boldsymbol{\sigma},\boldsymbol{\delta}\big)$; off the pole hyperplanes its period $P_F(\boldsymbol{\tau};\mathbf{s},\mathbf{t})$ is the pseudointegral $\wr W\,d\alpha_{\mathbf{m}}$ (Definition 16.10(iii)). Where the target lies on no pole hyperplane and $P_F(\boldsymbol{\tau};\mathbf{s},\mathbf{t})\neq0$, the *pseudo-MGF* of ω is

$$\mathsf{M}_\omega(c;\mathbf{a},\mathbf{b})=\frac{P_F\big(\boldsymbol{\tau}+\mathbf{m}_F(c;\mathbf{a},\mathbf{b});\,\mathbf{s}+\mathbf{a}+\mathbf{b},\,\mathbf{t}+\mathbf{a}-\mathbf{b}\big)}{P_F(\boldsymbol{\tau};\mathbf{s},\mathbf{t})}\qquad(c\in\mathbf{1}^\perp\otimes\mathbb{C},\ \mathbf{a},\mathbf{b}\in\mathbb{C}^N),$$

continued meromorphically (Lemma 16.9), and the *pseudo-cumulants* of ω are the derivatives of $\log\mathsf{M}_\omega$ at 0: the derivatives of $\log P_F$ at the Foreman's question in its pair coordinates.

Proposition 49.9 (The pseudo-MGF inside the walls)**.** *In Definition 49.8 let ω have a native gauge, and let Z be the tilt of $U \sim \mathrm{Breta}^{\circ}(F;\boldsymbol{\tau};\mathbf{s},\mathbf{t})$, the Foreman's law of Proposition 16.34(i); the law of Z is the law of the Foreman's question.*

(i) Wherever the real parts of the shifted data $\big(\boldsymbol{\tau}+\mathbf{m}_F(c;\mathbf{a},\mathbf{b});\,\mathbf{s}+\mathbf{a}+\mathbf{b},\,\mathbf{t}+\mathbf{a}-\mathbf{b}\big)$ have every proper wall positive, a region containing a neighbourhood of 0, $\mathsf{M}_{\omega}(c;\mathbf{a},\mathbf{b})$ is the moment generating function of the statistics $(2Z;-E_j(Z),-O_j(Z))_j$ under the Foreman's law (Corollary 17.2 at the Foreman's question); the pseudo-cumulants are their joint cumulants.

(ii) For a balanced shift $(\dot{\mathbf{m}};\dot{\mathbf{s}},\dot{\mathbf{t}})$ the function $U^{\dot{\mathbf{m}}}\prod_j K_j(U)^{-\dot{s}_j}\Psi_j(U)^{-\dot{t}_j}$ has degree 0, a function of the ray of U, and where the shifted data have every proper wall positive its expectation under the Foreman's law is $P_F(\boldsymbol{\tau}+\dot{\mathbf{m}};\mathbf{s}+\dot{\mathbf{s}},\mathbf{t}+\dot{\mathbf{t}})/P_F(\boldsymbol{\tau};\mathbf{s},\mathbf{t})$ (the case of Proposition 49.22(i) below at the Foreman's question); $\mathsf{M}_{\omega}(c;\mathbf{a},\mathbf{b})$ is this ratio at the shift of pair coordinates $(c;\mathbf{a},\mathbf{b})$, so M_{ω} is the moment generating function of $(\log U;-\log K_j(U),-\log\Psi_j(U))_j$ along the balanced shifts.

(iii) The normaliser is $P_F(\boldsymbol{\tau};\mathbf{s},\mathbf{t}) = P_{\mathrm{c}}\,\mathsf{E}_{U\sim\mathbb{P}_{\mathrm{c}}}[(\omega_{\boldsymbol{\tau}}/\omega_{\mathrm{c}})(U)]$ (Theorem 18.1(i)). The centre ω_{c} has the target $\sigma\mathbf{1}$ and the Foreman's question $(\sigma\mathbf{1};\boldsymbol{\sigma},\boldsymbol{\sigma})$, and the pseudoexpectation is the pseudo-MGF of the centre at the departure:

$$\mathsf{E}_{U\sim\mathbb{P}_{\mathrm{c}}}\Big[\frac{\omega_{\boldsymbol{\tau}}}{\omega_{\mathrm{c}}}(U)\Big] = \mathsf{M}_{\omega_{\mathrm{c}}}\Big(\boldsymbol{\tau}-\frac{\tau_{\mathcal{E}}}{n}\mathbf{1};\ \mathbf{0},\ \boldsymbol{\delta}\Big) = \mathbb{E}_{U\sim\mathbb{P}_{\mathrm{c}}}\Big[e^{2\langle\boldsymbol{\tau}-\frac{\tau_{\mathcal{E}}}{n}\mathbf{1},Z\rangle-\sum_j\delta_jO_j(Z)}\Big],$$

Z the tilt of U: at fixed strengths the pseudoexpectations of all the questions are values of one moment generating function, that of $(2Z;-O_j(Z))_j$ under the law of the centre.

Past the walls M_{ω} is the continuation, as the moments of the distribution of Theorem 16.17(i) are, and $\mathsf{M}_{\omega}(0)=1$ throughout.

Proposition 49.10 (Two layers: the word evaluated at the draws)**.** *Let a family have real data with $\mathbf{m}>0$, and let $U_1,\dots,U_q$ be independent draws from $\mathrm{Dir}_{\mathbf{m}}$, the shapes $\alpha/|\alpha|$ of $\alpha\sim\mathrm{Gamma}_{\mathbf{m}}$ (Proposition 8.12(ii)).*

(i) By Proposition 8.12(i), $\mathbb{E}_{U\sim\mathrm{Dir}_{\mathbf{m}}}[W(U)] = P_F(\mathbf{m};\mathbf{s},\mathbf{t})/\Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}$, and it is finite exactly when every proper wall at $(\mathbf{m};\mathbf{s},\mathbf{t})$ is positive.

(ii) $\mathbb{E}_{U\sim\mathrm{Dir}_{\mathbf{m}}}[W(U)^k] = P_F(\mathbf{m};k\mathbf{s},k\mathbf{t})/\Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}$, and the sample mean $\overline{W}_q=\frac{1}{q}\sum_i W(U_i)$ has the mean $P_F(\mathbf{m};\mathbf{s},\mathbf{t})/\Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}$ and the variance

$$\frac{1}{q}\left[\frac{P_F(\mathbf{m};2\mathbf{s},2\mathbf{t})}{\Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}}-\left(\frac{P_F(\mathbf{m};\mathbf{s},\mathbf{t})}{\Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}}\right)^2\right],$$

finite exactly when every proper wall at $(\mathbf{m};2\mathbf{s},2\mathbf{t})$ is positive.

(iii) Where every proper wall at $(\mathbf{m};\mathbf{s},\mathbf{t})$ is positive, $\mathrm{Breta}^{\circ}(F;\mathbf{m};\mathbf{s},\mathbf{t})$ has the density $W\,\Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}/P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ with respect to $\mathrm{Dir}_{\mathbf{m}}$, and under it a second word $W'=\prod_j K_j^{-s'_j}\Psi_j^{-t'_j}$ of the same tables has $\mathbb{E}_{U\sim\mathrm{Breta}^{\circ}(F;\mathbf{m};\mathbf{s},\mathbf{t})}[W'(U)^k] = P_F(\mathbf{m};\mathbf{s}+k\mathbf{s}',\mathbf{t}+k\mathbf{t}')/P_F(\mathbf{m};\mathbf{s},\mathbf{t})$.

Definition 49.11 (The Grey law)**.** For a family F and masses $\mathbf{m} > 0$ the *Grey law* $\mathrm{Grey}(F;\mathbf{m})$ is the joint law of

$$(G_j, G_j^*)_j = \big(-\log K_j(U),\, -\log \Psi_j(U)\big)_j \qquad \text{for } U \sim \mathrm{Dir}_{\mathbf{m}};$$

it depends on the tables of F and on $\mathbf{m}$, and not on the exponents.

Proposition 49.12 (The Grey law and its exponential family)**.** *Let $\mathbf{m} > 0$ and let $(G_j, G_j^*)_j \sim \mathrm{Grey}(F;\mathbf{m})$.*

(i) For complex exponents $(\mathbf{s},\mathbf{t})$ whose real parts keep every proper wall at $\mathbf{m}$ positive,

$$\mathbb{E}_{(G_j,G_j^*)_j \sim \mathrm{Grey}(F;\mathbf{m})}\Big[e^{\sum_j (s_j G_j + t_j G_j^*)}\Big] = \frac{P_F(\mathbf{m};\mathbf{s},\mathbf{t})}{\Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}} \quad \textit{(Proposition 8.12(i),(iii))}:$$

on real exponents the moment generating function, on imaginary exponents the characteristic function; the joint cumulants are the derivatives of $\log P_F(\mathbf{m};\mathbf{s},\mathbf{t})$ in the exponents at $(\mathbf{0},\mathbf{0})$.

(ii) For real exponents with every proper wall positive, under $\mathrm{Breta}^\circ(F;\mathbf{m};\mathbf{s},\mathbf{t})$ the vector $\big(-\log K_j(U), -\log \Psi_j(U)\big)_j$ has the law

$$e^{\sum_j (s_j g_j + t_j g_j^*)}\, \frac{\Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}}{P_F(\mathbf{m};\mathbf{s},\mathbf{t})}\, \mathrm{Grey}(F;\mathbf{m})(dg\, dg^*):$$

over the exponents these laws form the exponential family with base $\mathrm{Grey}(F;\mathbf{m})$ and cumulant function $\log\big(P_F(\mathbf{m};\mathbf{s},\mathbf{t})/\Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}\big)$.

(iii) For a real direction $(\mathbf{a},\mathbf{b}) \neq 0$ of the exponents let $g(S) = \sum_j \big(a_j d_j(S) + b_j d_j^*(S)\big)$ and $k^* = \min\{m_S/g(S) :\ S \text{ nonempty proper},\ g(S) > 0\}$, the value of λ at which the ray $\lambda(\mathbf{a},\mathbf{b})$, $\lambda > 0$, first meets a wall at $\mathbf{m}$, with $k^* = \infty$ if no $g(S)$ is positive. If $k^* < \infty$,

$$\mathbb{P}\Big(\sum_j \big(a_j G_j + b_j G_j^*\big) > x\Big) = e^{-k^* x + o(x)} \qquad (x \to \infty),$$

and if $k^* = \infty$ the sum is bounded above.

(iv) For q independent copies the sum has the Laplace transform $\big(P_F(\mathbf{m};\mathbf{s},\mathbf{t})/\Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}\big)^q$, and the sample mean $\overline{W}_q$ of Proposition 49.10(ii) is the empirical counterpart of the transform of (i) at the exponents $(\mathbf{s},\mathbf{t})$.

Corollary 49.13 (The Grey law at the target)**.** *Let a connected family carry real exponents $s_j, t_j \geq 0$, not all zero, and masses $\mathbf{m} > 0$ with a native gauge and the target $\boldsymbol{\tau}$. Then*

$$\mathbb{E}_{U\sim \mathrm{Dir}_{\boldsymbol{\tau}}}[W(U)] = \mathbb{E}_{(G_j,G_j^*)_j \sim \mathrm{Grey}(F;\boldsymbol{\tau})}\Big[e^{\sum_j (s_j G_j + t_j G_j^*)}\Big] = \frac{P_F(\boldsymbol{\tau};\mathbf{s},\mathbf{t})}{\Gamma_1^n\begin{bmatrix}\boldsymbol{\tau}\\ \tau_{\mathcal{E}}\end{bmatrix}}$$

$$= \frac{P_{\mathrm{c}}}{\Gamma_1^n\begin{bmatrix}\boldsymbol{\tau}\\ \tau_{\mathcal{E}}\end{bmatrix}}\, \mathsf{E}_{U\sim \mathbb{P}_{\mathrm{c}}}\Big[\frac{\omega_{\boldsymbol{\tau}}}{\omega_{\mathrm{c}}}(U)\Big]:$$

the moment generating function of the Grey law at the target, read at the exponents, is the pseudoexpectation times the period of the centre divided by $\Gamma_1^n\begin{bmatrix}\boldsymbol{\tau}\\ \tau_{\mathcal{E}}\end{bmatrix}$. *With* $\boldsymbol{\tau}$ *held at the target, the logarithmic derivatives of* $(\mathbf{s}',\mathbf{t}')\mapsto P_F(\boldsymbol{\tau};\mathbf{s}',\mathbf{t}')$ *at* $(\mathbf{s},\mathbf{t})$ *are the joint cumulants of* $\big(-\log K_j(U),-\log\Psi_j(U)\big)_j$ *under the Foreman's law* $\mathrm{Breta}^\circ(F;\boldsymbol{\tau};\mathbf{s},\mathbf{t})$.

Proposition 49.14 (A Laplace transform with a moving target)**.** *Let a connected family carry real exponents* $s_j,t_j\geq 0$, *not all zero, and masses* $\mathbf{m}>0$ *whose target* $\boldsymbol{\tau}$ *has every proper wall positive, and let* $g(S)=\sum_j\big(s_jd_j(S)+t_jd_j^*(S)\big)$ *be the set function of Theorem 8.19. With the tails* U_k *of the orders* π *of* $\mathcal{E}$ *(Lemma 8.3),*

$$\lim_{\lambda\to 0^+}\mathbb{E}_{V\sim\mathrm{Dir}_{\lambda\boldsymbol{\tau}}}\Big[\prod_j K_j(V)^{-\lambda s_j}\Psi_j(V)^{-\lambda t_j}\Big]=\frac{\sum_\pi\prod_{k=2}^n\big(\tau_{U_k}-g(U_k)\big)^{-1}}{\sum_\pi\prod_{k=2}^n\tau_{U_k}^{-1}}\ \geq\ 1,$$

with equality exactly when $g(S)=0$ *for every nonempty proper* S. *The limit is the ratio of the limits of Theorem 17.5(i) for the question of data* $(\boldsymbol{\tau};\mathbf{s},\mathbf{t})$ *and for the list* $\binom{\mathcal{E}}{1}$ *at a full basis lean at the masses* $\boldsymbol{\tau}$, *whose walls are the* τ_S *(Proposition 16.3).*

The word read at Dirichlet draws is a random variable whose expectation, as a function of the exponents, is the period divided by the stacked Gamma of the masses over their total: the Laplace transform of the Grey law of the family. At fixed masses the Grey law is the base of an exponential family over the exponents, and its tail along a direction of exponents is set by the first wall met along that direction. Read at the target of each exponent, as the normaliser $\binom{\mathcal{E}}{1}$ of Proposition 16.35(ii) reads it, the expectation of the word is not a moment generating function in the exponents: its limit at the origin exceeds 1 as soon as the word has a floor on a proper set, since at each exponent it reads the Grey law at another target. The pseudo-MGF fixes the target once, at the Foreman's question, and the pseudoexpectation fixes the law once for given strengths, at the centre.

Proposition 49.15 (The exponent is a dial between the mean and the maximum)**.** *In Proposition 49.10 let the exponents be real, not all zero, and put* $Y_i=\log W(U_i)$ *and* $Y=\log W(U)$ *for* $U\sim\mathrm{Dir}_{\mathbf{m}}$; *in this statement* $\mathbb{E}$ *is the expectation of independent* $U,U_1,\dots,U_q\sim\mathrm{Dir}_{\mathbf{m}}$. *Let* $g(S)=\sum_j\big(s_jd_j(S)+t_jd_j^*(S)\big)$, $k^*=\min\{m_S/g(S):\ S$ *nonempty proper,* $g(S)>0\}$, *with* $k^*=\infty$ *if no* $g(S)$ *is positive, and for* $k>0$ *let* $A_k=\frac{1}{k}\log\big(\frac{1}{q}\sum_i e^{kY_i}\big)$.

(i) A_k *is nondecreasing in* k, *tends to the sample mean of the* Y_i *as* $k\to 0$ *and to* $\max_i Y_i$ *as* $k\to\infty$, *and* $\max_i Y_i-\frac{\log q}{k}\leq A_k\leq\max_i Y_i$.

(ii) For $k<k^*$, $\mathbb{E}[e^{kA_k}]=P_F(\mathbf{m};k\mathbf{s},k\mathbf{t})/\Gamma_1^n\begin{bmatrix}\mathbf{m}\\ m_{\mathcal{E}}\end{bmatrix}$, *and* e^{kA_k} *has a finite variance exactly when* $2k<k^*$.

(iii) For $k\geq k^*$, $\mathbb{E}[e^{kY}]=\infty$; *and* $\mathbb{P}(\max_i Y_i\leq x)=\mathbb{P}(Y\leq x)^q$.

(iv) If $k^*<\infty$, $\mathbb{P}(Y>x)=e^{-k^*x+o(x)}$ *as* $x\to\infty$, *and if* $k^*=\infty$, Y *is bounded above (Proposition 49.12(iii)). For* $s_j,t_j\geq 0$ *and a set* S *attaining* k^* *the scale* $\rho=|U_S|$ *has* $(\rho,1-\rho)\sim\mathrm{Dir}_{(m_S,m_{\mathcal{E}\setminus S})}$, *so* ρ *has density proportional to* $\rho^{m_S-1}(1-\rho)^{m_{\mathcal{E}\setminus S}-1}$, *and* $W(U)\geq\prod_j K_j(\mathbf{1})^{-s_j-t_j}\rho^{-g(S)}$.

Proposition 49.16 (The even and odd statistics from a centre)**.** *Let a family carry the centre of strengths* $\boldsymbol{\sigma}=(\sigma_j)_j$, $\sigma_j\geq 0$, *inside its walls, let* Z *be the tilt of* $U\sim\mathrm{Breta}^\circ(F;\sigma\mathbf{1};\boldsymbol{\sigma},\boldsymbol{\sigma})$, *with density proportional to* $e^{-\sum_j\sigma_jE_j(z)}$ *on* $\mathcal{T}$, *and let* $\ell^*_{\boldsymbol{\sigma}}$ *be the slope of Proposition 17.7. In this statement* $\mathbb{E}$ *is the expectation of* $U\sim\mathrm{Breta}^\circ(F;\sigma\mathbf{1};\boldsymbol{\sigma},\boldsymbol{\sigma})$.

(i) $\sum_j \sigma_j E_j(Z) \geq 2\sum_j \sigma_j \log K_j(\mathbf{1})$, *with equality only at* $Z = 0$ *(Proposition 17.4), where* $\sum_j \sigma_j E_j$ *has the Hessian* $8\sum_j \sigma_j\big(\kappa_{j,\mathbf{1}}(X_e, X_f)\big)_{e,f}$, *rung two of the still of the realization* $\big((\sigma_j,\sigma_j)_j;\mathbf{1}\big)$ *of the active tables, eight times the covariance of the indicators under the weight laws; and each* $E_j(Z) \geq 2\log K_j(\mathbf{1})$, *with equality exactly where* Z *is constant on the molecules of table* j. *For real* $\mathbf{k} = (k_j)_j$,

$$\mathbb{E}\Big[e^{-\sum_j k_j E_j(Z)}\Big] = \frac{P_F\big((\sigma + |\mathbf{k}|)\mathbf{1}; \boldsymbol{\sigma} + \mathbf{k}, \boldsymbol{\sigma} + \mathbf{k}\big)}{P_F(\sigma\mathbf{1}; \boldsymbol{\sigma}, \boldsymbol{\sigma})},$$

the ratio of the periods of the centres of strengths $\boldsymbol{\sigma} + \mathbf{k}$ *and* $\boldsymbol{\sigma}$, *finite exactly when* $\sum_j (\sigma_j + k_j)c_j(S) > 0$ *for every nonempty proper* S: *along the even direction* $\mathbf{k} = \lambda\boldsymbol{\sigma}$ *every wall closes at once, at* $\lambda = -1$, *and along any other even direction* $\lambda\mathbf{k}$, $\lambda > 0$, *the first wall closes at the least of the ratios* $\kappa_S^{\mathbf{E}}(\boldsymbol{\sigma})/(-\kappa_S^{\mathbf{E}}(\mathbf{k}))$ *with* $\kappa_S^{\mathbf{E}}(\mathbf{k}) < 0$.

(ii) $\big(Z, (E_j(Z))_j, (O_j(Z))_j\big)$ *and* $\big(-Z, (E_j(Z))_j, (-O_j(Z))_j\big)$ *have one law, so every joint moment of odd total degree in* Z *and the* $O_j(Z)$ *vanishes. For real* $c \in \mathbf{1}^\perp$ *and* $\mathbf{b} \in \mathbb{R}^N$, $\mathbb{E}\big[e^{2\langle c, Z\rangle - \sum_j b_j O_j(Z)}\big]$ *is finite exactly when* $\ell^*_{\boldsymbol{\sigma}}(c, \mathbf{b}) > 1$ *(Proposition 17.7(i)), where it is*

$$P_F\big(\mathbf{m}_F(c; \boldsymbol{\sigma}, \mathbf{b});\, \boldsymbol{\sigma} + \mathbf{b},\, \boldsymbol{\sigma} - \mathbf{b}\big)/P_F(\sigma\mathbf{1}; \boldsymbol{\sigma}, \boldsymbol{\sigma}),$$

for $|b_j| \leq \sigma_j$ *the pseudoexpectation of the question of pair coordinates* $(c; \boldsymbol{\sigma}, \mathbf{b})$. *If* $\ell^*_{\boldsymbol{\sigma}}(c, \mathbf{b}) < \infty$, *both tails of* $Y = 2\langle c, Z\rangle - \sum_j b_j O_j(Z)$ *have the rate* $\ell^*_{\boldsymbol{\sigma}}(c, \mathbf{b})$: $\mathbb{P}(\pm Y > x) = e^{-\ell^*_{\boldsymbol{\sigma}}(c,\mathbf{b})x + o(x)}$ *as* $x \to \infty$; *if it is infinite,* Y *is bounded (Proposition 17.8).*

(iii) At $\alpha = e^{2z}$, $K_j(\alpha)^{-s_j} = e^{-s_j\langle \mathbf{1}, z\rangle} e^{-\frac{s_j}{2}(E_j(z) + O_j(z))}$ *and* $\Psi_j(\alpha)^{-t_j} = e^{-t_j\langle \mathbf{1}, z\rangle} e^{-\frac{t_j}{2}(E_j(z) - O_j(z))}$: *every letter is its table at a full lean,* $K_j^{-s_j}$ *at the pair coordinates* $(\sigma, \delta) = (\frac{s_j}{2}, \frac{s_j}{2})$ *and* $\Psi_j^{-t_j}$ *at* $(\frac{t_j}{2}, -\frac{t_j}{2})$, *with the masses shifted by* $-\frac{s_j}{2}\mathbf{1}$, *resp.* $-\frac{t_j}{2}\mathbf{1}$; *a family is the family of its letters, and its pair coordinates are the sums of theirs.*

Proposition 49.17 (What the two statistics are)**.** *For table* j *of a family and a tilt* z, $\log \Lambda_j(z) = \log \sum_T \theta_{j,T} e^{\langle \chi_T, z\rangle}$ *is a soft maximum and* $-\log \Lambda_j(-z)$ *a soft minimum of the scores* $\langle \chi_T, z\rangle$ *of its bases, weighted by* $\theta_{j,T}$.

(i) $E_j(z)$ *is the soft maximum less the soft minimum, and* $O_j(z)$ *is their sum; the centred potential* $\Phi^\circ = \sum_j (\sigma_j E_j + \delta_j O_j)$ *is the sum over the tables of* s_j *times the soft maximum less* t_j *times the soft minimum.*

(ii) With $Y_j = \langle \chi_T, z\rangle$ *for* T *under the weight law of table* j, *near* $z = 0$

$$E_j(z) = 2\log K_j(\mathbf{1}) + \sum_{k\ even} \frac{2}{k!}\,\kappa_{j,\mathbf{1}}(Y_j^{\times k}),$$
$$O_j(z) = \sum_{k\ odd} \frac{2}{k!}\,\kappa_{j,\mathbf{1}}(Y_j^{\times k}),$$

so $E_j(z) = 2\log K_j(\mathbf{1}) + \kappa_{j,\mathbf{1}}(Y_j, Y_j) + \frac{1}{12}\kappa_{j,\mathbf{1}}(Y_j^{\times 4}) + \cdots$ *and* $O_j(z) = 2\kappa_{j,\mathbf{1}}(Y_j) + \frac{1}{3}\kappa_{j,\mathbf{1}}(Y_j^{\times 3}) + \cdots$, *with* $\kappa_{j,\mathbf{1}}(Y_j) = \sum_e (2R_{j,e}(\mathbf{1}) - 1)z_e$ *and, for* $k \geq 2$, $\kappa_{j,\mathbf{1}}(Y_j^{\times k}) = 2^k \sum_{w \in \mathcal{E}^k} \kappa_{j,\mathbf{1}}(w)\, z^w$, $z^w = z_{w_1} \cdots z_{w_k}$. *Summed with the strengths and the leans, the terms of order* $k \geq 2$ *of* Φ° *are* $\frac{1}{k!}\sum_{w \in \mathcal{E}^k} 2^k \sum_j \big(s_j + (-1)^k t_j\big)\kappa_{j,\mathbf{1}}(w)\, z^w$, *which for the exponents of a realization* $\Upsilon = ((s_j, t_j)_j; \mathbf{1})$ *is* $\frac{1}{k!}\sum_w \kappa_\Upsilon(w)\, z^w$, *rung* k *of its still (Proposition 9.7): the even statistics carry the even rungs and the odd statistics the odd rungs.*

(iii) *As* $\lambda \to \infty$, $E_j(\lambda z)/\lambda \to \mathrm{wd}_j(z)$, *the width of Proposition 17.4, and* $O_j(\lambda z)/\lambda \to h_j(z) - h_j(-z)$, *the maximum of the scores being at the greedy basis* $T^+_{j,\pi}$ *and the minimum at* $T^-_{j,\pi}$ *for an order* π *along which the coordinates of* z *decrease (Lemma 8.3). So* $\Phi^\circ(\lambda z)/\lambda \to \langle 2v_\pi - 2\sigma\mathbf{1}, z\rangle$ *with* $v_\pi = \sum_j \big(s_j \mathbf{1}_{T^+_{j,\pi}} + t_j \mathbf{1}_{\mathcal{E}\setminus T^-_{j,\pi}}\big)$, *for* $s_j, t_j \geq 0$ *a vertex of the Newton sum at which* $\langle \cdot, z\rangle$ *is largest, the* greedy vertex *of* π*; and for a question the exponent of Proposition 17.4 has* $X(\lambda z)/\lambda \to -2\kappa(z) = 2\langle \mathbf{m} - v_\pi, z\rangle$ *on* $\mathbf{1}^\perp$*: the walls of the tails of* π *are the tail sums of the masses less the greedy vertex,* $\kappa_{U_k} = m_{U_k} - (v_\pi)_{U_k}$.

Proposition 49.18 (The laws of the questions are an exponential family)**.** *Let a connected family be such that* 1, *the coordinates* z_e, $e \neq g$, *of a chart* $z_g = 0$ *of* $\mathcal{T}$ *and the statistics* E_j, O_j *are linearly independent functions on* $\mathcal{T}$. *Then the laws of its questions with every proper wall positive form a regular exponential family of dimension* $n-1+2N$, *with natural parameter* $(2\boldsymbol{\mu}_\perp; -\boldsymbol{\sigma}, -\boldsymbol{\delta})$, *statistic* $(z; E_j(z), O_j(z))_j$ *and cumulant function* $\log P_F\big(\mathbf{m}_F(\boldsymbol{\mu}_\perp; \boldsymbol{\sigma}, \boldsymbol{\delta}); \boldsymbol{\sigma} + \boldsymbol{\delta}, \boldsymbol{\sigma} - \boldsymbol{\delta}\big)$. *For the sample means* $(\bar{Z}; \bar{E}_j, \bar{O}_j)_j$ *of* q *independent tilts, as in Proposition 49.7:*

(i) $(\bar{Z}; \bar{E}_j, \bar{O}_j)_j$ *is sufficient, and a function of it with expectation zero under every law of the family vanishes almost surely;*

(ii) *it is the unbiased estimator of least variance of the mean parameters*

$$\Big(\frac{1}{2}\nabla_{\boldsymbol{\mu}_\perp} \log P_F;\ -\partial_{\sigma_j} \log P_F,\ -\partial_{\delta_j} \log P_F\Big)_j,$$

with covariance $\frac{1}{q}$ *times the Hessian of* $\log P_F$ *in the natural parameter;*

(iii) *the likelihood equations have a solution, unique, exactly when* $(\bar{Z}; \bar{E}_j, \bar{O}_j)_j$ *is interior to the convex hull of the image of* $z \mapsto (z; E_j(z), O_j(z))_j$*;*

(iv) *for* $\delta_j \leq \delta_0$ *against* $\delta_j > \delta_0$, *with the other parameters unknown, rejecting for small* $\bar{O}_j$ *given the other coordinates of the sample means is uniformly most powerful among unbiased tests, with a conditional null law free of the other parameters; likewise for* σ_j *and* $\bar{E}_j$*;*

(v) *the law of the sums* $q\bar{Z}$, $q\bar{E}_j$, $q\bar{O}_j$ *has the Laplace transform of Proposition 49.7(iv), so the power of every test is a computation in the family.*

When the complement of every basis of table j *is a basis with the same weight,* $O_j \equiv 0$ *and the statements hold with* δ_j *removed.*

A word read at Dirichlet draws is a dial: its power means run from the mean of the logarithms to their maximum as the exponent grows, and they keep a finite expectation up to the first wall met along the ray of exponents, where the tail of the logarithm takes over with the rate of that wall. At a centre the centred potential $\sum_j \sigma_j E_j$ is least at the table's gauge and its exponential moments along the strengths close every wall at once, while the odd statistics are jointly symmetric and every odd direction has both tails at the rate of its slope. The two statistics of a table are the soft maximum and the soft minimum of the scores of its bases, read as their difference and their sum: at the table's gauge their Taylor terms are the rungs of the still, the even ones carried by the strengths and the odd ones by the leans, and at infinity they read the greedy vertex of the Newton sum, whose tail sums against the masses are the walls. The laws of the questions are a regular exponential family in the tilt and these statistics, so the classical optimal estimators and tests are computations with periods.

49.3 Draws, orders and races

Proposition 49.19 (A sorted draw lives on the sector of its order)**.** *Let a family have real data on its balance wall with every proper wall positive, and let* $U \sim \mathrm{Breta}^{\circ}(F;\mathbf{m};\mathbf{s},\mathbf{t})$*. For an order* π *of* $\mathcal{E}$ *let* κ_k *be the walls of its tails and* I_π *its sector integral (Corollary 8.6), so that* $P_F(\mathbf{m};\mathbf{s},\mathbf{t}) = \sum_\pi I_\pi$ *(Theorem 8.5(ii)).*

(i) $\mathbb{P}\big(U_{\pi(1)} > \cdots > U_{\pi(n)}\big) = I_\pi / P_F(\mathbf{m};\mathbf{s},\mathbf{t})$*.*

(ii) Given that order, the gaps $u_k = \log\big(U_{\pi(k-1)}/U_{\pi(k)}\big)$*,* $2 \le k \le n$*, have the density*

$$I_\pi^{-1} \exp\Big(-\sum_{k=2}^{n} \kappa_k u_k\Big) \prod_j k_{j,\pi}(e^{-u})^{-s_j}\, \psi_{j,\pi}(e^{-u})^{-t_j}$$

on $[0,\infty)^{n-1}$*, with the sector letters* $k_{j,\pi}, \psi_{j,\pi}$ *of Theorem 8.5(ii).*

(iii) $\theta_{j,T^+_{j,\pi}} \le k_{j,\pi} \le K_j(\mathbf{1})$ *and* $\theta_{j,T^-_{j,\pi}} \le \psi_{j,\pi} \le K_j(\mathbf{1})$ *on the cube, so the density of (ii) lies between constant multiples of the density of independent exponential gaps of the rates* κ_k*; for* $s_j, t_j \ge 0$*,* I_π *lies between* $\prod_j K_j(\mathbf{1})^{-s_j-t_j} \prod_k \kappa_k^{-1}$ *and* $\prod_j \theta_{j,T^+_{j,\pi}}^{-s_j}\, \theta_{j,T^-_{j,\pi}}^{-t_j} \prod_k \kappa_k^{-1}$*.*

(iv) On the sector of π *the largest monomial* U^T *over the bases of table* j *is at its greedy basis* $T^+_{j,\pi}$ *and the smallest at* $T^-_{j,\pi}$ *(Lemma 8.3): the best and the worst basis of a draw are functions of its order, and the best basis of table* j *at* U *is* T *with probability* $\sum_{\pi:\, T^+_{j,\pi}=T} I_\pi / P_F(\mathbf{m};\mathbf{s},\mathbf{t})$*.*

Proposition 49.20 (An ordered sample and a cut)**.** *Let* $Y_1, \dots, Y_q$ *be independent with a probability law* ϕ *on* $\mathbb{R}$*, an input (Definition 5.4) that charges no point.*

(i) The ordered sample has the law $q!\,\phi^{\otimes q}$ *on the region* $\{y_1 < \cdots < y_q\}$*.*

(ii) The number of observations above a cut N *is binomial with* q *trials and the chance* $\phi((N,\infty))$*, which for* ϕ *living on* $(0,\infty)$ *and* $N \ge 0$ *is the Trailmoment* $(\mathsf{T}_{0;(1)}[x]\,\phi)((N,\infty))$ *at index* 0*; given that it is* d*, the ordered observations above the cut have the law* $d!\,\phi^{\otimes d}/\phi((N,\infty))^d$ *on the trail region* $X_N = \{N < y_1 < \cdots < y_d\}$*.*

(iii) If ϕ *lives on* $(0,\infty)$ *and* $N \ge 0$*, the empirical input* $\hat\phi = \frac{1}{q}\sum_i \delta_{Y_i}$ *has* $(\mathsf{T}_{\nu;(1)}[x]\,\hat\phi)((N,\infty)) = \frac{1}{q}\sum_{Y_i > N} Y_i^{-\nu}$*, with the mean* $(\mathsf{T}_{\nu;(1)}[x]\,\phi)((N,\infty))$ *and the variance*

$$\frac{1}{q}\Big[(\mathsf{T}_{2\nu;(1)}[x]\,\phi)((N,\infty)) - (\mathsf{T}_{\nu;(1)}[x]\,\phi)((N,\infty))^2\Big].$$

Proposition 49.21 (The races and the dilation relation)**.** *For table* j *of a family and a tilt* z*, with* $\alpha = e^{2z}$*, the laws of the winners of the basis race and the cobasis race (Theorem 18.5) are* $\mathbb{P}_{j,\alpha}$ *and* $\mathbb{P}^*_{j,\alpha}$*; let*

$$\mathrm{Ent}_j(z) = -\sum_T \mathbb{P}_{j,\alpha}(T) \log \frac{\mathbb{P}_{j,\alpha}(T)}{\theta_{j,T}}, \qquad \mathrm{Ent}^*_j(z) = -\sum_T \mathbb{P}^*_{j,\alpha}(T) \log \frac{\mathbb{P}^*_{j,\alpha}(T)}{\theta_{j,T}}$$

be their entropies relative to the weights.

(i) $E_j(z) = \langle z, \nabla E_j(z)\rangle + \mathrm{Ent}_j(z) + \mathrm{Ent}^*_j(z)$ *and* $O_j(z) = \langle z, \nabla O_j(z)\rangle + \mathrm{Ent}_j(z) - \mathrm{Ent}^*_j(z)$*, with*

$$\langle z, \nabla E_j(z)\rangle = \mathbb{E}_{T\sim\mathbb{P}_{j,\alpha}}\big[\langle \chi_T, z\rangle\big] - \mathbb{E}_{T\sim\mathbb{P}^*_{j,\alpha}}\big[\langle \chi_T, z\rangle\big],$$
$$\langle z, \nabla O_j(z)\rangle = \mathbb{E}_{T\sim\mathbb{P}_{j,\alpha}}\big[\langle \chi_T, z\rangle\big] + \mathbb{E}_{T\sim\mathbb{P}^*_{j,\alpha}}\big[\langle \chi_T, z\rangle\big].$$

Let the family be connected and let a question $(\mathbf{m};\mathbf{s},\mathbf{t})$ *of pair coordinates* $(\boldsymbol{\mu}_\perp;\boldsymbol{\sigma},\boldsymbol{\delta})$ *have every proper wall positive. In the rest of this statement* $\mathbb{E}$ *is the expectation of* $U\sim\mathrm{Breta}^\circ(F;\mathbf{m};\mathbf{s},\mathbf{t})$*, Z is its tilt and* $\mathbf{u}(\alpha)=\sum_j\big(s_jR_j(\alpha)+t_jR_j^*(\alpha)\big)$ *the usage.*

(ii) Dilation relation.

$$2\langle\boldsymbol{\mu}_\perp,\mathbb{E}[Z]\rangle-\sum_j\big(\sigma_j\mathbb{E}[E_j(Z)]+\delta_j\mathbb{E}[O_j(Z)]\big)=-(n-1)-\sum_j\big(s_j\mathbb{E}[\mathrm{Ent}_j(Z)]+t_j\mathbb{E}[\mathrm{Ent}_j^*(Z)]\big);$$

at a centre, $\sum_j\sigma_j\mathbb{E}[E_j(Z)]=n-1+\sum_j\sigma_j\mathbb{E}[\mathrm{Ent}_j(Z)+\mathrm{Ent}_j^*(Z)]$.

(iii) $\mathrm{Cov}\big(\mathbf{u}_e(U),Z_f\big)=\frac12\big(\mathbf{1}[e=f]-\frac1n\big)$*, Z read on* $\mathbf{1}^\perp$.

(iv) $\log P_F$ *is convex in the pair coordinates of the question, so for a balanced direction* $v=(\dot{\mathbf{m}};\dot{\mathbf{s}},\dot{\mathbf{t}})$ *with the questions at the data* $(\mathbf{m}\pm\dot{\mathbf{m}};\mathbf{s}\pm\dot{\mathbf{s}},\mathbf{t}\pm\dot{\mathbf{t}})$ *inside their walls,*

$$\log\frac{P_F(\mathbf{m};\mathbf{s},\mathbf{t})}{P_F(\mathbf{m}-\dot{\mathbf{m}};\mathbf{s}-\dot{\mathbf{s}},\mathbf{t}-\dot{\mathbf{t}})}\le D_v\log P_F(\mathbf{m};\mathbf{s},\mathbf{t})\le\log\frac{P_F(\mathbf{m}+\dot{\mathbf{m}};\mathbf{s}+\dot{\mathbf{s}},\mathbf{t}+\dot{\mathbf{t}})}{P_F(\mathbf{m};\mathbf{s},\mathbf{t})},$$

bracketing each mean of Proposition 49.7(ii) by neighbouring values of the period.

Proposition 49.22 (Moments are steps; entropies are derivatives one column up)**.** *Let a connected family carry a question* $(\mathbf{m};\mathbf{s},\mathbf{t})$ *with every proper wall positive, and in this statement let* $\mathbb{E}$ *be the expectation of* $U\sim\mathrm{Breta}^\circ(F;\mathbf{m};\mathbf{s},\mathbf{t})$.

(i) For a real balanced shift $(\dot{\mathbf{m}};\dot{\mathbf{s}},\dot{\mathbf{t}})$ *with every proper wall of the shifted question positive,*

$$\mathbb{E}\Big[U^{\dot{\mathbf{m}}}\prod_j K_j(U)^{-\dot{s}_j}\Psi_j(U)^{-\dot{t}_j}\Big]=\frac{P_F(\mathbf{m}+\dot{\mathbf{m}};\mathbf{s}+\dot{\mathbf{s}},\mathbf{t}+\dot{\mathbf{t}})}{P_F(\mathbf{m};\mathbf{s},\mathbf{t})}.$$

(ii) For a basis T of table j the columns $v_{j,T}=(\mathbf{1}_T;\mathbf{e}_j,\mathbf{0})$ *and* $v_{j,T}^*=(\mathbf{1}_{\mathcal{E}\setminus T};\mathbf{0},\mathbf{e}_j)$ *are balanced, and for* $a\ge0$

$$\mathbb{E}\Big[\Big(\frac{\mathbb{P}_{j,U}(T)}{\theta_{j,T}}\Big)^a\Big]=\frac{P_F(\mathbf{m}+a\mathbf{1}_T;\,\mathbf{s}+a\mathbf{e}_j,\,\mathbf{t})}{P_F(\mathbf{m};\mathbf{s},\mathbf{t})},$$
$$\mathbb{E}\Big[\Big(\frac{\mathbb{P}^*_{j,U}(T)}{\theta_{j,T}}\Big)^a\Big]=\frac{P_F(\mathbf{m}+a\mathbf{1}_{\mathcal{E}\setminus T};\,\mathbf{s},\,\mathbf{t}+a\mathbf{e}_j)}{P_F(\mathbf{m};\mathbf{s},\mathbf{t})},$$

the walls only growing along a column.

(iii) With the entropies of Proposition 49.21,

$$\mathbb{E}[\mathrm{Ent}_j(Z)]=-\sum_T\theta_{j,T}\,\frac{(D_{v_{j,T}}P_F)(\mathbf{m}+\mathbf{1}_T;\,\mathbf{s}+\mathbf{e}_j,\,\mathbf{t})}{P_F(\mathbf{m};\mathbf{s},\mathbf{t})},$$
$$\mathbb{E}[\mathrm{Ent}_j^*(Z)]=-\sum_T\theta_{j,T}\,\frac{(D_{v^*_{j,T}}P_F)(\mathbf{m}+\mathbf{1}_{\mathcal{E}\setminus T};\,\mathbf{s},\,\mathbf{t}+\mathbf{e}_j)}{P_F(\mathbf{m};\mathbf{s},\mathbf{t})},$$

Z the tilt of U: an entropy is a derivative of the period one column up.

Corollary 49.23 (A derivative adds one finite sum)**.** *The series of Corollary 15.11 may be differentiated term by term along a balanced direction* $v=(\dot{\mathbf{m}};\dot{\mathbf{s}},\dot{\mathbf{t}})$ *at a point inside the walls, with* $\dot\kappa_S$ *the change of the walls; each factor of a term has an elementary logarithmic derivative,*

$$D_v\log\frac{(s_j)_{n_j}}{n_j!}=\dot s_j\sum_{i<n_j}\frac{1}{s_j+i},\qquad D_v\log\frac{(t_j)_{n'_j}}{n'_j!}=\dot t_j\sum_{i<n'_j}\frac{1}{t_j+i},$$

$$D_v \log K_j(\mathbf{1})^{-s_j - t_j} = -(\dot{s}_j + \dot{t}_j) \log K_j(\mathbf{1}),$$
$$D_v \log {}_1^2\Gamma \begin{bmatrix} \kappa_{U_k} + \beta_k,\ \gamma_k + 1 \\ \kappa_{U_k} + \beta_k + \gamma_k + 1 \end{bmatrix} = -\dot{\kappa}_{U_k} \sum_{i=0}^{\gamma_k} \frac{1}{\kappa_{U_k} + \beta_k + i},$$

so every quantity of Proposition 49.22 is the same positive series, at the question or one column up, with each term multiplied by a finite sum of reciprocals and logarithms of total weights.

Sorting a draw of the shape law lands it in one sector of the period: the chance of an order is the fraction of the period carried by its sector, the gaps of the sorted draw are exponential at the rates of the walls of the tails up to bounded factors, and the best and the worst basis of the draw are the greedy bases of its order. The races read the statistics as entropies, and the dilation relation is the balance between the strength of a question and the entropies of its winners. Every moment of a letter, of a winner's chance or of the shape is a step of the data, and every entropy is a derivative one column up, so on the closing series of the period each is a positive series whose terms carry one extra finite sum.

49.4 The interaction of a bunch

Proposition 49.24 (The interaction belongs to the room)**.** *Let a family have a bunch B, $|B| \geq 2$, with $\mathrm{pat}_j(B) = 2^B$ in every active table.*

(i) $\iota_{j,B}$ and $\iota^*_{j,B}$, and so $\iota^{\mathbf{E}}_B$ and $\iota^{\mathbf{O}}_B$, are homogeneous of degree 0 in α_R.

(ii) At a gauge α put, for $P \subseteq B$, $w(P) = \prod_j \pi_{j,P}(\alpha)^{s_j} \pi^*_{j,B\setminus P}(\alpha)^{t_j}$, with the pattern probabilities $\pi_{j,p}(\alpha) = \alpha_B^p K_{j,(p)}(\alpha_R)/K_j(\alpha)$ and $\pi^*_{j,p}(\alpha) = \alpha_B^{B\setminus p} \Psi_{j,(p)}(\alpha_R)/\Psi_j(\alpha)$ of Definition 12.25; for a sample as in Proposition 49.1 it is the chance that every draw uses exactly P on B, its basis draws meeting B in P and its cobasis draws missing exactly P. In the expansion $\log w(P) = \sum_{A \subseteq P} \lambda_A$ over the subsets of B, the top term is $\lambda_B = \iota^{\mathbf{E}}_B + \iota^{\mathbf{O}}_B$, and for $A \subsetneq B$ with $|A| \geq 2$, λ_A is the sum $\iota^{\mathbf{E}}_A + \iota^{\mathbf{O}}_A$ of the interaction of A in the face $F^{\mathcal{E}\setminus(B\setminus A)}$ of the wall at $B \setminus A$ (Theorem 16.25), whose tables are the restrictions $\mathcal{B}_j|\big(\mathcal{E} \setminus (B \setminus A)\big)$, the deletions of $B \setminus A$, at the exponents $(s_j, 0)$ and the contractions $\mathcal{B}_j/(B \setminus A)$ at $(0, t_j)$; none of them depends on α_B. For one table at the exponents $(1, 0)$, $w(P) = \pi_P(\alpha)$ and $\lambda_B = \iota_B$, the top term of the log-linear expansion of the pattern probabilities.

Theorem 49.25 (The interaction totals the joint cumulants over the bunch's scales)**.** *Let a family with real exponents have a bunch $B = \{e_1, \dots, e_k\}$, $k \geq 2$, with $\mathrm{pat}_j(B) = 2^B$ in every active table. Then for both parts $\mathbf{X} \in \{\mathbf{E}, \mathbf{O}\}$*

$$\iota^{\mathbf{X}}_B(\alpha_R) = \int_{\mathbb{R}^B} \partial_{y_{e_1}} \cdots \partial_{y_{e_k}} \Phi_{\mathbf{X}}(y_B, \log \alpha_R)\, dy_B,$$

converging absolutely; at a realization the integrand of the sum of the parts is $2^{-k} \kappa_\Upsilon(e_1, \dots, e_k) = \sum_j \big(s_j \kappa_{j,\alpha}(e_1, \dots, e_k) + (-1)^k t_j \kappa_{j,\alpha^{-1}}(e_1, \dots, e_k)\big)$, with κ_Υ the still at the gauge $\alpha = (e^{y_B}, \alpha_R)$ (Proposition 9.6). For one table at the exponents $(1, 0)$ the integrand is the joint cumulant of the indicators of the marks of B under the basis law at (e^{y_B}, α_R) (Definition 7.17), and the total is $\iota_B(\alpha_R)$.

Proposition 49.26 (Both sides, and parity)**.** *For a table with $\mathrm{pat}(B) = 2^B$, with $\Psi = \sum_p \alpha_B^{B\setminus p} \Psi_{(p)}(\alpha_R)$, as functions of the tilt z_R of the room $\iota^*_B(z_R) = (-1)^{|B|} \iota_B(-z_R)$. So for a*

family

$$\iota_B^{\mathbf{E}}(z_R) = \sum_j \sigma_j \big(\iota_{j,B}(z_R) + (-1)^{|B|}\iota_{j,B}(-z_R)\big), \qquad \iota_B^{\mathbf{O}}(z_R) = \sum_j \delta_j \big(\iota_{j,B}(z_R) - (-1)^{|B|}\iota_{j,B}(-z_R)\big) :$$

for $|B|$ even the even part of the interaction is even in z_R and the odd part is odd, for $|B|$ odd the reverse, and at the table's gauge of the room the interaction is $\big(2\sum_j \sigma_j\iota_{j,B}, 0\big)$ for $|B|$ even and $\big(0, 2\sum_j \delta_j\iota_{j,B}\big)$ for $|B|$ odd: the strengths read the even bunches and the leans the odd ones, as they read the even and the odd rungs of the still at the table's gauge (Proposition 9.7). The total of Theorem 49.25 for the logarithm $-\Phi$ of the family word is $-\sum_j \big(s_j\iota_{j,B}(z_R) + (-1)^{|B|}t_j\iota_{j,B}(-z_R)\big)$.

Proposition 49.27 (A design)**.** *Let $\mathbf{X} \in \mathbb{R}^{\mathcal{E}\times C}$ have full column rank, with rows x_e, and for $J \subseteq C$ let $K_J(\alpha) = \det\big(\mathbf{X}_J^{\mathsf{T}} \operatorname{diag}(\alpha)\mathbf{X}_J\big)$, $\mathbf{X}_J$ the columns in J, with $K_\varnothing = 1$.*

(i) The marks are the observations of the determinantal table with the slice $\mathbf{X}^{\mathsf{T}}$ (Definition 7.20) and the weights $\theta_T = \det(\mathbf{X}_{T,C})^2$, $|T| = |C|$: $K = K_C$, and the occupation of a mark is its leverage, $R_e(\alpha) = \alpha_e\, x_e^{\mathsf{T}}\big(\mathbf{X}^{\mathsf{T}} \operatorname{diag}(\alpha)\mathbf{X}\big)^{-1}x_e$.

(ii) Add one prior mark *γ^{p} for each column $\gamma \in C$, with the rows of the identity and the scales β: $K(\alpha,\beta) = \det\big(\mathbf{X}^{\mathsf{T}} \operatorname{diag}(\alpha)\mathbf{X} + \operatorname{diag}(\beta)\big) = \sum_{J\subseteq C} \beta^{C\setminus J} K_J(\alpha)$. The prior marks form a bunch C^{p} with $\operatorname{pat}(C^{\mathrm{p}}) = 2^{C^{\mathrm{p}}}$, and the child of the pattern q^{p}, $q \subseteq C$, is $K_{C\setminus q}$.*

(iii) For a split $C = J_1 \sqcup J_2$ the generalized variance inflation factor is $\frac{K_{J_1}K_{J_2}}{K_C K_\varnothing} = \exp\big(-\iota_{(J_1^{\mathrm{p}}, J_2^{\mathrm{p}})}\big)$, and for two columns γ, γ', one minus the squared partial correlation given the rest is $\exp(\iota_{\{\gamma^{\mathrm{p}},\gamma'^{\mathrm{p}}\}})$ in the table with the other prior marks deleted.

(iv) The dual multivector of the table of (ii) has the slice $[\, I_{\mathcal{E}} \mid -\mathbf{X}\,]$, and the basis polynomial of its dual table, $\det\big(\operatorname{diag}(\alpha') + \mathbf{X}\operatorname{diag}(\beta')\mathbf{X}^{\mathsf{T}}\big)$, is the polynomial of (ii) for the matrix $\mathbf{X}^{\mathsf{T}}$: the columns of $\mathbf{X}$ are its observations, at the scales β', and the marks of $\mathcal{E}$ its prior marks, at the scales α'. Its child with every prior mark deleted, $\det\big(\mathbf{X}\operatorname{diag}(\beta')\mathbf{X}^{\mathsf{T}}\big)$, is nonzero exactly when $\mathbf{X}$ has rank $|\mathcal{E}|$.

A bunch all of whose subsets are patterns sees the room through its children, one for each subset of the bunch, and the alternating sum of their logarithms is the interaction: it is homogeneous of degree zero in the room, it is the top term of the log-linear expansion of the chance that a sample uses one pattern of the bunch throughout, and it is the total, over the bunch's scales, of the joint cumulants of the use of the bunch's marks under the basis and cobasis laws, weighted by the exponents. The dual table reads the same interaction at the opposite tilt with the sign of the parity of the bunch, so a family reads the interaction of an even bunch through its strengths and that of an odd bunch through its leans, as it reads the rungs of the same parities. In a regression design the prior marks of the columns are such a bunch: the interactions are minus the logarithms of the generalized variance inflation factors and the logarithms of one minus the squared partial correlations, and the occupations are the leverages.

Part X

Proofs of the general forms

Chapter 50

Proofs of the general forms

This part proves the statements that are more general than their counterparts in the reference *The Foreman and the serif family* (16 October 2026), and those with no counterpart there; in the source file the comment before each such statement says so. Statements are cited by their numbers, and every symbol and term is that of the chapter the statement belongs to. A statement of the reference that is a special case of a statement proved here is not proved again; where reading it off needs a word, the word follows the proof. Lemmas that belong to this part alone are numbered S1, S2, ... The chapters are taken in order, one section each, and the last section records the checks run on small families.

50.1 Chapter 1: conventions, the stacked Gamma and the finite part

Lemma S1. *Let $\Theta \subset \mathbb{R}$ be finite and $\phi(y) = \sum_{\theta\in\Theta} a_\theta e^{i\theta y}$ with $a_\theta \in \mathbb{C}$. If $\phi(y) \to 0$ as $y \to -\infty$, then every a_θ is 0.*

Proof. Fix $\theta_0 \in \Theta$. For $Y > 0$,

$$\frac{1}{Y}\int_{-2Y}^{-Y} \phi(y)\, e^{-i\theta_0 y}\, dy = a_{\theta_0} + \sum_{\theta\neq\theta_0} a_\theta\, \frac{1}{Y}\int_{-2Y}^{-Y} e^{i(\theta-\theta_0)y}\, dy,$$

and each integral on the right has modulus at most $2/|\theta-\theta_0|$, so the sum is $O(Y^{-1})$. The left side has modulus at most $\sup_{y\le -Y}|\phi(y)|$, which tends to 0. Letting $Y \to \infty$ gives $a_{\theta_0} = 0$. □

Lemma S2. *Let $g(x) = \sum_{(k,j)\in F} c_{k,j}\, x^k \log^j x$ for $x \in (0,1)$, where $F \subset \mathbb{C}\times\mathbb{N}$ is finite and nonempty and every $c_{k,j}$ is nonzero. Let κ be the least real part of the exponents k, $(k,j) \in F$, and J the largest j such that $(k,j) \in F$ for some k with $\operatorname{Re} k = \kappa$. Then $g(x)/(x^\kappa \log^J x)$ does not tend to 0 as $x \to 0$.*

Proof. Put $y = \log x$, so that $y \to -\infty$ as $x \to 0$ and $x^k = e^{ky}$. Then

$$\frac{g(x)}{x^\kappa \log^J x} = \sum_\theta c_{\kappa+i\theta,J}\, e^{i\theta y} + \sum_{(k,j)} c_{k,j}\, e^{(k-\kappa)y}\, y^{j-J},$$

the first sum over the real θ with $(\kappa + i\theta, J) \in F$ and the second over the other elements of F. Every term of the second sum tends to 0: if $\operatorname{Re} k = \kappa$, then $j < J$, $|e^{(k-\kappa)y}| = 1$ and $|y|^{j-J} \to 0$;

if $\operatorname{Re} k > \kappa$, then $|e^{(k-\kappa)y} y^{j-J}| = e^{(\operatorname{Re} k-\kappa)y} |y|^{j-J} \to 0$. The first sum is a function $\phi(y)$ as in Lemma S1 with a nonzero coefficient, so it does not tend to 0 as $y \to -\infty$, and neither does the left side. □

Definition 1.5 (The finite part). As stated: the exponents of a log-power expansion are complex numbers, and its coefficients are determined by the function.

Proof. What is to be shown is that the coefficients of a log-power expansion are determined by h, so that the finite parts are well defined; the rest of the definition is that of the reference, with complex exponents.

(1) One remainder. Let two finite sums S_1 and S_2 of terms $c\,x^k \log^j x$, every exponent of real part below N, both differ from h by $O(x^N)$ as $x \to 0$. Their difference $g = S_1 - S_2$ is a finite sum of the same kind with $g(x) = O(x^N)$. If g had a nonzero coefficient, then, with $\kappa < N$ and J as in Lemma S2, $|g(x)/(x^\kappa \log^J x)| \le C x^{N-\kappa} |\log x|^{-J} \to 0$, which that lemma excludes. So S_1 and S_2 have the same coefficients.

(2) Two remainders. Let $N < N'$, and let S and S' be finite sums for N and for N'. A term $x^k \log^j x$ of S' with $\operatorname{Re} k \ge N$ is $O(x^{N-\delta})$ for every $\delta > 0$, so the part $S'_{<N}$ of S' with exponents of real part below N has $h - S'_{<N} = O(x^{N-\delta})$. Choose $\delta > 0$ smaller than $N - \operatorname{Re} k$ for every exponent k of S and of $S'_{<N}$. Then S and $S'_{<N}$ both differ from h by $O(x^{N-\delta})$, with all exponents of real part below $N - \delta$, so they coincide by (1). Hence the coefficient of a term $x^k \log^j x$ is the same for every $N > \operatorname{Re} k$, and the coefficient of $x^0 \log^0 x$, read with any $N > 0$, is determined by h. At ∞ the same holds for $h(1/x)$ at 0: the term $x^{-k} \log^j x$ is $(-1)^j x'^k \log^j x'$ in $x' = 1/x$, and $x^0 \log^0 x$ is $x'^0 \log^0 x'$.

(3) The primitive. Two primitives of f differ by a constant C, whose expansion at either end is the single term $C\,x^0 \log^0 x$; by (2) the finite parts of the second primitive at 0 and at ∞ are those of the first plus C. So $\operatorname{Reg}_{x\to\infty} h - \operatorname{Reg}_{x\to 0} h$ and $h(b) - \operatorname{Reg}_{x\to 0} h$ do not depend on the primitive. □

Proposition 1.6 (A convergent integral is its own finite part). *As stated, for log-power expansions with complex exponents.*

Proof. Let h be a primitive of f with log-power expansions at both ends. Since $\int_0^\infty f\,dx$ converges, $h(x) = h(1) - \int_x^1 f$ has a limit L_0 as $x \to 0$, h has a limit L_∞ as $x \to \infty$, and $\int_0^\infty f\,dx = L_\infty - L_0$. Take the expansion at 0 for some $N > 0$, and let G be its part with exponents of real part at most 0. The other terms and the remainder tend to 0, so $G(x) \to L_0$. Write $G - L_0$ as a finite sum of terms $c\,x^k \log^j x$, the constant $-L_0$ joining the coefficient of $x^0 \log^0 x$, and suppose it has a nonzero coefficient; let $\kappa \le 0$ and J be as in Lemma S2. If $(\kappa, J) \ne (0,0)$, then $|x^\kappa \log^J x| \to \infty$, so $(G - L_0)/(x^\kappa \log^J x) \to 0$. If $(\kappa, J) = (0,0)$, every exponent of $G - L_0$ has real part 0 and every power of the logarithm is 0, and $(G - L_0)/(x^0 \log^0 x) = G - L_0 \to 0$. Both are excluded by Lemma S2. So G is the constant L_0: the expansion at 0 has no term with an exponent of real part at most 0 other than $L_0\,x^0 \log^0 x$, and $\operatorname{Reg}_{x\to 0} h = L_0$. In the same way, for $h(1/x)$ at 0, $\operatorname{Reg}_{x\to\infty} h = L_\infty$. Hence $\operatorname{Reg} \int_0^\infty f\,dx = L_\infty - L_0 = \int_0^\infty f\,dx$. □

Theorem 1.7 (A finite part is a constant term). *As stated, for log-power expansions with complex exponents.*

Proof. The steps are those of the reference, proof of 1.7; they hold at complex exponents as follows.

The end at 0. On $(0,1]$ write $f = \sum c_{b,j} x^b \log^j x + r_N$, the sum over the finitely many terms of the expansion at 0 with $\operatorname{Re} b < N$, where $N > 0$ and $r_N = O(x^N)$ as $x \to 0$; r_N is integrable on $(0,1]$. For $b \neq -1$ put

$$Q_{b,j}(y) = \sum_{i=0}^{j} (-1)^{j-i} \frac{j!}{i!\,(b+1)^{j-i+1}}\, y^i;$$

then $(b+1)Q_{b,j} + Q'_{b,j} = y^j$, so $\frac{d}{dx}\big(x^{b+1} Q_{b,j}(\log x)\big) = x^b \log^j x$, and $Q_{b,j}(0) = (-1)^j j!/(b+1)^{j+1}$. Hence

$$\int_x^1 t^b \log^j t\, dt = Q_{b,j}(0) - x^{b+1} Q_{b,j}(\log x) \quad (b \neq -1), \qquad \int_x^1 t^{-1} \log^j t\, dt = -\frac{\log^{j+1} x}{j+1},$$

and $\int_x^1 r_N = \int_0^1 r_N - \int_0^x r_N$ with $\int_0^x r_N = O(x^{N+1})$. So $\int_x^1 f$ has a log-power expansion at 0, and its coefficient of $x^0 \log^0 x$ is $\sum_{b \neq -1} c_{b,j} Q_{b,j}(0) + \int_0^1 r_N$: a term $x^{b+1} \log^i x$ has the exponent $b+1 \neq 0$, and a term $\log^{j+1} x$ has a positive power of the logarithm. For a primitive h of f, $h(1) - \operatorname{Reg}_{x\to 0} h = \operatorname{Reg}_{x\to 0} \int_x^1 f$, so by 1.5

$$\operatorname{Reg} \int_0^1 f\, dx = \sum_{b \neq -1} c_{b,j} \frac{(-1)^j j!}{(b+1)^{j+1}} + \int_0^1 r_N\, dx.$$

On the other side, by $\int_0^1 x^{s-1} \log^j x\, dx = (-1)^j j!/s^{j+1}$ for $\operatorname{Re} s > 0$,

$$\int_0^1 x^\varepsilon f\, dx = \sum c_{b,j} \frac{(-1)^j j!}{(b+1+\varepsilon)^{j+1}} + \int_0^1 x^\varepsilon r_N\, dx$$

for $\operatorname{Re}\varepsilon$ large, the last term holomorphic on $\operatorname{Re}\varepsilon > -N-1$; this is the meromorphic continuation there. Its constant term at $\varepsilon = 0$ is the sum displayed above: a term with $b \neq -1$ gives its value, and a term with $b = -1$ is the pure pole $(-1)^j j!\,\varepsilon^{-j-1}$, of constant term 0.

The end at ∞. By $x \mapsto 1/x$, $\int_1^\infty x^\varepsilon f\, dx = \int_0^1 x^{-\varepsilon} x^{-2} f(1/x)\, dx$ and $\int_1^x f = \int_{1/x}^1 t^{-2} f(1/t)\, dt$; the function $x^{-2} f(1/x)$ has a log-power expansion at 0, the coefficient of $x^0 \log^0 x$ at ∞ is that of $x'^0 \log^0 x'$ at 0 in $x' = 1/x$, and a constant term at $\varepsilon = 0$ does not change under $\varepsilon \mapsto -\varepsilon$. So $\operatorname{Reg}_{x\to\infty} \int_1^x f = \operatorname{CT}_{\varepsilon=0} \int_1^\infty x^\varepsilon f\, dx$ by the end at 0.

Adding, $\operatorname{Reg} \int_0^\infty f\, dx = \operatorname{Reg}_{x\to\infty} h - \operatorname{Reg}_{x\to 0} h = \operatorname{Reg}_{x\to\infty} \int_1^x f + \operatorname{Reg}_{x\to 0} \int_x^1 f$ is the constant term of the sum of the two continuations. □

Corollary 1.8 (Finite parts at a pole of a Mellin integral). *As stated: for every f with a log-power expansion at* 0*, at every $a \in \mathbb{C}$.*

Proof. Fix a and $N > 1 - \operatorname{Re} a$, and write $f = \sum c_{k,j} x^k \log^j x + r_N$ on $(0,1]$, the finitely many terms of the expansion with $\operatorname{Re} k < N$, $r_N = O(x^N)$ at 0 and integrable on $[\delta, 1]$ for every $\delta > 0$. For $\operatorname{Re} a'$ large,

$$I(a') = \sum c_{k,j} \frac{(-1)^j j!}{(a'+k)^{j+1}} + \int_0^1 x^{a'-1} r_N\, dx,$$

the last term holomorphic on $\operatorname{Re} a' > -N$. This is the meromorphic continuation of I on $\operatorname{Re} a' > -N$; its poles lie at the points $-k$, a term $x^k \log^j x$ giving a pole of order at most $j+1$, and since N is arbitrary this describes the continuation on $\mathbb{C}$. Its constant term at $a' = a$ is

$$\operatorname*{CT}_{a'=a} I(a') = \sum_{a+k \neq 0} c_{k,j} \frac{(-1)^j j!}{(a+k)^{j+1}} + \int_0^1 x^{a-1} r_N\, dx,$$

a term with $a+k=0$ being the pure pole $(-1)^j j!\,(a'-a)^{-j-1}$; at an a that is not a pole it is $I(a)$. On the other side, $x^{a-1}f$ has the log-power expansion at 0 with the terms $c_{k,j}x^{a+k-1}\log^j x$ and the remainder $x^{a-1}r_N = O(x^{N+\operatorname{Re} a-1})$, $N+\operatorname{Re} a-1>0$. The end at 0 in the proof of 1.7 above, with $b=a+k-1$ (so $b\neq -1$ exactly when $a+k\neq 0$, and $b+1=a+k$), gives for $\operatorname{Reg}\int_0^1 x^{a-1}f\,dx$ the same sum. □

Lemma 1.9 (A finite part depends on the coordinate). *As stated: the dilation rule for every function with log-power expansions.*

Proof. (a) The finite part of $h(cx^p)$. Let $h(y)=\sum c_{k,j}\,y^{-k}\log^j y+O(y^{-N})$ as $y\to\infty$, finitely many terms with $\operatorname{Re} k<N$, so that $a_j=c_{0,j}$. For $y=cx^p$, $y^{-k}=c^{-k}x^{-pk}$ and $\log y=\log c+p\log x$, so

$$h(cx^p)=\sum c_{k,j}\,c^{-k}x^{-pk}\sum_{i=0}^{j}\binom{j}{i}(\log c)^{j-i}p^i\log^i x+O(x^{-pN}),$$

a log-power expansion at ∞ with the exponents pk, of real parts below pN; as N is arbitrary, so is pN. The term $x^0\log^0 x$ comes from $pk=0$, that is $k=0$, and $i=0$; by 1.5 its coefficient $\sum_j c_{0,j}(\log c)^j=\sum_j a_j(\log c)^j$ is $\operatorname{Reg}_{x\to\infty}h(cx^p)$. At 0 the computation is the same.

(b) The finite part of the integral. Let $F(x)=\int_1^x f$. At ∞, $f(t)=\sum f_{k,j}t^{-k}\log^j t+O(t^{-N})$ with $N>1$; integrating from 1 to x, a term with $k\neq 1$ gives $x^{1-k}Q_{-k,j}(\log x)$ up to a constant (with $Q_{b,j}$ as in the proof of 1.7 above), a term with $k=1$ gives $\log^{j+1}x/(j+1)$, and the remainder gives a constant plus $O(x^{1-N})$. So F has a log-power expansion at ∞, and for $i\geq 1$ its coefficient of $x^0\log^i x$ comes from the term $k=1$, $j=i-1$ alone: it is f^∞_{i-1}/i. In the same way, at 0 the coefficient of $x^0\log^i x$ in F is f^0_{i-1}/i for $i\geq 1$. Write A^∞_i and A^0_i for the coefficients of $x^0\log^i x$ of F at ∞ and at 0; $A^\infty_0-A^0_0=\operatorname{Reg}\int_0^\infty f\,dx$. The function $G(x)=F(cx^p)$ is a primitive of $f(cx^p)\,c\,p\,x^{p-1}$, and by (a) at both ends

$$\operatorname{Reg}\int_0^\infty f(cx^p)\,c\,p\,x^{p-1}dx=\sum_{i\geq 0}\big(A^\infty_i-A^0_i\big)(\log c)^i=\operatorname{Reg}\int_0^\infty f\,dx+\sum_{i\geq 1}\frac{f^\infty_{i-1}-f^0_{i-1}}{i}(\log c)^i,$$

which is the display with $i=j+1$. At $c=1$ the correction vanishes: a power of the coordinate leaves the finite part unchanged. □

Remark. The reference states the instance $f(x)=1/(1+cx)$, $c>0$. This f has the coefficient $f^\infty_0=1/c$ of x^{-1} at ∞ and no term $x^{-1}\log^j x$ at 0, and with the dilation c^{-1} and $p=1$ the lemma gives $\frac{1}{c}\operatorname{Reg}\int_0^\infty\frac{dx'}{1+x'}=\operatorname{Reg}\int_0^\infty\frac{dx}{1+cx}-\frac{\log c}{c}$. The left side is 0, the primitive $\log(1+x')=\log x'+\log(1+1/x')$ having no constant term at either end; so $\operatorname{Reg}\int_0^\infty\frac{dx}{1+cx}=\frac{\log c}{c}$, the value of the reference. A second check, with a logarithm: $f(x)=\log(1+x)/(1+x)$ has the primitive $\frac12\log^2(1+x)$, with no constant term at either end, so $\operatorname{Reg}\int_0^\infty f\,dx=0$; at ∞, $f=x^{-1}\log x+O(x^{-2}\log x)$, so $f^\infty_1=1$ and $f^\infty_0=0$, and at 0 it has no term $x^{-1}\log^j x$. The lemma gives $\operatorname{Reg}\int_0^\infty f(cx)\,c\,dx=\frac12\log^2 c$; directly, the primitive $\frac12\log^2(1+cx)=\frac12\big(\log c+\log x+\log(1+\frac{1}{cx})\big)^2$ has the constant term $\frac12\log^2 c$ at ∞ and none at 0.

50.2 Chapter 2: the Gramma and the Zamma

Proposition 2.3 (Affine changes of the logarithmic coordinates). *As stated: one statement for the reflection, the linear changes of the coordinates and the torus homogeneity.*

Proof. Let $A \in GL_{\mathcal{E}}(\mathbb{R})$ and $\mathbf{h} \in \mathbb{R}^{\mathcal{E}}$. The map $y' \mapsto y = Ay' + \mathbf{h}$ is a bijection of $\mathbb{R}^{\mathcal{E}}$ with $dy = |\det A|\, dy'$, and $\langle \nu, y\rangle = \langle A^{\mathsf{T}}\nu, y'\rangle + \langle \nu, \mathbf{h}\rangle$, $\langle t_k, y\rangle = \langle A^{\mathsf{T}} t_k, y'\rangle + \langle t_k, \mathbf{h}\rangle$. In the logarithmic form of 2.1,

$$e^{\langle \nu, y\rangle} \exp\Big(-\sum_k \xi_k e^{\langle t_k, y\rangle}\Big)\, dy = |\det A|\, e^{\langle \nu, \mathbf{h}\rangle}\, e^{\langle A^{\mathsf{T}}\nu, y'\rangle} \exp\Big(-\sum_k \big(e^{\langle t_k, \mathbf{h}\rangle}\xi_k\big)\, e^{\langle A^{\mathsf{T}} t_k, y'\rangle}\Big)\, dy'.$$

The moduli of the two sides are the same expressions with ν replaced by $\operatorname{Re}\nu$, so the integral of the left side converges exactly when that of the right side does. The left side is the integrand of $\mathsf{G}_{\nu;t}(\boldsymbol{\xi})$ and the right side, up to the constant factor, that of $\mathsf{G}_{A^{\mathsf{T}}\nu;A^{\mathsf{T}}t}\big((e^{\langle t_k, \mathbf{h}\rangle}\xi_k)_k\big)$, with positive coefficients; by 2.2, $\nu \in \mathcal{T}_t$ exactly when $A^{\mathsf{T}}\nu \in \mathcal{T}_{A^{\mathsf{T}}t}$, that is $\mathcal{T}_{A^{\mathsf{T}}t} = A^{\mathsf{T}}\mathcal{T}_t$, and integrating gives the display. At $A = -I_{\mathcal{E}}$ and $\mathbf{h} = 0$, $|\det A| = 1$ and $A^{\mathsf{T}}t = -t$: the reflection. At $A = I_{\mathcal{E}}$ and $\mathbf{h} = \log\lambda$, $\lambda \in \mathbb{R}^{\mathcal{E}}_{>0}$, $e^{\langle t_k, \mathbf{h}\rangle} = \lambda^{t_k}$ and $e^{\langle \nu, \mathbf{h}\rangle} = \lambda^{\nu}$: the torus homogeneity. □

Theorem 2.5 (Product). *As stated, for any number of blocks.*

Proof. Write $x = (x^{(1)}, \dots, x^{(q)})$ with $x^{(i)} \in \mathbb{R}^{\mathcal{E}_i}_{>0}$. Each t_k is supported in one $\mathcal{E}_i$, so $x^{t_k} = (x^{(i)})^{t_k|\mathcal{E}_i}$ for that i, and

$$x^{\nu-\mathbf{1}} \exp\Big(-\sum_k \xi_k x^{t_k}\Big) = \prod_{i=1}^{q} (x^{(i)})^{\nu|\mathcal{E}_i - \mathbf{1}} \exp\Big(-\sum_{k\in K_i} \xi_k\, (x^{(i)})^{t_k|\mathcal{E}_i}\Big),$$

K_i the set of the terms whose exponents are supported in $\mathcal{E}_i$, the zero vectors counted in K_1. The moduli of the factors are positive functions of separate variables, so by Tonelli the modulus of the product is integrable exactly when every factor is integrable over $\mathbb{R}^{\mathcal{E}_i}_{>0}$; by 2.2 this says $\mathcal{T}_t = \mathcal{T}_{t^{(1)}} \times \cdots \times \mathcal{T}_{t^{(q)}}$, and Fubini gives the product. □

Theorem 2.8 (Scale and shape along sets). *As stated, for several disjoint sets at once.*

Proof. Apply 2.7 on each B_i: $x_{B_i} = \rho_i u_i$ with $\rho_i > 0$ and $u_i \in \Delta_{B_i}$, and $x_{B_i}^{\nu|_{B_i}-\mathbf{1}} dx_{B_i} = \rho_i^{\nu_{B_i}-1} u_i^{\nu|_{B_i}-\mathbf{1}}\, d\rho_i\, d\omega_{B_i}(u_i)$. With x_R the coordinates on R, the map $(x_R, (\rho_i)_i, (u_i)_i) \mapsto x$ is a bijection onto $\mathbb{R}^{\mathcal{E}}_{>0}$, and since $(\rho_i u_i)^{t_k|_{B_i}} = \rho_i^{\langle t_k, \mathbf{1}_{B_i}\rangle} u_i^{t_k|_{B_i}}$,

$$x^{\nu-\mathbf{1}} dx = x_R^{\nu|_R-\mathbf{1}} \prod_i \rho_i^{\nu_{B_i}-1} u_i^{\nu|_{B_i}-\mathbf{1}}\, d\rho\, d\omega(u)\, dx_R, \qquad \xi_k x^{t_k} = b_k(u, x_R) \prod_i \rho_i^{\ell_{k,i}}.$$

At $\nu \in \mathcal{T}_t$ the Gramma converges (2.2), that is, its integrand is absolutely integrable. By Tonelli and Fubini the integral may be taken with the integral over $\rho = (\rho_i)_i \in \mathbb{R}^q_{>0}$ innermost, that integral converging absolutely for almost every (u, x_R), and it is

$$\int_{\mathbb{R}^q_{>0}} \rho^{(\nu_{B_i})_i - \mathbf{1}} \exp\Big(-\sum_k b_k(u, x_R)\, \rho^{\ell_k}\Big)\, d\rho = \mathsf{G}_{(\nu_{B_i})_i;\ell}\big(\mathbf{b}(u, x_R)\big),$$

the Gramma of 2.1 on q scales with the configuration ℓ. When R is empty there are no coordinates x_R. □

Proposition 2.13 (First facts about the Zamma). *As stated: (i) at every invertible square configuration and (iv) on any number of scales; (ii) and (iii) are those of the reference.*

Proof. (i) By 2.6, $\mathsf{G}_{\nu;t}(\boldsymbol{\xi}) = |\det t|^{-1}\prod_k \Gamma(b_k)\,\xi_k^{-b_k}$ on $\mathcal{T}_t = \{\nu : \operatorname{Re}\mathbf{b} \in (0,\infty)^N\}$; dividing by $\prod_e \Gamma(\nu_e)$ (2.12) gives the display, the quotient of Gammas being the stacked Gamma of 1.2, and the display carries the continuation. At the unit configuration $\mathbf{b} = \nu$ and the display is the monomial; on one scale with $t_1 > 0$, $|\det t| = t_1$ and $b_1 = \nu/t_1$, which is the formula of the reference.

(iv) Write $t'' = I_{\mathcal{E}} \oplus t'$ and $\boldsymbol{\xi}'' = \mathbf{1} \oplus \boldsymbol{\xi}'$. Since $\operatorname{cone}(t'') \supseteq \operatorname{cone}(I_{\mathcal{E}}) = [0,\infty)^{\mathcal{E}}$, every $\nu \in \mathbb{R}^{\mathcal{E}}_{>0}$ lies in $\operatorname{int}\operatorname{cone}(t'')$, hence in $\mathcal{T}_{t''}$. By 2.1,

$$\mathsf{G}_{\nu;t''}(\boldsymbol{\xi}'') = \int_{\mathbb{R}^{\mathcal{E}}_{>0}} x^{\nu-\mathbf{1}} e^{-\sum_e x_e} \exp\Big(-\sum_k \xi'_k x^{t'_k}\Big)\,dx = \prod_e \Gamma(\nu_e)\,\mathbb{E}_{U\sim\mathrm{Gamma}_\nu}\Big[\exp\Big(-\sum_k \xi'_k U^{t'_k}\Big)\Big],$$

Gamma_ν having the density $\prod_e x_e^{\nu_e-1}e^{-x_e}/\Gamma(\nu_e)$ (1.1(vii)); dividing by $\prod_e \Gamma(\nu_e)$ gives the display. The variable $\exp(-\sum_k \xi'_k U^{t'_k})$ lies in $(0,1]$ and decreases in each ξ'_k, and so does its expectation. Put $X = \sum_k \xi'_k U^{t'_k} \geq 0$. Where every $\nu + t'_k$ lies in $\mathbb{R}^{\mathcal{E}}_{>0}$, the coordinates of U being independent, $\mathbb{E}[U^{t'_k}] = \prod_e \mathbb{E}[U_e^{t'_{k,e}}] = \prod_e \Gamma(\nu_e + t'_{k,e})/\Gamma(\nu_e)$, so $\mathbb{E}X = \sum_k \xi'_k \prod_e \Gamma_1\begin{bmatrix}\nu_e + t'_{k,e}\\ \nu_e\end{bmatrix}$ is finite. The function $s \mapsto e^{-s}$ is convex, so $e^{-s} \geq e^{-s_0} - e^{-s_0}(s - s_0)$ for all real s, s_0; at $s = X$ and $s_0 = \mathbb{E}X$, taking expectations, $\mathbb{E}[e^{-X}] \geq e^{-\mathbb{E}X}$, which is the bound. □

Proposition 2.14 (Powers of a polynomial in the scales). *As stated: (i) and (iii) for every Zamma; (ii) and (iv) are those of the reference.*

Proof. Write $\boldsymbol{\xi}(\rho) = \boldsymbol{\xi}^{(0)} + \boldsymbol{\Delta}(\rho)$ with $\Delta_k(\rho) = \sum_{l\neq 0} \rho^l \xi_k^{(l)}$, a polynomial vanishing at $\rho = 0$.

(1) Derivatives. Away from the unit configuration, $\mathsf{Z}_{\nu;t} = \mathsf{G}_{\nu;t}/\prod_e \Gamma(\nu_e)$ on $(0,\infty)^N$. By 2.4(i), $\partial^{\mathbf{w}}\mathsf{G}_{\nu;t} = (-1)^{|\mathbf{w}|}\mathsf{G}_{\nu+t\mathbf{w};t}$, every $\nu + t\mathbf{w}$ lying in $\mathcal{T}_t$ because $\operatorname{int}\operatorname{cone}(t) + \operatorname{cone}(t) \subseteq \operatorname{int}\operatorname{cone}(t)$; so $\mathsf{Z}_{\nu;t}$ is infinitely differentiable on $(0,\infty)^N$ and

$$\partial^{\mathbf{w}}\mathsf{Z}_{\nu;t} = (-1)^{|\mathbf{w}|}\frac{\mathsf{G}_{\nu+t\mathbf{w};t}}{\prod_e \Gamma(\nu_e)} = (-1)^{|\mathbf{w}|}\prod_e \Gamma_1\begin{bmatrix}\nu_e + (t\mathbf{w})_e\\ \nu_e\end{bmatrix}\,\mathsf{Z}_{\nu+t\mathbf{w};t},$$

the second form wherever no entry of $\nu + t\mathbf{w}$ lies in $-\mathbb{N}$, the product being read as the first form otherwise, as in the statement. At the unit configuration $\mathsf{Z}_{\nu;I_{\mathcal{E}}}(\boldsymbol{\xi}) = \boldsymbol{\xi}^{-\nu}$ (2.12), holomorphic near $\boldsymbol{\xi}^{(0)}$ with the principal branch, and $\partial^{\mathbf{w}}\boldsymbol{\xi}^{-\nu} = (-1)^{|\mathbf{w}|}\prod_e (\nu_e)_{w_e}\,\boldsymbol{\xi}^{-\nu-\mathbf{w}}$ with $(\nu_e)_{w_e} = \nu_e(\nu_e + 1)\cdots(\nu_e + w_e - 1)$.

(2) Taylor coefficients. Each monomial of $\boldsymbol{\Delta}(\rho)^{\mathbf{w}}$ has total degree at least $|\mathbf{w}|$ in ρ, every $l \neq 0$ having $|l| \geq 1$. So Taylor's formula for $\mathsf{Z}_{\nu;t}$ at $\boldsymbol{\xi}^{(0)}$ to the order $|q|$, whose remainder is $O(|\boldsymbol{\Delta}|^{|q|+1}) = O(|\rho|^{|q|+1})$, gives

$$c_q^\nu = \sum_{|\mathbf{w}|\leq|q|} \partial^{\mathbf{w}}\mathsf{Z}_{\nu;t}(\boldsymbol{\xi}^{(0)})\,[\rho^q]\,\frac{\boldsymbol{\Delta}(\rho)^{\mathbf{w}}}{\mathbf{w}!}.$$

By the multinomial theorem, $\Delta_k^{w_k}/w_k! = \sum \prod_{l\neq 0} (\rho^l \xi_k^{(l)})^{n_{l,k}}/n_{l,k}!$, the sum over the $(n_{l,k})_l$ in $\mathbb{N}$ with $\sum_l n_{l,k} = w_k$; multiplying over k and taking the coefficient of ρ^q leaves the arrays $\mathbf{n}$ with $\sum_{l,k} l\,n_{l,k} = q$ and $\mathbf{w} = (\sum_l n_{l,k})_k$, $|\mathbf{w}| = |\mathbf{n}|$. With (1) this is (i). At one unit exponent, $t = (1)$, $\boldsymbol{\xi} = L$ and the index λ, the product in (i) is $\Gamma_1\begin{bmatrix}\lambda + |\mathbf{n}|\\ \lambda\end{bmatrix}(L^{(0)})^{-\lambda-|\mathbf{n}|}\prod_l (L^{(l)})^{n_l}/n_l!$, which is the formula of the reference.

(3) The coefficients as variables. The function $(\rho, (\xi_k^{(l)})) \mapsto \mathsf{Z}_{\nu;t}(\boldsymbol{\xi}(\rho))$ is infinitely differentiable, so derivatives in the coefficients commute with taking Taylor coefficients in ρ. Since $\partial \xi_k(\rho)/\partial \xi_k^{(l)} = \rho^l$, (1) with $\mathbf{w} = \mathbf{e}_k$ gives

$$\partial_{\xi_k^{(l)}} \mathsf{Z}_{\nu;t}(\boldsymbol{\xi}(\rho)) = -\rho^l \prod_e \Gamma_1 \begin{bmatrix} \nu_e + t_{k,e} \\ \nu_e \end{bmatrix} \mathsf{Z}_{\nu+t_k;t}(\boldsymbol{\xi}(\rho)),$$

and the coefficient of ρ^q is $-\prod_e \Gamma_1 \begin{bmatrix} \nu_e + t_{k,e} \\ \nu_e \end{bmatrix} c_{q-l}^{\nu+t_k}$, which is (iii). At $t = (1)$ the factor is $\Gamma_1 \begin{bmatrix} \lambda+1 \\ \lambda \end{bmatrix} = \lambda$, the formula of the reference. □

50.3 Chapter 3: the Breta

Proposition 3.4 (The Breta on the orthant). *As stated, for any data.*

Proof. By 3.1 and 2.12, with the dressed coefficients $\eta_k = u^{\pi_k}\xi_k$ and the bunch scales $\rho = (\rho_Q)_{Q\in\mathcal{P}}$,

$$\mathsf{Z}_{\boldsymbol{\nu};\ell}(\boldsymbol{\eta}) = \frac{1}{\prod_Q \Gamma(\nu_Q)} \int_{\mathbb{R}^{\mathcal{P}}_{>0}} \rho^{\boldsymbol{\nu}-\mathbf{1}} \exp\Big(-\sum_k \xi_k\, u^{\pi_k} \rho^{\ell_k} \Big)\, d\rho.$$

On each bunch, 2.7 with $x_Q = \rho_Q u_Q$ gives $x_Q^{\mathbf{m}|_Q - \mathbf{1}} dx_Q = \rho_Q^{m_Q-1} u_Q^{\mathbf{m}|_Q-\mathbf{1}} d\rho_Q\, d\omega_Q(u_Q)$, hence

$$u_Q^{\mathbf{m}|_Q-\mathbf{1}} \rho_Q^{\nu_Q-1}\, d\rho_Q\, d\omega_Q(u_Q) = x_Q^{\mathbf{m}|_Q-\mathbf{1}} |x_Q|^{\nu_Q-m_Q}\, dx_Q,$$

and each dressed term is

$$\xi_k\, u^{\pi_k}\rho^{\ell_k} = \xi_k \prod_Q \Big(\frac{x_Q}{|x_Q|}\Big)^{\pi_k|_Q} |x_Q|^{\ell_{k,Q}} = \xi_k\, x^{\pi_k} \prod_Q |x_Q|^{\ell_{k,Q}-\langle \pi_k, \mathbf{1}_Q\rangle}.$$

So, under the bijection $x \leftrightarrow (\rho_Q, u_Q)_Q$ of 2.7, the Breta with its Zamma written as the scale integral is the integral of the right side over $\mathbb{R}^{\mathcal{E}}_{>0}$. The moduli of the two integrands are the same functions with $\mathbf{m}$ and $\boldsymbol{\nu}$ replaced by their real parts, so, as in the reference, proof of 3.4, Tonelli gives that either side converges when the other does, and Fubini gives the equality. For homogeneous data the inner powers of the bunch totals are absent, and at $\nu_Q = m_Q$ so are the outer ones: the right side is then $\mathsf{G}_{\mathbf{m};t}(\boldsymbol{\xi})/\prod_Q \Gamma(m_Q)$, which is 3.2. □

Theorem 3.5 (Relations of the Breta). *As stated: (v) for any terms; (i) to (iv) are those of the reference.*

Proof. The proofs of (i) to (iv) in the reference, proof of 3.5, use no homogeneity. For (v), let $e \neq f$ be scales of the bunch Q, and in this proof write, with the products over the bunches Q' of $\mathcal{P}$,

$$F(x) = x^{\mathbf{m}-\mathbf{1}} \prod_{Q'} |x_{Q'}|^{\nu_{Q'}-m_{Q'}} \exp\Big(-\sum_k \xi_k \varphi_k(x) \Big), \qquad \varphi_k(x) = x^{\pi_k} \prod_{Q'} |x_{Q'}|^{\ell_{k,Q'}-\langle \pi_k, \mathbf{1}_{Q'}\rangle},$$

the integrand of 3.4 at $(\mathbf{m}, \boldsymbol{\nu})$ without the factor $1/\prod_{Q'} \Gamma(\nu_{Q'})$.

(1) Derivatives. For $e \in Q$, $x_e \partial_{x_e} |x_Q| = x_e$ and $x_e \partial_{x_e} |x_{Q'}| = 0$ for $Q' \neq Q$, so

$$x_e \partial_{x_e} F = F\Big[(m_e - 1) + (\nu_Q - m_Q)\frac{x_e}{|x_Q|} - \sum_k \xi_k \varphi_k \Big(\pi_{k,e} + \big(\ell_{k,Q} - \langle \pi_k, \mathbf{1}_Q \rangle\big)\frac{x_e}{|x_Q|}\Big)\Big],$$

and the same holds with f in place of e.

(2) The integrands. By 3.4: F is the integrand of $\prod_{Q'} \Gamma(\nu_{Q'})\, \mathsf{B}^{\mathcal{P}}_{\mathbf{m},\boldsymbol{\nu};(\pi,\ell)}(\boldsymbol{\xi})$; $F\, x_e/|x_Q|$ is that of $\prod_{Q'} \Gamma(\nu_{Q'})\, \mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\mathbf{e}_e,\boldsymbol{\nu};(\pi,\ell)}(\boldsymbol{\xi})$, the power of $|x_Q|$ being $\nu_Q - (m_Q + 1)$; $F\varphi_k$ is that of $\prod_{Q'} \Gamma(\nu_{Q'} + \ell_{k,Q'})\, \mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\pi_k,\boldsymbol{\nu}+\ell_k;(\pi,\ell)}(\boldsymbol{\xi})$, the power of each $|x_{Q'}|$ being $(\nu_{Q'} + \ell_{k,Q'}) - (m_{Q'} + \langle \pi_k, \mathbf{1}_{Q'} \rangle)$; and $F\varphi_k\, x_e/|x_Q|$ is that of $\prod_{Q'} \Gamma(\nu_{Q'} + \ell_{k,Q'})\, \mathsf{B}^{\mathcal{P}}_{\mathbf{m}+\pi_k+\mathbf{e}_e,\boldsymbol{\nu}+\ell_k;(\pi,\ell)}(\boldsymbol{\xi})$. Here $\prod_{Q'} \Gamma(\nu_{Q'} + \ell_{k,Q'}) = g_k \prod_{Q'} \Gamma(\nu_{Q'})$. These Bretas, and those with f in place of e, are the Bretas of (v), which converge by hypothesis; so all these functions are integrable on $\mathbb{R}^{\mathcal{E}}_{>0}$.

(3) No boundary terms. By (1) and (2), $\partial_{x_e}(x_e F) = F + x_e \partial_{x_e} F$ is integrable. By Fubini, for almost every value x' of the coordinates other than x_e the function $G(s) = s\, F(x', s)$ of $s = x_e > 0$ has G' and $G(s)/s$ integrable on $(0, \infty)$. Then $G(s) = G(1) + \int_1^s G'$ has limits at 0 and at ∞, and both are 0: a nonzero limit L at one end would make $|G(s)/s| \geq |L|/(2s)$ near that end, which is not integrable there. So $\int_0^\infty G'(s)\, ds = 0$, and by Fubini $\int \partial_{x_e}(x_e F)\, dx = 0$; likewise for f. Hence

$$\int_{\mathbb{R}^{\mathcal{E}}_{>0}} \big(x_e \partial_{x_e} - x_f \partial_{x_f}\big) F\, dx = \int \big[\partial_{x_e}(x_e F) - F\big] dx - \int \big[\partial_{x_f}(x_f F) - F\big] dx = 0.$$

(4) Collecting. By (1), $(x_e \partial_{x_e} - x_f \partial_{x_f})F$ is F times

$$(m_e - m_f) + (\nu_Q - m_Q)\frac{x_e - x_f}{|x_Q|} - \sum_k \xi_k \varphi_k \Big((\pi_{k,e} - \pi_{k,f}) + \big(\ell_{k,Q} - \langle \pi_k, \mathbf{1}_Q \rangle\big)\frac{x_e - x_f}{|x_Q|}\Big).$$

Integrating, using (2) and dividing by $\prod_{Q'} \Gamma(\nu_{Q'})$ gives (v). For homogeneous data $\ell_{k,Q} = \langle \pi_k, \mathbf{1}_Q \rangle$ and the second line of the right side of (v) is absent.

(5) The closing sentences. A term k raises the shape total of a bunch Q' by $\langle \pi_k, \mathbf{1}_{Q'} \rangle$ and its scale index by $\ell_{k,Q'}$, which are equal for homogeneous data; so the ladder, the scale exchange and the shifts $(\mathbf{m} + \pi_k, \boldsymbol{\nu} + \ell_k)$ of (v) keep the condition $\nu_Q = m_Q$, and in (v) the shifts $\mathbf{m} + \mathbf{e}_e$, $\mathbf{m} + \mathbf{e}_f$ of the shape index alone carry the factor $\nu_Q - m_Q$. The shape split and (iv) shift the shape index alone. □

Remark. Relation (v) was checked in exact arithmetic on one bunch of two scales with one term whose level is not the degree of its shape exponent, where the Breta has a closed form, for shape exponents $(1, 0)$, $(\frac{3}{2}, -\frac{1}{3})$ and symbolic (`sweep/s0107/breta_v.py`).

Proposition 3.6 (Letter presentation). *As stated, for a partition of the scales B into any number of bunches.*

Proof. (1) The presentation. The bunches of $\mathcal{P}$ are those of $\mathcal{Q}$, with the scales ρ_Q, and the singletons $\{v_i\}$, whose scales are written v_i and whose shapes are the point $u_{v_i} = 1$ of $\Delta_{\{v_i\}}$, with $\omega_{\{v_i\}}$ the Dirac measure (1.1(iii)). The dressed coefficients of the columns are $g_j u^{\pi_j}$ and $C_{i,p} u^{\pi_{i,p}}$, and $u^{(\mathbf{m},\mathbf{s})-\mathbf{1}} = u^{\mathbf{m}-\mathbf{1}}$. By 2.1, the Gramma on the bunch scales with the configuration $\widetilde{\ell}$ and these coefficients is

$$\int \rho^{\boldsymbol{\nu}-\mathbf{1}} \prod_i v_i^{s_i - 1} \exp\Big(-\sum_j g_j u^{\pi_j} \rho^{\lambda_j} - \sum_{i,p} C_{i,p} u^{\pi_{i,p}} \rho^{\ell_{i,p}} v_i\Big)\, d\rho\, dv,$$

the level of the pattern (i,p) on $\{v_i\}$ being 1. For $\operatorname{Re} s_i > 0$, integrating v_i gives $\Gamma(s_i)\,P_i(\rho,u)^{-s_i}$ (2.6 on one scale, $P_i > 0$). Dividing by $\prod_Q \Gamma(\nu_Q)\prod_i \Gamma(s_i)$ gives the Zamma (2.12), and integrating against $u^{\mathbf{m}-\mathbf{1}}d\omega(u)$ over $\prod_Q \Delta_Q$ gives $1/\prod_Q \Gamma(\nu_Q)$ times the left side of the display; Tonelli on the moduli and Fubini justify the order of the integrals, either side converging when the other does.

(2) The relations. They are 3.5(ii),(iii) for the terms $(\widetilde{\pi},\widetilde{\ell})$. For the scale exchange at $\{v_i\}$ the columns of nonzero level there are the patterns (i,p), of level 1, with the factor $\Gamma_1{}_1\begin{bmatrix} s_i+1 \\ s_i+1\end{bmatrix} = 1$ at $\{v_i\}$; the other singletons give $\Gamma_1{}_1\begin{bmatrix} s_{i'} \\ s_{i'}\end{bmatrix} = 1$ and each $Q \in \mathcal{Q}$ gives $\Gamma_1{}_1\begin{bmatrix} \nu_Q+\ell_{i,p,Q} \\ \nu_Q\end{bmatrix}$: this is the letter split. In the ladders the factor g_k of 3.5 is $\prod_Q \Gamma_1{}_1\begin{bmatrix} \nu_Q+\lambda_{j,Q} \\ \nu_Q\end{bmatrix}$ for a kernel column and $s_i\prod_Q \Gamma_1{}_1\begin{bmatrix} \nu_Q+\ell_{i,p,Q} \\ \nu_Q\end{bmatrix}$ for a pattern, by $\Gamma_1{}_1\begin{bmatrix} s_i+1 \\ s_i\end{bmatrix} = s_i$. The scale exchange on $Q \in \mathcal{Q}$ is 3.5(iii) multiplied by ν_Q, with $\nu_Q\Gamma_1{}_1\begin{bmatrix} \nu_Q+\lambda \\ \nu_Q+1\end{bmatrix} = \Gamma_1{}_1\begin{bmatrix} \nu_Q+\lambda \\ \nu_Q\end{bmatrix}$ (1.3(iii)), the singletons contributing the factors 1 for a kernel column and s_i for a pattern. □

Proposition 3.7 (Letter data on the orthant). *As stated, for any levels and any number of bunches.*

Proof. In the left side of the display of 3.6 apply 2.7 on each bunch $Q \in \mathcal{Q}$, $\alpha_Q = \rho_Q u_Q$: $u_Q^{\mathbf{m}|_Q-\mathbf{1}}\rho_Q^{\nu_Q-1}d\rho_Q\,d\omega_Q = \alpha_Q^{\mathbf{m}|_Q-\mathbf{1}}|\alpha_Q|^{\nu_Q-m_Q}d\alpha_Q$, and for $\lambda \in \mathbb{R}^{\mathcal{Q}}$, $\pi \in \mathbb{R}^B$, $\rho^\lambda u^\pi = \alpha^\pi\prod_Q|\alpha_Q|^{\lambda_Q-\langle\pi,\mathbf{1}_Q\rangle}$. So each kernel term becomes $g_j\alpha^{\pi_j}\prod_Q|\alpha_Q|^{\lambda_{j,Q}-\langle\pi_j,\mathbf{1}_Q\rangle}$ and each letter $P_i(\alpha)$. Tonelli on the moduli gives the equivalence of convergence and Fubini the equality, and 3.6 identifies the left side with $\prod_Q\Gamma(\nu_Q)$ times the Breta. For homogeneous letter data every exponent $\lambda_Q-\langle\pi,\mathbf{1}_Q\rangle$ is 0, and at $\nu_Q = m_Q$ so is $\nu_Q - m_Q$. □

Theorem 3.13 (The Shruffle). *As stated, for any number of bunches.*

Proof. Apply 3.12 to $A = A_1\sqcup\cdots\sqcup A_q$ with $J = \{1,\dots,q\}$: $u|_{A_i} = w_i v^{(i)}$ with $w \in \Delta_J$, $v^{(i)} \in \Delta_{A_i}$, and

$$u^{\mathbf{m}-\mathbf{1}}d\omega_A = \prod_i w_i^{m_{A_i}-1}\,d\omega_J(w)\prod_i (v^{(i)})^{\mathbf{m}|_{A_i}-\mathbf{1}}d\omega_{A_i}(v^{(i)}), \qquad \bigotimes_i f_i(u) = \prod_i f_i(v^{(i)}).$$

Scaling by $w_i > 0$ keeps the order of the coordinates of $u|_{A_i}$, which is that of $v^{(i)}$. Up to the null set where two coordinates of u are equal, the points u whose restrictions follow every ς_i form the disjoint union of the sets Δ_A^ς over the orders ς of A that restrict to every ς_i, and they are the images of $\Delta_J\times\prod_i\Delta_{A_i}^{\varsigma_i}$. The integrals converge absolutely, so by Fubini

$$\sum_\varsigma I_A^\varsigma\Big(\bigotimes_i f_i;\mathbf{m}\Big) = \int_{\Delta_J}\prod_i w_i^{m_{A_i}-1}\,d\omega_J(w)\;\prod_i I_{A_i}^{\varsigma_i}(f_i;\mathbf{m}|_{A_i})$$
$$= \Gamma_q{}_1\begin{bmatrix} m_{A_1},\ \dots,\ m_{A_q} \\ m_A\end{bmatrix}\prod_i I_{A_i}^{\varsigma_i}(f_i;\mathbf{m}|_{A_i}),$$

by 3.9 on J, where $\operatorname{Re} m_{A_i} > 0$. Dividing by the stacked Gamma, whose reciprocal is $\Gamma_1{}_q\begin{bmatrix} m_A \\ m_{A_1},\ \dots,\ m_{A_q}\end{bmatrix}$, gives the statement; at $q = 2$ it is the factor $\Gamma_1{}_2\begin{bmatrix} m_A+m_B \\ m_A,\ m_B\end{bmatrix}$ of the reference. □

Theorem 3.15 (Relations of the Beta port). *As stated: (iii) for linear letters of either slope and complex exponents, and (v) at every pair of exponents; (i), (ii) and (iv) are those of the reference.*

Proof. (iii) On $[0,1]$ every letter $L_i = c_i + d_i x$ is positive, since it is affine with the positive values c_i and $c_i + d_i$ at the ends, so $L_i^{-w_i}$ is infinitely differentiable there for every $w_i \in \mathbb{C}$, with $\partial_x^v L_i^{-w_i} = (-1)^v (w_i)_v d_i^v L_i^{-w_i - v}$, d_i real. Leibniz's rule gives

$$\partial_x^q \prod_i L_i^{-w_i} = \sum_{|v|=q} \frac{q!}{\prod_i v_i!} \prod_i (-1)^{v_i} (w_i)_{v_i} d_i^{v_i} L_i^{-w_i - v_i},$$

which is the first display. Then (ii), with $g = \prod_i L_i^{-w_i}$ and $\operatorname{Re} a, \operatorname{Re} b > 0$, gives the second display, by $x^{a+q-1}(1-x)^{b+q-1} = x^{a-1}(1-x)^{b-1} \prod_i (x(1-x))^{v_i}$ for $|v| = q$. Let $a, b > 0$ and $w_i \geq 0$. Each integrand on the right is $x^{a-1}(1-x)^{b-1} \prod_i L_i^{-w_i} > 0$ times $\prod_i (x(1-x) d_i / L_i)^{v_i}$, which is nonnegative if every $d_i \geq 0$, and is $(-1)^{|v|} = (-1)^q$ times a nonnegative function if every $d_i \leq 0$; the coefficients $\prod_i (w_i)_{v_i} / v_i!$ are nonnegative. This gives the two signs. If $x(1-x)|d_i|/L_i \leq \varepsilon$ on $[0,1]$ for every i, each integrand has modulus at most $\varepsilon^q x^{a-1}(1-x)^{b-1} \prod_i L_i^{-w_i}$, and

$$\sum_{|v|=q} \prod_i \frac{(w_i)_{v_i}}{v_i!} = \frac{(|\mathbf{w}|)_q}{q!},$$

the coefficient of y^q on both sides of $\prod_i (1-y)^{-w_i} = (1-y)^{-|\mathbf{w}|}$, $|y| < 1$, by $(1-y)^{-w} = \sum_v \frac{(w)_v}{v!} y^v$. This gives the bound.

(v) Fix $q \geq 1$, write $s = a + b$, and first let $\operatorname{Re} a, \operatorname{Re} b > 0$.

(1) Coefficients. Expanding $x^k (1-x)^{q-k}$ in the second form of 3.14,

$$[x^j]\, \Pi_q^{a,b} = (-1)^{q+j} \sum_k \binom{a+q-1}{q-k} \binom{q-k}{q-j} \binom{b+q-1}{k}.$$

By $\binom{N}{M}\binom{M}{L} = \binom{N}{L}\binom{N-L}{M-L}$, a polynomial identity in N, at $N = a+q-1$, $M = q-k$, $L = q-j$, this is $(-1)^{q+j}\binom{a+q-1}{q-j} \sum_k \binom{a+j-1}{j-k}\binom{b+q-1}{k}$, and $\sum_k \binom{A}{j-k}\binom{B}{k} = \binom{A+B}{j}$, a polynomial identity in A and B that holds at nonnegative integers by counting the j-subsets of a disjoint union, gives $\binom{s+q+j-2}{j}$: the coefficient formula. At $j = q$, $\lambda_q := [x^q]\Pi_q^{a,b} = \binom{s+2q-2}{q} = (s+q-1)_q / q!$, which is nonzero since $\operatorname{Re} s > 0$. Also

$$\frac{[x^{q-1}]\Pi_q^{a,b}}{\lambda_q} = -\frac{q(a+q-1)}{s+2q-2}, \qquad \frac{[x^q]\Pi_{q+1}^{a,b}}{\lambda_{q+1}} = -\frac{(q+1)(a+q)}{s+2q}.$$

(2) Pairing. Put $\langle g, h \rangle_\circ = \int_0^1 x^{a-1}(1-x)^{b-1} g\, h\, dx$ for polynomials g, h. By (i) at $c = a + j$, $\langle \Pi_k^{a,b}, x^j \rangle_\circ = \binom{j}{k} \Gamma \begin{bmatrix} a+j,\ b+k \\ s+j+k \end{bmatrix}$, which is 0 for $j < k$ and $\beta_k := \Gamma \begin{bmatrix} a+k,\ b+k \\ s+2k \end{bmatrix} \neq 0$ for $j = k$.

(3) Span. Let g be a polynomial of degree at most $q+1$ with $\langle g, x^j \rangle_\circ = 0$ for $j \leq q-2$. Since $\deg \Pi_k^{a,b} = k$ by (1), $g = \sum_{k \leq q+1} \gamma_k \Pi_k^{a,b}$; pairing with $x^0, x^1, \ldots, x^{q-2}$ in turn, by (2) the pairing with x^j involves only $\gamma_0, \ldots, \gamma_j$, with γ_j multiplied by $\beta_j \neq 0$, so $\gamma_0 = \cdots = \gamma_{q-2} = 0$ and $g \in \operatorname{span}(\Pi_{q-1}^{a,b}, \Pi_q^{a,b}, \Pi_{q+1}^{a,b})$.

(4) Multiplication by x. $\langle x\Pi_q^{a,b}, x^j \rangle_\circ = \langle \Pi_q^{a,b}, x^{j+1} \rangle_\circ = 0$ for $j \leq q-2$, so by (3) $x\Pi_q^{a,b} = A\Pi_{q+1}^{a,b} + B\Pi_q^{a,b} + C\Pi_{q-1}^{a,b}$. The coefficients of x^{q+1} give $A = \lambda_q / \lambda_{q+1} = \frac{(q+1)(s+q-1)}{(s+2q)(s+2q-1)}$. Pairing

with x^{q-1} gives $\beta_q = C\beta_{q-1}$, so $C = \frac{(a+q-1)(b+q-1)}{(s+2q-1)(s+2q-2)}$. The coefficients of x^q give $[x^{q-1}]\Pi_q^{a,b} = A\,[x^q]\Pi_{q+1}^{a,b} + B\lambda_q$, so by (1) $B = \frac{(q+1)(a+q)}{s+2q} - \frac{q(a+q-1)}{s+2q-2}$.

(5) The operator $D = x(1-x)\partial_x$. For a polynomial g, integrating by parts, the boundary terms $x^{a+j}(1-x)^b g$ vanishing at both ends,

$$\langle Dg, x^j\rangle_\circ = \int_0^1 x^{a+j}(1-x)^b g'\,dx = -(a+j)\langle g, x^j\rangle_\circ + (s+j)\langle g, x^{j+1}\rangle_\circ,$$

which is 0 at $g = \Pi_q^{a,b}$ for $j \le q-2$. By (3), $D\Pi_q^{a,b} \in \operatorname{span}(\Pi_{q-1}^{a,b}, \Pi_q^{a,b}, \Pi_{q+1}^{a,b})$, and eliminating $\Pi_{q+1}^{a,b}$ by (4), $A \neq 0$, $D\Pi_q^{a,b} = (e\,x + e_0)\Pi_q^{a,b} + e_1\Pi_{q-1}^{a,b}$. Since $Dx^k = kx^k - kx^{k+1}$, the coefficients of x^{q+1} give $e = -q$. Pairing with x^{q-1}: the left side is $(s+q-1)\beta_q$ and the right side $-q\beta_q + e_1\beta_{q-1}$, so $e_1 = (s+2q-1)\beta_q/\beta_{q-1} = \frac{(a+q-1)(b+q-1)}{s+2q-2}$. The coefficients of x^q give $q\lambda_q - (q-1)[x^{q-1}]\Pi_q^{a,b} = -q[x^{q-1}]\Pi_q^{a,b} + e_0\lambda_q$, so $e_0 = q + [x^{q-1}]\Pi_q^{a,b}/\lambda_q = \frac{q(b+q-1)}{s+2q-2}$.

(6) Continuation. The three displays compare polynomials in x whose coefficients are rational functions of (a,b), the coefficients of the Beta ports being polynomials in (a,b). They agree on the open set $\operatorname{Re} a, \operatorname{Re} b > 0$, hence wherever the coefficients are finite, which is the condition $a+b+2q-i \neq 0$, $i = 0,1,2$; the coefficient formula is a polynomial identity and holds for all a, b and every $q \in \mathbb{N}$. □

Remark. At $a = b = n+1$ the middle coefficient of the three-term relation is $\frac{1}{2}$, and the relations become those of the reference: $(1-2x)\Pi_r^{n+1,n+1} = -2A\,\Pi_{r+1}^{n+1,n+1} - 2C\,\Pi_{r-1}^{n+1,n+1}$ and $x(1-x)\partial_x\Pi_r^{n+1,n+1} = \frac{r}{2}(1-2x)\Pi_r^{n+1,n+1} + \frac{r+n}{2}\Pi_{r-1}^{n+1,n+1}$, with the leading coefficient $\binom{2n+2r}{r}$, and at $a = b = 1$ the coefficient formula gives $(-1)^r\Pi_r^{1,1} = \sum_k (-1)^k\binom{r}{k}\binom{r+k}{k}x^k$. The three displays and the coefficient formula were checked in exact arithmetic with a and b symbolic for $q \le 9$, together with these diagonal forms (`sweep/s0107/betaport.py`).

50.4 Chapter 4: fibre integrals and closing

Theorem 4.3 (The native gauge of a configuration). *As stated: (iii) with a fixed offset ν' of the index; (i) and (ii) are those of the reference.*

Proof. By (i), $\Phi_{\boldsymbol{\xi}}$ is smooth and strictly convex with its minimum at $y^\star$, where its Hessian $H^\star = \sum_k w_k^\star t_k t_k^{\mathsf{T}}$ is positive definite.

(1) The integral. In the logarithmic form of 2.1,

$$\mathsf{G}_{\lambda\nu+\nu';t}(\lambda\boldsymbol{\xi}) = \int_{\mathbb{R}^{\mathcal{E}}} e^{\langle\nu',y\rangle}\,e^{-\lambda\Phi_{\boldsymbol{\xi}}(y)}\,dy,$$

which converges when $\lambda\nu+\nu' \in \mathcal{T}_t$ (2.2). Since $\operatorname{int}\operatorname{cone}(t)$ is an open cone containing ν, it contains $\nu + \lambda^{-1}\operatorname{Re}\nu'$ for λ large, so the integral converges for $\lambda \ge \lambda_0$, some $\lambda_0 > 0$.

(2) Away from $y^\star$. Fix $\delta > 0$ and put $\mu_\delta = \min_{|y-y^\star|=\delta}\big(\Phi_{\boldsymbol{\xi}}(y) - \Phi_{\boldsymbol{\xi}}(y^\star)\big) > 0$. For a unit vector d the function $\sigma \mapsto \Phi_{\boldsymbol{\xi}}(y^\star+\sigma d) - \Phi_{\boldsymbol{\xi}}(y^\star)$ is convex and vanishes at $\sigma = 0$, so for $\sigma \ge \delta$ it is at least $\sigma\mu_\delta/\delta$. With $|e^{\langle\nu',y\rangle}| \le e^{|\operatorname{Re}\nu'|\,|y^\star|}e^{|\operatorname{Re}\nu'|\,|y-y^\star|}$,

$$\Big|\int_{|y-y^\star|\ge\delta} e^{\langle\nu',y\rangle}e^{-\lambda(\Phi_{\boldsymbol{\xi}}(y)-\Phi_{\boldsymbol{\xi}}(y^\star))}\,dy\Big| \le e^{|\operatorname{Re}\nu'|\,|y^\star|}\int_{|u|\ge\delta} e^{-(\lambda\mu_\delta/\delta - |\operatorname{Re}\nu'|)|u|}\,du,$$

which, once $\lambda\mu_\delta/\delta \ge 2|\operatorname{Re}\nu'|$ and $\lambda\mu_\delta \ge 2\delta$, is at most a constant times $e^{-\lambda\mu_\delta/4}$: on $|u| \ge \delta$, $e^{-\Lambda|u|} \le e^{-\Lambda\delta/2}e^{-\Lambda|u|/2}$ for $\Lambda = \lambda\mu_\delta/\delta - |\operatorname{Re}\nu'| \ge \lambda\mu_\delta/(2\delta) \ge 1$. So it is $O(\lambda^{-|\mathcal{E}|/2-1})$.

(3) Near $y^\star$. Laplace's method at the nondegenerate minimum $y^\star$, with the smooth amplitude $e^{\langle \nu', y\rangle}$, gives

$$\int_{|y-y^\star|<\delta} e^{\langle \nu', y\rangle} e^{-\lambda(\Phi_{\boldsymbol{\xi}}(y)-\Phi_{\boldsymbol{\xi}}(y^\star))}\, dy = \Big(\frac{2\pi}{\lambda}\Big)^{|\mathcal{E}|/2} \det(H^\star)^{-1/2}\Big(e^{\langle \nu', y^\star\rangle} + O(\lambda^{-1})\Big),$$

as in the reference, proof of 4.3, where the amplitude is 1: the amplitude enters the leading term through its value at $y^\star$, and its derivatives only the term $O(\lambda^{-1})$.

Adding (2) and (3), multiplying by $e^{-\lambda\Phi_{\boldsymbol{\xi}}(y^\star)}$ and factoring out $e^{\langle \nu', y^\star\rangle} \neq 0$ gives (iii). □

Corollary 4.7 (Four Gammas on a line). *As stated: the display is 4.6 on two coefficients.*

Proof. (1) A straight contour. Let first $\max(-\operatorname{Re} a, -\operatorname{Re} b) < \min(\operatorname{Re} c, \operatorname{Re} d)$, and take the line $\operatorname{Re} z = \gamma$ with $\max(-\operatorname{Re} a, -\operatorname{Re} b) < \gamma < \min(\operatorname{Re} c, \operatorname{Re} d)$; it separates the two sets of poles. Apply 4.6 with $k = 2$, the exponents $a + c$ and $b + d$, and $(a + d,\, b + c)$, of total $a + b + c + d$, in the place of the merged shares. In the shares $(\alpha_1, \alpha_2, \beta_1, \beta_2)$ the fibre has the pins $\alpha_1 + \alpha_2 = a + c$, $\alpha_1 + \beta_1 = a + d$, $\alpha_2 + \beta_2 = b + c$, and it is parametrized by $\alpha = (a + z,\, c - z)$, $\beta = (d - z,\, b + z)$. The matrix P of the pins has the rows $(1, 1, 0, 0)$, $(1, 0, 1, 0)$, $(0, 1, 0, 1)$, so $\det PP^{\mathsf{T}} = 4$, and its kernel is spanned by $(1, -1, -1, 1)$, of length 2. By 4.1, with the admissible real point on the line $\operatorname{Re} z = \gamma$, where all four shares have positive real parts, the fibre integral of a function G is $(2\pi)^{-1} \cdot 4^{-1/2} \cdot 2 \int G\, d\tau = \frac{1}{2\pi i} \int_{\gamma + i\mathbb{R}} G\, dz$, $z = \gamma + i\tau$. The integrand of 4.6 is

$$\Gamma_{\,1}^{\,2}\begin{bmatrix} a+z,\ c-z \\ a+c \end{bmatrix} \Gamma_{\,1}^{\,2}\begin{bmatrix} d-z,\ b+z \\ b+d \end{bmatrix} = \frac{\Gamma(a+z)\Gamma(b+z)\Gamma(c-z)\Gamma(d-z)}{\Gamma(a+c)\Gamma(b+d)},$$

and its right side is $\Gamma_{\,1}^{\,2}\begin{bmatrix} a+d,\ b+c \\ a+b+c+d \end{bmatrix}$. Multiplying by $\Gamma(a + c)\Gamma(b + d)$ (1.3(i)) gives the display.
